Diethyl-dioxybenzoic acid, $C^6H^4(C^2H^5O)^4$, is produced by heating the ethylic ether of dioxybenzoic acid with ethyl iodide, caustic potash, and a little alcohol in sealed tubes to 130° for some hours. The ethylic diethyl-dioxybenzoate thus formed is an oily liquid which is readily decomposed by boiling it with potash; and by acidulating the resulting alkaline solution with sulphuric acid, agitating with ether, and evaporating the ethereal solution, the free acid is obtained as an oily liquid, which soon solidifies to a crystalline mass, and crystallises from water in needle-shaped prisms melting at 87° – 88° . The barium salt has the composition $(C^6H^4O^4)_2Ba$.

By heating diethyl-dioxybenzoic acid with quicklime, an oil is obtained boiling $2nd\ Sup.$

between 200°–260°, containing probably the diethyl ether of resorcin. The latter compound is easily obtained by heating resorcin with ethyl iodide and potash; it is an oily liquid boiling at 250° and giving no colour with ferric chloride. By heating it with hydriodic acid it is not reconverted into resorcin, but a resinous body is produced, the alkaline solution of which exhibits, even when very dilute, a strong dichroism, appearing green in reflected light and yellowish-red by transmitted light. Exactly the same reaction is shown by the distillate of a mixture of diethyl-dioxybenzoic acid and lime.

Constitution of the Dioxybenzoic acid obtained from Disulphobenzoic acid.—The monobrominated derivative of this acid fused with potash, yields gallic acid, $C^7H^3O^5$, which has also been formed synthetically from di-iodosalicylic and monobromoprotocatechuic acid. Admitting then, that in salicylic acid the hydroxyl groups occupy the positions 1 : 2, and in protocatechuic acid, the places 1 : 3 : 4, it follows that the constitutional formula of gallic acid must be either 1 : 2 : 3 : 4, or 1 : 3 : 4 : 6. Further the disulphobenzoic acid from which the dioxybenzoic acid under consideration is prepared is converted by fusion with sodium formate into isophthalic acid (1 : 3); consequently one of the groups SO^2H in this acid, and therefore the corresponding hydroxyl in the dioxybenzoic acid, must occupy the position 3. Hence it appears that the only possible relative positions for the carboxyl and hydroxyl in this dioxybenzoic acid, are

Of the six possible arrangements indeed 1 : 2 : 4 is excluded as belonging to Ascher's dioxybenzoic acid (p. 432); 1 : 3 : 4 as belonging to protocatechuic acid; and 1 : 2 : 6 cannot easily be reconciled with the formation of isophthalic acid. Finally 1 : 3 : 5 is inconsistent with the formation of gallic acid. Between the two remaining formulae 1 : 2 : 3 and 1 : 3 : 6 the results hitherto obtained by Barth and Senhofer do not enable them to decide with certainty, but from experiments not yet completed, they regard the latter as the more probable of the two.

DIOXYMETHYLENE, $C^8H^4O^2$. This compound, which Butlerow obtained by the action of silver oxide or oxalate on methyl iodide, and by the dry distillation of ethyl-glycollic acid (iii. 1006), is also produced by the dry distillation of glycollic acid itself. This acid, heated first to 120°, then for several hours to 160°, and finally for a day to 200°–220°, yields a carbonaceous residue, and a solid sublimate consisting of dioxymethylene (Krapsky, *Zeitschr. f. Chem.* vi. 178). According to Girard (*Bull. Soc. Chim.* [2], xiv. 217) it is also produced by heating methylene sulphide CH_2S to 170° in a closed vessel with sulphate or borate of silver.

DIPHENIC ACID, $C^{14}H^{10}O^4 =$ $C^{14}H^8.CO^2H$. This acid is a product of the

oxidation of phenanthrene-quinone $C^{14}H^8O^2$ (p. 93), and is always obtained in small quantity in the preparation of the latter. It is most conveniently prepared by heating the impure hydrocarbon containing anthracene with chromic acid solution, and crystallising the mixture of the quinones from alcohol, in order to remove an amorphous substance. The quinones are again treated with the oxidising mixture, which does not act on anthraquinone, and the acid is extracted from the product by ammonia.

Diphenic acid is sparingly soluble in cold water, more freely in hot water, and readily in alcohol and ether; it crystallises on quickly cooling the solution, in small shining plates, but if the solution cools down slowly, it is obtained in transparent compact anhydrous prisms; it separates also in the latter form on allowing an alcoholic solution to evaporate. By the evaporation of a solution in dilute alcohol, it was once obtained in very large transparent crystals containing two molecules of water. It melts at 226°, and sublimes in long transparent needles; when heated above its melting point, it blackens and decomposes. It is a strong bibasic acid.

Barium diphenate, $C^{14}H^8BaO^4 + 4H^2O$, is readily soluble in water and forms large transparent crystals. *Calcium diphenate*, $C^{14}H^8CaO^4 + 2\frac{1}{2}H^2O$, is a very soluble salt and does not crystallise well. *Magnesium diphenate*, $C^{14}H^8MgO^4 + 4H^2O$, crystallises in plates. *Silver diphenate*, $C^{14}H^8Ag^2O^4$, is a bulky white precipitate dissolving in a large quantity of hot water.

Diphenic acid heated with excess of quick lime, is converted, not into diphenyl, as might have been expected ($C^{14}H^{10}O^4 - 2CO^2 = C^{14}H^{10}$), but into diphenylene ketone $C^{14}H^8O$:

(Fittig & Ostermayer, *Ann. Ch. Pharm.* clxvi. 361).

DIPHENINE. This compound, which Laurent & Gerhardt obtained by reduction of dinitrozobenzene with hot alcoholic ammonium sulphide (ii. 336) is generally regarded as diamido-azobenzene $C^6H^4N^2 = C^6H^4N^2(NH^2)^2$; but from the experiments of Lermontoff (*Deut. Chem. Ges. Ber.* v. 231), it appears to be really diamido-hydrazo-benzene $C^6H^4N^2 = C^6H^4N^2(NH^2)^2$, formed by addition of H^2 to diamido-azobenzene (see HYDRAZOBENZENE).

DIPHENYL. See PHENYL.

DIPHENYL KETONE, $CO(C^6H^5)^2$, is formed, together with a small quantity of a substance which boils at a very high temperature, by heating a mixture of benzoic acid and benzoic acid to 180° – 200° with phosphorus pentoxide:

No ketone is formed by heating benzoic acid alone with phosphorus pentoxide, and benzene alone is not acted upon at all (Kollarits & Merz. *Deut. Chem. Ges. Ber.* v. 447).

DIPHENYL-ALLOPHANIC ETHERS. See CYANIC ETHERS (p. 408).

DIPHENYLAMINE. See PHENYLAMINES.

DIPHENYL-BIURET. See BIURET (p. 193).

DIPHENYLENE KETONE, $C^{12}H^{10}O$, is produced by heating diphenic acid with excess of quick-lime. It crystallises from alcohol in large, transparent, pale-yellow plates or thick compact crystals, melting at 83.5° – 84° and boiling above 300° ; it volatilises slowly with vapour of water; dissolves in cold concentrated sulphuric acid with a wine-red colour; and is again precipitated by water, but only if the solution has not previously been heated. Diphenylene ketone introduced in small portions into fused caustic potash is converted into phenyl-benzoic acid $C^6H^4(C^6H^5).CO^2H$; and on heating the calcium salt of this acid with quick lime, the ketone is regenerated, but at the same time a small quantity of diphenyl is produced, and a larger quantity of the latter may be obtained by heating the calcium salt without quick lime.

Regarding diphenylene ketone as $C^{12}H^{10}O$, its formation from diphenic acid is exactly analogous to that of dimethyl ketone (common acetone) from acetic acid:

Fittig & Ostermayer, however, who regard anthraquinone as a double ketone, $C^6H^4 \begin{array}{c} \diagup CO \\ CO \diagdown \end{array} C^6H^4$, think that diphenylene ketone may be better represented by the double formula $C^{12}H^{10}O^2$, in which case its formation from phenyl-benzoic acid will be analogous to that of anthraquinone from benzoic acid:

On this view, diphenylene-ketone is diphenyl-anthraquinone. When fused with potash, it again yields phenyl-benzoic acid, just as anthraquinone is resolved by the same reaction into two molecules of benzoic acid (see ANTHRAQUINONE, pp. 94, 95).

DIPHENYLENE OXIDE, $C^{12}H^{10}O$. This, according to Hoffmeister (*Zeitschr. f. Chem.* [2], vii. 24), is the composition of the supposed phenyl oxide, $C^{12}H^{10}O$, which Lesimple obtained (*Ann. Ch. Pharm.* cxxviii. 375), by distilling phenyl phos-

phate with excess of lime, and treating the oily distillate with potash. It crystallises from alcohol in fine colourless laminae having an aromatic odour, melting at 80°, and resolidifying at 51° (Lesimple). It is not attacked when its vapour is passed over red-hot zinc-filings. Heated to 220° in a sealed tube with phosphorus pentachloride, it is converted into a chlorinated body which crystallises from alcohol, and melts at 92° (Hoffmeister).

FIG. 14.

DIPHENYL-METHANE. See PHENYL-METHANES.

DIPHENYLSULPHOCARBAMIDE, N²(CS)² (C⁶H⁵)₂NH². This compound, treated with a cold solution of nitrous ether in alcohol (obtained by saturating cooled absolute alcohol with nitrogen trioxide) is instantly

decomposed, evolving torrents of gas, which consists chiefly of nitric oxide and is free from carbon dioxide and oxysulphide. Some time after the termination of the experiment, the liquid, which is turbid at first, becomes perfectly clear, and a quantity of free sulphur is deposited, exactly equal to half the amount contained in the sulphocarbamido employed. The alcoholic liquid then contains phenylsulphocyanate and triphenylguanidine, nearly in the calculated proportion. The decomposition appears to be represented by the equation :

according to which the action of nitrous acid in alcoholic solution is perfectly analogous to that of iodine, chloride of sulphur, &c. (Claus, *Deut. Chem. Ges. Ber.* iv. 143).

DISTILLATION. Linnemann (*Ann. Ch. Pharm.* clx. 195) has contrived, for fractional distillation on the laboratory scale, an apparatus founded on the same principle as the so-called *Dephlegmators* used in distillation on the manufacturing scale, the vapour which rises from the boiling liquid being partially condensed in a tube interposed between the still and the condenser, so that the succeeding portions of vapour are forced to pass through this previously condensed liquid, whereby they undergo a kind of washing.

This is effected by fixing into the neck of the distillation flask a wide vertical glass tube (fig. 14), into which are inserted a number of thimble-shaped cups made of platinum gauze, the shape of which is shown at *a b*. The gauze of which these cups are made is formed of platinum wire about the thickness of a horse-hair, and the meshes are about $\frac{3}{4}$ of a square millimeter in area. The cups are easily formed by stamping square pieces of this wire into a box-wood mould. To facilitate the condensation further, a bulb is blown on the tube after every two or three of the cups. The temperature of the vapour is measured by a thermometer inserted into the upper end of the tube, with its bulb in the uppermost enlargement. The lateral tube leads to the principal condenser.

The tube with six cups, represented in the figure at half its actual size, is used

for liquids boiling between 150° and 180° ; for those which boil between 180° and 250° , a shorter tube with two bulbs and five cups is used; and for those which boil below 150° , a larger one with three bulbs and eight cups.

As the distillation goes on, the liquid condenses in the cups and in the bulbs, faster than it can run back through the meshes of the gauze into the flask; consequently all the vapour has to pass through this condensed liquid, before it can pass off by the side tube into the condenser. To prevent too great an accumulation of liquid in the cups and bulbs, it is necessary to remove the flame now and then, and sometimes even to cool the upper part of the tube by blowing on it.

The advantages attributed to this apparatus are twofold: 1. It brings the purification of organic liquids by fractional distillation to a degree of perfection hitherto unattained. 2. It gives great exactness to determinations of boiling point, partly because it ensures the purity of the distilled liquids; and partly because the cooling influence of the masses of metal interposed between the boiling liquid and the thermometer prevents the so-called over-heating of the vapour, which is apt to take place with the apparatus commonly employed.

To ensure the purity of a liquid distilled with this apparatus, the several fractions are to be weighed, in order to find the principal fraction, and this latter is to be regarded as pure only when the loss which it suffers by repeated distillation does not exceed the average loss which occurs in the process, and when, after all parts of the apparatus and the bulb of the thermometer have been thoroughly heated, and the mercury has attained a constant height, it remains at that height till the last drop of liquid has distilled over, and falls as soon as the quantity of vapour left in the distillation vessel is no longer sufficient to yield any liquid distillate.

As an example of the use of the apparatus, Linnemann describes the purification of ethyl iodide, prepared in the ordinary way by the action of iodine and phosphorus on alcohol, washed with potash-solution and with water, then distilled with water, and dehydrated by phosphoric anhydride. The crude iodide thus obtained—yielded, after repeated distillation of the secondary fractions, and preservation of the fractions boiling: below 70.9° ; between 70.9° and 71.9° ; between 71.9° and 72.5° ; between 72.5° and 72.9° ; and between 72.9° and 74° ,—the twice distilled principal fraction 70.9° to 71.9° amounting to 570 grams. The further progress of the distillation is shown in the following table:—

Fractional Distillation of Ethyl Iodide.

	Weight of the Fractions in Grams.							Total	Loss
	a. to 71.0°	b. 71.0° – 71.8°	c. 71.8° – 71.9°	d. 71.9° – 72.1°	e. 72.1° – 72.3°	f. 72.3° – 72.5°	g. Residue		
Fraction 70.9° – 71.9° , 570 grams distilled once	5	21	39	309	94	90	5	563	7
f distilled once	5	21	44	379	100	13		562	1
e once	5	24	47	460		22		558	4
d and e once	5	42	68	402		37		554	4
d once more	5	63	88	344		51		551	3
b and c dehy- drated with P_2O_5 and distilled twice.	56	27	14	384		59		540	11
e, f, g distilled once	56	27	14	417		10		533	7
				78 p.c.				Total 37 grms	

Hence it appears that 570 grams of ethyl iodide, originally boiling at 70.9° to 71.9° yielded, after twelve distillations, in which 37 grams were lost, chiefly by evaporation, 417 grams, or 78 p.c. of iodide boiling between 71.9° and 72.1° . On again distilling this quantity, after further dehydration with phosphoric anhydride, only 8 grams went over at 71.9° , but 393 grams between 71.9° and 72.1° ; and of this quantity

360 grams passed over at 72° . This point may therefore be regarded as the directly observed boiling point of the ethyl iodide. This observation was made under a barometric pressure of 730 mm.; and, by reducing this to the pressure of 760° , and making the necessary correction for the temperature of the portion of the mercurial column which projected above the condensing tube (for the details of which the original paper must be consulted), Linnemann calculates that the true boiling point of ethyl iodide is 72.38° .

For determinations, by this method, of the boiling points of homologous organic compounds, see p. 203.

On the Theory of Fractional Distillation, see Wanklyn (*Phil. Mag.* [4], xiv. 129); also J. C. Glashan, *ibid.* 373.

Pierre a. Puchot (*Compt. rend.* lxxiii. 443, 599) have made experiments on the distillation of mixtures of liquids insoluble one in the other. In this case the temperature of ebullition and the relative quantities of the two liquids in the distillate remain nearly constant. In the distillation of a mixture of water and amyl valerate, the temperature of ebullition was found to remain constant at 100° , and 13 volumes of water distilled over constantly to 7 volumes of amyl valerate.

In the distillation of a mixture of amyl alcohol and water, ebullition commences at 96° , and remains nearly constant at this point for a considerable time. Moreover, so long as the temperature remains constant, the volumes of water and of amyl alcohol condensed during any given time are invariably in a constant ratio, viz. 2 to 3; and the temperature does not begin to rise until either the water or the alcohol has wholly distilled over, leaving a surplus of alcohol or of water (as the case may be) in the retort. If the water was originally more than two-thirds of the volume of the alcohol, the temperature rises to 100° as soon as the whole of the alcohol has distilled over; but if less than the two-thirds of water was originally present, the boiling point rises to 130° as soon as the whole of the water has distilled over, the residue consisting wholly of amyl alcohol.

Butyl alcohol [of fermentation] gives similar results, the volumetric ratio in this case being 1 of water to 5 of the alcohol. The mixture boils constantly at 90.5° , i.e. 9.5° below the boiling point of water, and 17.5° below that of isobutyl alcohol.

When a mixture of water, butyl alcohol, and amyl alcohol is distilled, the temperature of ebullition is not constant, but regularly rises, always, however, remaining between 95° and 96° , and being higher as the quantity of amyl alcohol present is larger. The relative volume of water which distils over also increases continually, being, however, always greater than $\frac{1}{4}$ th of the total volume which passes over, and less than $\frac{2}{3}$ th; i.e. between the relative numbers found with butyl alcohol and water, and with amyl alcohol and water.

Distillation of over-heated Liquids.—Berthelot remarks that over-heated liquids not in the state of ebullition by no means cease to distil, but, on the contrary, often distil more rapidly than during ebullition. In distilling oil of turpentine, for example, under diminished pressure, the distillation might be advantageously accelerated by cautiously diminishing the pressure after the boiling has ceased. Many liquids behave in the same way when heated in open vessels; thus ethyl bromide, which ordinarily boils at 38.5° , may be heated to 51° without entering into ebullition. A liquid in such a state may be brought by agitation into sudden explosive ebullition, the temperature falling at the same time. Drops of such liquids often float about on the surface (*Bull. Soc. Chim.* [2], xiii. 315).

DISULPHAMMONATES. DISULPHYDRALATES.

See SULPHAZOTIC ACIDS.

DIURAMIDES (E. Mulder, *Dent. Chem. Ges. Ber.* v. 1011).

Diglycollamic Diuramide $(\text{NH}^2.\text{CO}.\text{NH}.\text{CO}.\text{CH}^2)^2\text{NH}$, is produced, together with other products (apparently amidacetyl urea and hydantoin) by the action of ammonia on bromacetyl urea at the heat of the water bath:

When the solid substance which separates out on cooling is recrystallised from water, dissolved in hydrochloric acid, precipitated by ammonia, redissolved in hydrochloric acid, and treated with platinic chloride, a platinochloride is obtained in needles or prisms having the composition $2[(\text{NH}^2.\text{CO}.\text{NH}.\text{CO}.\text{CH}^2)^2\text{NH}.\text{HCl}].\text{PtCl}_6$; and this platinum salt, treated with sul-ammoniac, yields diglycollamic diuramide in the free state, as a colourless crystalline body, insoluble in alcohol and moderately soluble in hot water.

The residue left when the crude product of the preceding reaction is treated with hydrochloric acid yields, on recrystallisation from water, a compound which appears to be triglycollamic triuramide $(\text{NH}^2.\text{CO}.\text{NH}.\text{CO}.\text{CH}^2)^3\text{N}$.

DIXYLIT COMPOUNDS. See XYLIT COMPOUNDS.

DOLERITE. Peterson (*Jahrbuch f. Mineralogie*, 1869, 36) and Sandberger (*ibid.* 1870, 205) regard dolerite and anamesite as merely structural varieties of the same rock-formation, and separate basalt from them as a chemically different rock. Sandberger regards, as a distinguishing character of the two former, the sparing occurrence, or total absence, of magnetic iron ore, and its replacement by hexagonal titanite iron ore.

H. Mohl (*ibid.* 1871, 885) has analysed the dolerite and tachylite of the Sababerg in Hesse, a basaltic mountain overlooking the sandy table land of the Reinhardswald between the Oberweser and the mouth of the Diemel, and consisting mainly of a true feldspathic dolerite, together with tachylitic and basaltic rocks. The dolerite (a) and tachylite (b) have the following composition :

	SiO ²	TiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	CaO	MO	K ² O	Na ² O	P ² O ⁵	H ² O
a	54.62	1.26	16.42	3.92	7.88	0.33	7.23	2.08	1.35	4.23	0.83	1.24 = 101.39
b	51.93	0.28	19.36	3.68	6.48	0.06	6.27	2.16	0.73	3.14	0.04	2.16 = 99.29

DOLIUM. The saliva of *Dolium Galea* contains in 100 parts by weight :

Sulphuric acid, free	3.42	3.30
Sulphuric acid, combined	0.20	0.15
Hydrochloric acid, combined	0.58	0.60
Other substances, organic and inorganic	1.08	2.35
Water	94.00	93.60

A comparison of the weights of the animals with those of their shells and of the salivary glands, gave :

	I.	II.
Molluscs	1305	520
Shells	550	255
Glands	850	80

(Pancieri and de Luca, *Sill. Am. J.* [2] xlix, 421).

DOLOMITE. This rock is commonly regarded—independently of necessary constituents amounting to 2 or 3 per cent.—as a double carbonate of magnesium and calcium having the same composition as bitterspar, viz. $\text{CaCO}_3 \cdot \text{MgCO}_3$. Korsten, who analysed 96 dolomites, concluded that in crystallised dolomites this proportion always holds good. According to other authorities, however, this is not always the case, and G. Bischof found that in dolomites whose composition only approximates to the formula above given, the magnesium carbonate is always below, and the calcium carbonate always above the calculated quantity. Experiment likewise shows that in non-crystallised dolomites, the two carbonates are present in very varying proportions, the calcium carbonate however always predominating. Rammelsberg, from a comparison of the published analyses of dolomites, deduces the three following formulae :

a	b	c
$\text{CaCO}_3 \cdot \text{MgCO}_3$	$3\text{CaCO}_3 \cdot 2\text{MgCO}_3$	$2\text{CaCO}_3 \cdot \text{MgCO}_3$
100 or 51.34	100 or 64.10	100 or 70.42
84 or 45.66	56 or 35.90	42 or 29.58
184	100.00	142
		100.00

He however points out distinctly that these simple stoichiometrical relations hold good only for the purer forms of dolomite.

The action of water containing carbonic acid on dolomites, differs according to their composition. Bischof's experiments show that from dolomites containing not more than 11 p.c. magnesium carbonate, carbonic acid water extracts only calcium carbonate, and hence it is probable that dolomites having the composition b or c would yield to carbonic acid water, chiefly calcium carbonate, and but little magnesium carbonate. From dolomites of the normal constitution a on the other hand, carbonic acid water takes up the whole without separation, and according to Bischof, deposits it again in the form of bitter spr. Hence he infers that dolomites containing druses of calc spar are imperfect dolomites, still in course of formation, whereas those which contain crystals of bitter spar are perfectly formed.

According to these results, the condition of a dolomitic formation may be inferred from the composition of the spring waters which issue from it, provided these waters have not previously passed through other strata from which they can take up any soluble ingredients. Such is the case with the dolomitic springs of that part of the Franconian Jurassic formation known as the Franconian Switzerland.

The valleys in this locality abound in springs, whereas the high table-lands are almost destitute of water, the rain which falls on them percolating quickly through the porous and fissured rocks, and issuing in the valleys in the form of springs.

The water of a considerable number of these springs has been analysed by Gorup-Besanez (*Ann. Ch. Pharm.* viii. Supplement-band 230). The only important constituents are calcium carbonate, magnesium carbonate, and silica, while chlorine, iron, alkalis, and bituminous organic matter occur only in minute quantities.

Many of these springs are pure dolomite waters, their percentage amounts of calcium and magnesium carbonates agreeing closely with those of dolomites occurring in the neighbourhood: these dolomites in fact, gave by analysis 57.32 and 57.21 p.c. CaCO_3 , and 42.68, and 42.79 MgCO_3 , while the mean of the water-analyses gave 58.71 CaCO_3 , and 41.29 MgCO_3 . Some of the waters, however, differed widely from these numbers, containing as much as 88 or 89 p.c. CaCO_3 to 12 or 11 MgCO_3 , and in the case of two other springs, 70 and 68 p.c. CaCO_3 to 30 and 32 MgCO_3 .

The occurrence of true dolomitic springs in the immediate neighbourhood of dolomite rock of normal composition, corroborates Bischof's view, that water containing carbonic acid dissolves true dolomites in fixed proportions, forming a solution from which by quick evaporation, a residue may be obtained, having the composition of the original dolomite. This is further corroborated by the experiments of Gorup-Besanez, on the amounts of calcium and magnesium carbonates taken up from dolomite by carbonated water in 5 to 8 and in 21 days.

From further experiments by the same chemist, it appears, however, that although carbonated water takes up from normal dolomites, fixed relative quantities of calcium and magnesium carbonates, the solution, when left to evaporate slowly, first deposits a large quantity of the calcium carbonate, while the magnesium carbonate is deposited only after long evaporation. Gorup-Besanez finds, moreover, that carbonated water takes up fixed relative quantities of the two carbonates from imperfect as well as from perfect dolomites, but that in no case is crystalline bitter-spar ever deposited from such a solution on evaporation. He therefore dissents from Bischof's conclusion, that a dolomite containing druses of bitter-spar is necessarily a perfectly formed dolomite.

The geological formation of dolomite is not yet completely understood, but the preceding facts seem to militate against Bischof's theory, that when magnesium limestone is subjected to the action of carbonated water, nothing but calcium carbonate is dissolved out till the molecular proportion $1\text{CaCO}_3 : 1\text{MgCO}_3$, belonging to true dolomite, is attained.

All the dolomites of the Franconian Jurassic formation are found by spectroscopic examination to contain lithium.

DULCITAMINE, $\text{C}^6\text{H}^{13}\text{NO}^3$. (G. Bouchardat *Compt. rend.* lxxiv. 1406). A base produced by heating 1 part of monoehlorhydric dulcitan $\text{C}^6\text{H}^{11}\text{ClO}^4$ or of dichlorhydric (or dibromhydric) dulcite, $\text{C}^6\text{H}^{12}\text{Cl}_2\text{O}^4$, with 10 parts of alcoholic ammonia to 100° for six hours.

The dulcitamine hydrochloride may be dissolved out by absolute alcohol and precipitated in long needles by very gradual addition of ether. This salt is very soluble in alcohol or water, very slightly in ether-alcohol. The aqueous solution is neutral and has a faintly sweet taste. Treated with silver oxide, it yields free dulcitamine as a powerful base analogous to glyceramine, strongly blueing litmus, expelling ammonia from its combinations, absorbing carbon dioxide from the air, and forming by evaporation an uncrystallisable syrup, which gives with acids neutral salts crystallising with difficulty. The hydrochloride forms with platinic chloride orange-yellow needles of the salt $2(\text{C}^6\text{H}^{13}\text{NO}^3.\text{HCl}).\text{PtCl}_4$, very soluble in water and absolute alcohol, but not in ether, decomposed by heating, with a smell of burnt sugar and burnt horn. Auric chloride gives a difficultly crystallisable compound.

DULCITE, $\text{C}^6\text{H}^{11}\text{O}^6 = (\text{C}^6\text{H}^9)^{11}(\text{OH})^6$ (Bouchardat, *Ann. Chim. Phys.* [4], xxvii. 68; *Comp. rend.* lxxiii. 199; lxxiv. 665, 866, 1406; *Bull. Soc. Chim.* [2], xviii. 115). This saccharine substance, isomeric with mannite, is produced by the action of sodium amalgam on milk-sugar, on inverted milk-sugar, and on galactose, the glucose of milk-sugar:

An aqueous solution of galactose is acted upon by 2 p.c. sodium amalgam, the liquid being neutralised by dilute sulphuric acid from time to time; at the termination of the reaction, the liquid is exactly neutralised by acid, and the greater part of the sodium sulphate removed by crystallisation, the last portions by mixing the solution

with twice its volume of strong alcohol. It is then filtered and concentrated to the consistence of a syrup. After some time small crystalline warty groups separate out, which may be removed and drained on filter-paper; a further quantity of crystals is deposited on leaving the liquid at rest. The substance thus obtained is readily purified by recrystallisation from water; on analysis it gave 39.3 and 39.1 p.c. of carbon, 7.85 and 7.9 p.c. of hydrogen, the theoretical numbers for dulcite being 39.5 p.c. carbon, and 7.7 p.c. hydrogen. The crystals are gritty between the teeth, but scarcely saccharine in taste; they are not fermentable in contact with beer-yeast; they melt at 187°, pure dulcite melting at 188.5°; they are very slightly soluble in strong alcohol; 100 parts of water at 21° dissolve 4.1 parts, pure dulcite dissolving to the extent of 3.6 to 3.7 parts, the difference being, doubtless, due to slight impurity. The solution of the artificially prepared substance has no appreciable action on polarised light. It is not browned on boiling with potash; neither does it reduce a cupro-potassic solution. Treated with dilute nitric acid, it yields crystals of mucic acid. All these characters show that the substance obtained by hydrogenation of galactose is identical with natural dulcite from the manna of Madagascar and from *Melanopyrum nemorosum*.

Milk-sugar, treated in like manner with sodium amalgam containing 4 p.c. sodium, likewise yields dulcite in monoclinic crystals, the angles of which agree exactly with those of the crystals of natural dulcite (ii. 349). The mother-liquors contain lactic acid. Inverted milk-sugar yields dulcite together with mannite, the latter crystallising in silky needles from the mother-liquors of the dulcite.

Ethers of Dulcite. 1. *Haloïd Ethers*.—Dulcite dissolves easily in aqueous hydrochloric acid (saturated at 0°) with slight decrease of temperature, and the solution left to itself for 24 hours deposits bulky crystals of the hydrochloride, $C^6H^{14}O^8$, $HCl + 3H^2O$. This compound is very unstable, and can exist only in an atmosphere saturated with hydrochloric acid; the crystals, when exposed to a current of air, give off the whole of their hydrochloric acid. The hydrobromide and hydriodide are similarly constituted, and somewhat more stable.

2. *Acetic Ethers*.—Dulcite submitted to the action of acetic acid produces a great number of neutral compounds, some of which are ethers of dulcite having the general formula—

while others are ethers of dulcitan, $C^6H^{12}O^8$, having the general formula—

Diaceto-dulcite, $C^8H^{18}O^8 = (C^6H^{14})^1 \left\{ \begin{smallmatrix} (OC^2H^3O)^2 \\ (OH)^4 \end{smallmatrix} \right\}$.—Crystalline scales, fusible at 176°, volatile without residue on ignition; inodorous, insipid, slightly soluble in cold water, alcohol, or ether, soluble in lukewarm water; saponified by dilute alkalis.

Diaceto-dulcitan, $C^8H^{16}O^7 = (C^6H^{12})^1 \left\{ \begin{smallmatrix} (OC^2H^3O)^2 \\ (OH)^2 \\ O \end{smallmatrix} \right\}$.—Volatile without residue on ignition; tastes very bitter; soluble in water, alcohol, and ether. At the ordinary temperature this substance is a colourless liquid, of the consistence of oil beginning to congeal.

Hexaceto-dulcite, $C^{10}H^{20}O^{12} = (C^6H^{12})^1 (OC^2H^3O)^6$.—Hard, friable, crystalline plates, fusible at 171°; sublimes at 200°–220° without alteration of its chemical composition. The sublimed product acquires for a time different properties, but gradually resumes its former state.

Tetraceto-dulcitan, $C^{10}H^{20}O^9 = (C^6H^{12})^1 \left\{ \begin{smallmatrix} (OC^2H^3O)^4 \\ O \end{smallmatrix} \right\}$. Colourless and resinous in appearance; sublimes without residue; insupportably bitter; has a disagreeable odour when warm; nearly insoluble in water, soluble in alcohol and ether; saponified by alkali.

Pentacetomonochlorhydro-dulcite, $C^{10}H^{19}ClO^{10} = (C^6H^{12})^1 \left\{ \begin{smallmatrix} (OC^2H^3O)^8 \\ Cl \end{smallmatrix} \right\}$, obtained by acting on dulcite with a mixture of acetic and hydrochloric acids, is an unstable compound, which, when heated in water, decomposes into pentaceto-dulcite, and hydrochloric acid.

Pentaceto-dulcite, $C^{10}H^{20}O^{11} = (C^6H^{12})^1 \left\{ \begin{smallmatrix} (OC^2H^3O)^5 \\ OH \end{smallmatrix} \right\}$.—Crystalline body with properties very similar to those of hexaceto-dulcite, but less soluble in alcohol and ether. Heated for a long time to about 200°, it is partially transformed into pentaceto-dulcitan, with separation of water.

3. *Benzoic Ethers*.—*Hexabenzodulcite*, $C^{18}H^{30}O^{12} = (C^6H^{12})^1 (OC^6H^5O)^6$.—When

1 mol. dulcite is heated to 150° with 8 mols. benzoyl chloride containing benzoic acid, hydrochloric acid is evolved and the dulcite dissolves. The temperature is then raised to 200°; the excess of benzoyl chloride expelled by a current of carbonic anhydride; two volumes of alcohol added for one of the liquor, and the whole again heated. After some days small crystals are deposited, which, after another crystallisation from alcohol, consist of pure hexbenzodulcite. This body is solid and without taste or odour at ordinary temperatures. It melts at 147°, is quite insoluble in water or ether, and only slightly soluble in alcohol. When heated to 200° and suddenly cooled, it becomes amorphous, in which state it is much more soluble in alcohol, and even soluble in ether. After a few minutes, however, crystals are deposited from these solutions, having all the properties of ordinary hexbenzodulcite. Hexbenzodulcite is difficultly saponifiable. When it is treated with nitrosulphuric acid, the benzoic radical is attacked and hexnitrobenzodulcite is formed, which, when acted on by sodium-amalgam in presence of alcohol, furnishes dulcite and sodium amidobenzoate.

Tetrazobenzodulcitean, $C^8H^8O^8 = (C^8H^8)^{+1} \left\{ \begin{matrix} (OC^7H^8O)^+ \\ O^- \end{matrix} \right\}$.—When the mother-liquor obtained in the preparation of hexbenzodulcite is agitated with ether and sodium carbonate, and two volumes of alcohol are added to one of the liquor, a resinous precipitate is formed, which, after drying at 140°, has the composition of tetrazobenzodulcitean. Like hexbenzodulcite, it is solid and without taste or smell at the ordinary temperature; is insoluble in water, and only slightly soluble in alcohol; but differs from that body in emitting, at 150°, an odour of benzoic ether, in volatilising without blackening, and in being very soluble in ether. It is saponified with difficulty. Nitrosulphuric acid apparently converts it into a nitrobenzodulcitean.

DUPLOSULPHACETONE, $C^8H^{12}S^2$. See SULPHACETONE (1st Suppl. 1047).

DUST, VOLCANIC. See VOLCANIC EMISSIONS.

DURANGITE. An orange-coloured mineral occurring with tinstone and topaz, near Durango in Mexico. It becomes transiently black when heated, and at a higher temperature yields a yellow glass and a scanty white sublimate, etching the glass at the same time; on charcoal it gives the reactions of arsenic with iron and manganese. It is partly decomposed by hydrochloric and nitric acids, completely by sulphuric acid, with evolution of hydrofluoric acid. The quantity of fluorine in the mineral is considerable, but could not be determined on account of the smallness of the quantity available for analysis. Hardness = 5. Sp. gr. = 3.95–4.03.

As ² O ³	Al ² O ³	Fe ² O ³	MnO	Na ² O	Si ² O	F.
65.10	20.68	4.78	1.30	11.66	0.51	undetermined
55.22	20.09	5.06	1.28	11.86	0.70	„

The mineral consists, therefore, of an arsenate with a fluoride, corresponding with amblygonite among the phosphates. The degrees of oxidation of the iron and manganese are hypothetical (G. J. Brush, *Sill. Am. J.* [2], xlviii. 179). The crystals, according to measurements by J. M. Blake, are monoclinic, exhibiting the faces ∞P , $\pm 2P$, $-P$, $\infty P\infty$, $4P\infty$, and agreeing nearly in the magnitude of the angles and in type with yttritanite. Cleavage parallel to ∞P at an angle of 110° 10' (in yttritanite at 114°).

DYNAMITE. This name is applied to various mixtures of nitroglycerin with earthy substances. The original dynamite prepared by Nobel (*Dingl. pol. J.* xc. 124), consists of nitroglycerin mixed with $\frac{1}{3}$ of its weight of porous silica (*infusorial silica*, *Kieselguhr*). It is said to exhibit the full power of the nitroglycerin contained in it, and to have the advantage, on account of its pasty consistence, of filling the bore-holes completely without overflowing, and to be less dangerous both in carriage and in manipulation.

The superior safety in the use of dynamite has been confirmed by the experiments of v. Wolfskrön (*ibid.* excli. 174), and of Bolley, Postolozzi and Kundt (*ibid.* excli. 140). The latter, however, recommend that dynamite should not be hermetically enclosed in metallic or other very solid receptacles, since it explodes when heated in a brass case tightly screwed or closed with a cork, also by a hard blow when placed between two metal plates. From 100 parts of dynamite, strong alcohol extracted 76.6 parts of nitroglycerin.

H. Schwarz (*ibid.* ccv. 429) found in two samples of explosives called dynamite the following materials:—

	No. 1, strong.	No. 2, weak, for coal-blasting.
Nitroglycerin	67.5	58.9
Chalk and sawdust	30.11	42.18
Moisture and loss	2.39	0.97

Experiments on the relative explosibility of nitroglycerin and various kinds of dynamite have been made by Girard, Millat and Nogt (*Moniteur scientifique*, xlii, 58); on dynamite and its use in war by P. Champion (*ibid.* 91); and on the use of dynamite for breaking up large castings, by P. Champion (*Compt. rend.* lxxii, 770). See also *Chem. Soc. J.* [2] ix, 766-772.

DYSLYTE. See EULYTE.

E.

EARTHNUOT OIL. This oil, expressed in the cold, contains about 4.5 p.c. of arachidic acid; that expressed with the aid of heat contains about 5 p.c. It is sometimes used to adulterate olive-oil, and its presence may be detected by separating out the arachidic acid. For this purpose the oil is saponified; the soap decomposed by hydrochloric acid; the resulting fatty acids converted into lead salts; the oleate of lead is removed by ether; and the remaining salts are again decomposed by hydrochloric acid. The fatty acids are then dissolved in alcohol of 90°, and the solution is left to cool. If earthenut oil be present, abundant crystals of arachidic acid will soon be seen to form. The crystals are washed with alcohol of 70°, in which they are perfectly insoluble, dissolved in boiling absolute alcohol, and the solution is evaporated to dryness and weighed. In reckoning the amount of arachidic acid obtained, allowance must be made for the quantity dissolved by the alcohol. 100 parts of 90 p.c. alcohol dissolve 0.25 of arachidic acid. The process does not succeed with a mixture containing less than 4 p.c. of earthenut oil, but with a 10 p.c. mixture the amount may be ascertained within 1 p.c. of the truth (A. Renard, *Compt. rend.* lxxiii, 1330).

ECBOLINE. See ERGOT.

EGG. On the nuclear structures of the yolk of the hen's egg, see NUCLEIN.

ELLITE. A hydrated cupric phosphate from Cornwall (see PHOSPHATES).

ELDER OIL. See OILS, VOLATILE.

ELECAMPANE INULIN. See INULIN.

ELECTRICITY. *Electromotive Force developed by the Contact of Metals, and the Modification of that Force by Heat* (Edlund, *Pogg. Ann.* cxxxvii, 474; cxi, 435; cxliii, 404, 534. *Phil. Mag.* [4] xxxviii, 263; xliii, 81, 213, 264).—It was observed by Peltier, in 1834, that when an electric current is passed through the point of contact of two different metals, that point becomes heated or cooled according as the direction of the current is opposed to or coincides with that which would be developed by the contact of the metals. The quantity of heat thus absorbed or developed has been shown by Edlund to be proportional to the product of the strength of the current into the electromotive power of the metallic couple, which may, therefore, be determined by measuring the quantity of heat absorbed or developed by a current of known strength.

With an apparatus constructed on this principle, for the description of which we must refer to Edlund's paper (*Pogg. Ann.* cxliii, 404, 534), the following results have been obtained:—

1. The electric tension series of the metals, as determined by electroscopic experiments by Volta, Péclet, and others, exhibits no immediate relation to the electromotive forces developed by the contact of the metals: consequently, the amount and nature of these forces cannot be determined from the electric tension series. It appears probable, also, that the electric tension depends, not entirely on the contact between the two metals, but also on the film of gas or water condensed on their surfaces.

2. The order of the metals in the electromotive series is the same as that in the thermo-electric series.

3. The electromotive force for the combinations of copper with iron, cadmium, zinc, silver, gold, lead, tin, aluminium, platinum, palladium, and bismuth, increases with the temperature when the experiments take place at a temperature not exceeding +30°.

4. The thermo-electric forces which, at a given difference of temperature, arise in different metallic combinations, are not proportional to the electromotive forces of these same metallic combinations.

5. If, with the aid of the second fundamental principle of the mechanical theory of

hent, we calculate the modifications undergone by the electromotive forces of contact in consequence of the increase of temperature, results are obtained which do not agree with experiment.

According to Crova (*Compt. rend.* lxxiii. 440) the electromotive power of voltaic batteries with two liquids varies with their temperatures, decreasing as the temperature rises in Daniell's arrangement, and increasing with the temperature in that of Grove, while, in one-liquid batteries like that of Smee, it is independent of the temperature. This is easily shown by arranging two galvanic couples of the same kind with their poles in opposite directions, and interposing a galvanometer in the circuit. On heating one of the couples, the needle will be deflected in a direction varying according to the nature of the arrangement.

Electromotive Force of Platinum in Contact with various Liquids.—

When two electrodes of non-platinised platinum have remained for a certain time in an acid liquid, dilute sulphuric acid for example, they, for the most part, do not give rise to any perceptible current; but if one of them be washed with distilled water and wiped with bibulous paper, it is found, on reimmersion in the acidulated liquid, to be strongly negative with regard to the one which has remained in the liquid. The electromotive force of the circuit quickly diminishes, but an hour generally elapses before it is reduced to nothing. If the acidulated water be replaced by potash solution, the electrode which is washed with water and dried with bibulous paper, becomes distinctly positive towards that which has remained in the alkaline liquid. With the alkaline solution either non-platinised or platinised electrodes may be used, and in the latter case the electromotive force is considerably stronger than in the former. When a platinised and a non-platinised platinum electrode are immersed in the same liquid, the former is always the positive element. These effects may, perhaps, be attributed to the formation, on the surface of the platinum, of compounds of that metal with the acid or alkaline constituents of the liquid, the formation and decomposition of these compounds requiring a considerable time. This view is supported by the fact that, if one of two similar platinum wires which give no current when placed in distilled water be immersed for a long time in dilute sulphuric acid, then quickly washed, dried between filter-paper, and again plunged into the distilled water, it will be distinctly negative towards the other. As all acids which have been examined give the same result as sulphuric acid, whereas all alkaline solutions produce the opposite effect, the experiment just described may be used to ascertain whether a liquid is acid or alkaline, even when, on account of its great dilution, it no longer exhibits any reaction with test-paper. In this manner it has been found that no solution is strictly neutral; the salts of the heavy metals exhibit a decided acid reaction, while those of the alkali-metals react more or less distinctly alkaline (Gaugain, *Compt. rend.* lxxix. 1300).

Subsequent experiments by Gaugain (*ibid.* lxx. 74) leave it undecided whether the unstable surface-modification of the platinum is due to superficial impregnation with distilled water, which then acts electrically towards the acid, or whether the action of the acid on the platinum produces on the surface a more electropositive compound, which is gradually destroyed on subsequent immersion in distilled water. The drying of the platinum at different temperatures gives rise to complications of the phenomena similar to those observed by Becquerel (p. 445).

If two plates of platinum, the surfaces of which have been polished with emery-paper, are allowed to remain in distilled water for 48 hours, no electric current is generated when the two plates are brought into metallic connection through a delicate galvanometer. If, however, one of the plates be taken from the liquid, and its surface rubbed with any soft substance, it is found, when plunged again into the distilled water, to be negative to the plate which has remained in the water. When the surface is rubbed with filter-paper, a force of 30 units is developed: during friction with linen moistened with water 40 units are developed; and if the plate be rubbed with wet linen for some time, and then with dry linen, the force rises to 56 units. The unit of force which serves as a measure is the electromotive force of a thermoelectric couple

$$\left(\begin{array}{c} \text{Bi} - \text{Cu} \\ 0^{\circ} - 100^{\circ} \end{array} \right).$$

The above values are given for the force developed when the plate is plunged into distilled water immediately after rubbing; if, however, the plate, after rubbing, be allowed to remain either in dry or in damp air for some time, the force generated on immersion gradually decreases. The current generated diminishes very quickly after the plate has been immersed for a short time; after 10 minutes it diminishes to about one-half, but it is some hours before the two plates become perfectly neutral to each other. The cause of these currents may be that after rubbing the plate does not immediately become thoroughly moistened by the water, so that if it be taken out of the water, the liquid on the surface will be seen to run together into drops. The plate, however, recovers its power of being thoroughly moistened if it be

heated in a spirit-lamp flame. It seems as if the rubbing caused a small film of grease to be deposited on the surface, which is destroyed by heat (Gauguin, *Compt. rend.* lxxiv. 610).

Development of Electricity by Contact of Metals, Charcoal, &c. with Water, Acids and Saline Solutions (Becquerel, *Compt. rend.* lxx. 481).—1. The contact of a neutral saturated solution of potassium sulphate with a similar solution of potassium nitrate, produces, with two platinum plates, an electro-motive force = 3·4, and with two gold plates, a force = 2 (that of a Grove's element = 100).

2. Circuits formed of pure gold plates, and of gold plates alloyed with 0·1, 0·2 and 0·5 copper, in distilled water gave the values 5·6, 7·5 and 11·2. The electromotive power increases therefore with the proportion of copper; the pure gold is less attacked than its alloys.

3. Gold and its alloys were always positive* towards platinum, and gave the electromotive forces 2·8, 4·50, 6·8 and 7·5.

4. Gold and its alloys were also positive to nearly pure graphite, giving the electromotive forces 5·6, 8·7, 12 and 14.

5. Platinum is negative to palladium and iridium.

6. Graphite containing traces of iron is positive to pure graphite. The latter body is less attacked by water than any other.

The other bodies examined by Becquerel are divided into three classes: (1) charcoal is usually positive when plunged into distilled water (kept in platinum vessels to ensure the absence of soda). (2) Gold, platinum, palladium and iridium are sometimes negative. (3) Silver and the base metals, after being moderately heated, are always negative. The positive excitement of charcoal is due to the fact that after it has absorbed air, it slowly produces carbonic acid, this chemical action rendering the charcoal positive, and the water negative. This property may be intensified by strong ignition. The action of distilled water on the non-oxidable metals is intimately related to their capability of absorbing gases, especially hydrogen and oxygen, on their surface, and giving them up again at higher temperatures. The predominance of one or the other gas determines the positive or negative excitation.

The following experiments relate to the polarising property of platinum:—

A platinum wire enclosed in a tube and heated on the sand-bath, becomes after heating:

For a few minutes	positive to water.
For half-an-hour	negative "
To a little below a red heat	positive "
To a white heat	negative "

Heated for a few seconds in boiling distilled water, it loses nearly all its polarisation. These effects can only be explained by supposing: 1. That the aqueous vapour in the atmosphere is decomposed under the influence of the metal, at a more or less elevated temperature. 2. That a difference in the mode of absorption of the hydrogen and oxygen takes place, according to the time for which the heating is prolonged. When perfectly depolarised, neither platinum nor gold gives a current with water. The negative excitation of silver and the oxidable metals after moderate heating, arises from their becoming covered with a thin film of oxides, which protects them from the further action of the water, whereas a perfectly clean surface is attacked, and thereby becomes positive. This effect is analogous to the passivity of iron immersed in nitric acids. Many non-metallic bodies, as white quartz and white topaz, possess the same property as the non-oxidisable metals of absorbing gases, especially hydrogen, and becoming positive after heating.

Contact of Metals with Acids, &c.—When the free ends of two wires of gold or platinum connected with the polar wires of a galvanometer, are dipped into strong nitric acid, and one of them withdrawn, heated in a lamp-flame to free it from adhering liquid, and then immersed again, this wire becomes successively positive, negative, positive. The first effect is probably due to capillary affinity; the second to the polarisation of the two wires by the incipient current, and the decomposition of the solution; the third to a second polarisation. If the acid is dilute, the wire remains positive for a few seconds, in consequence of absorbing hydrogen liberated by the decomposition of the water induced by heating. With hydrochloric acid, sulphuric acid, ammonia and neutral saline solutions, such as sodium chloride or sulphate, barium chloride, potassium nitrate, &c., the platinum becomes negative in consequence of the air absorbed during cooling, which in contact with the liquid acquires negative electricity.

* The terms positive and negative are used in Becquerel's memoir, with reference to the direction of the current in the portion of the circuit external to the battery, that is to say in the sense opposite to that which is usually assigned to them (ll. 416). In the account of his experiments here given, the usual meaning of the terms has been retained, that is to say, the more active metal is called positive.

According to Skeay (*Chem. News*, xxiii. 221) electric currents of considerable intensity are developed by either gold or platinum under the following circumstances:—

Two plates of gold (prepared chemically pure) are taken; one is placed in a cell partly filled with sea-water, and the other in a porous cell containing ammonium sulphide, or sea-water charged with hydrogen sulphide. On making connection, a small current passes from the gold plate in the inner cell to that in the outer, the electric currents obtained in this way being able to decompose solutions of gold, silver, and copper.

To avoid the electromotive action described by Becquerel, the solutions must be previously boiled to expel the air from them, and the plates of gold or platinum immersed, while red hot, in the solutions.

When potash or ammonia is substituted for ammonium sulphide, the currents obtained are very much weaker.

Electromotive Power of Metallic Sulphides. (W. Skeay, *Chem. News*, xxiii. 255, 291).—Those sulphides which have the power of conducting are also capable of generating electricity. A mass of iron pyrites and another of galena immersed in sea-water and connected by copper-wires with a decomposing cell of cupric sulphate, deposited the metal in a coherent form. The relative polarity of other sulphides is given in the following list, which is so arranged that each body is positive to all that succeed it:

Ferrous sulphide.	Cupric ferro-sulphide (copper pyrites).
Manganous sulphide (manganese blende).	Ferrie disulphide (cubical pyrites).
Zinc sulphide (zinc blende).	Antimonious sulphide (stibnite).
Stannic sulphide.	Auric sulphide.
Mercurous sulphide.	Platinic sulphide.
Argentie sulphide (artificial).	Ferrous arseno-sulphide (mispickel).
Lead sulphide (galena).	Carbon (graphite) sulphurised.
Cuprous sulphide (copper glance).	

Among the metals, zinc stands above ferrous sulphide, silver between silver sulphide and galena, platinum between platinic sulphide and mispickel, and carbon must be placed at the negative end of the series.

When a piece of massive galena is placed in voltaic contact with amalgamated zinc, and both are immersed in dilute sulphuric acid, in such a manner as to expose nearly the whole surface of the couple to the action of the acid, a galvanic current is at once established, gas is liberated at the surface of the galena, and the zinc is rapidly dissolved. If three or four such elements be connected together, a current is produced capable of decomposing acidulated water, and exhibiting all the effects of a small galvanic battery.

The galena which forms the negative element in these combinations may be replaced by other metallic sulphides, such as zinc blende, copper pyrites, ferrous sulphide, &c.: a difficulty, however, arises in establishing a current with iron pyrites, which may be overcome by completely immersing the couple in the acid for a short time; gas is immediately evolved at the point of contact, and the area of evolution rapidly spreads, until the whole surface of the specimen has become active. The gas liberated in a battery of this description is sulphuretted hydrogen, the nascent hydrogen exerting a desulphurising action upon the metallic sulphide, the ultimate effect of which is in some cases to completely reduce the mineral to the metallic state. These sulphides are also able to form among themselves a series of voltaic couples in presence of saline solutions, according as they differ from each other in respect to their affinities for oxygen. Thus, galena and copper pyrites produce a voltaic couple in which the galena is the negative element, but the functions of the galena are reversed when combined with silver sulphide, this latter mineral being decomposed with less facility.

The fact that several metallic sulphides are capable of performing the functions of the negative element of a galvanic couple, shows that these minerals are fairly good conductors of electricity, to an extent, indeed, not hitherto recognised. Moreover since dissimilar sulphides generally are capable of setting up a galvanic action, and inducing chemical decomposition among themselves, these phenomena may perhaps have some relation to the formation and decomposition of metalliferous lodes.

Galvanic Batteries. Favre (*Compt. rend.* lxxi. 214) has constructed a modification of Daniell's battery, in which the zinc plate is replaced by a plate of hydrogenised palladium. This battery acts just like the original zinc-copper combination, and exhibits in a very striking manner the chemical resemblance of hydrogen to the metals, the hydrogen constituting in fact the active element.

Zalowski (*Compt. rend.* lxx. 321) has constructed a circuit of three fluids, consisting

of two porous vessels placed one within the other, the inner one containing nitric acid and a plate of carbon, the outer one sulphuric acid, and the whole being enclosed in a vessel containing solution of sal-ammoniac and a zinc plate.

Nettleton (*Chem. News*, xxii. 228) replaces the platinum plates of Grove's battery by aluminium. He finds that two couples with aluminium plates, 4 inches long and $1\frac{1}{4}$ inch wide, decompose water very quickly.

Figuiet (*J. Pharm.* [4] xi. 280) replaces the platinised platinum in Smee's battery by charcoal covered with platinum or silver. To produce the platinum deposit the plate of gas-rotort charcoal is painted with a moderately strong solution of platinum chloride and heated over a Bunsen's burner till the metal is reduced. The silver coating is obtained by painting the charcoal with a solution of silver nitrate, converting the nitrate into chloride by holding the plate over fuming hydrochloric acid and heating it till the silver chloride melts. The reduction to the metallic state takes place in the battery itself, being produced by the hydrogen evolved at the commencement of the action. With plates thus coated, the hydrogen all escapes in bubbles, without polarising the charcoal.

Still more economical is a coating of finely divided carbon, which may be produced by heating up the contents of an egg with five or six times its bulk of water and half its bulk of syrup, coating the charcoal with this mixture two or three times, drying it each time on the surface, and then heating it over a gas or alcohol flame till it no longer gives off smoke.

Plates thus prepared and well washed with water are said to give currents which remain constant for years; and the batteries, which are clean and easily managed, appear to be well adapted for applications in which large quantities of electricity are required, such as electrodeposition of metals, electric lighting, magneto-electric machines, &c.

H. Highton (*Chem. News*, xxiv. 142) describes some new galvanic combinations contrived chiefly with the view of removing the hydrogen and its products of combination from the surface of the negative plate. This may be effected in all known batteries by heating the liquid from below, so that the bubbles of vapour thereby liberated may carry the hydrogen with them. Every form of battery is said to be greatly increased in power by this expedient. In Daniell's battery Highton proposes to surround the zinc with a solution of a neutral sodium salt and sodium silicate, or better, to use magnesium as the positive plate, and surround it with a solution of nitrate and silicate of sodium; this combination is rather costly, but affords a very strong and constant current. A very complete and not too costly oxidation of the hydrogen evolved on the carbon plate may be effected by surrounding this plate with sodium permanganate; the supply of this salt must, however, be continually renewed if a constant current is to be kept up.

The best and cheapest oxidising agent, however, is said to be atmospheric air. To render it available in this way, the negative plate of platinum or charcoal is placed in a deep earthenware cell, and packed in ash or similar porous material, which is wetted, but not filled, with nitric acid. A moist porous envelope is thus obtained, in which the deoxidised substances find sufficient atmospheric oxygen [and nitric acid vapour] to reoxidise them.

S. O. Sharples (*Sill. Am. J.* [3] i. 247) has examined a number of liquids with regard to their use in galvanic combinations. The following arrangement was found to give a constant current for 12 hours, without the inconvenience of acid fumes. The outer space round the hollow zinc cylinder of an ordinary Bunsen's cell is filled with sulphuric acid of sp. gr. 1.84, mixed with 9 vol. water. It is recommended to leave the acid thus diluted to stand for some time till all the lead sulphate has settled down, and make use of the clear liquid. To fill the porous cell containing the carbon cylinder, commercial nitric acid is saturated in a warm place with potassium bicarbonate, and mixed with a third of its volume of sulphuric acid, after which a quantity of water is added sufficient to redissolve the precipitated chromic acid. The addition of the sulphuric acid gives to the last-named mixture a greater conducting power, and renders it less costly. The electromotive force of this combination is equal to that of a Bunsen's element, and the internal resistance one-half that of the latter.

The replacement of the inner liquid by a solution of chromic acid in nitric acid, suggested by W. Gibbs, was found also to give a constant current, having an electromotive force equal to 1.2 that of a Bunsen's element; the internal resistance was the same. The high price of chromic acid, however, is an obstacle to the general use of this combination.

A combination consisting of zinc and charcoal in a solution of chromic acid in dilute sulphuric acid, devised by Bunsen, is described by Roscoe in the *Reports of the British Association* (1870, p. 47). Its electromotive power is there said to be that of a Grove's element as 25 : 18. Sharples found it to be twice that of a Daniell's

and 1.2 that of an ordinary Bunsen's element; but the current was not constant and the zinc was strongly attacked by the chromic acid. The use of manganese dioxide and nitric acid in the porous cell of Bunsen's battery gave feeble results, the strength of the current being = 1.43 of a Daniell's element. The current was variable, and nitrous fumes were evolved.

J. H. Koosen (*Pogg. Ann.* cxliv. 627) replaces the nitric acid in Grove's battery by a solution of potassium permanganate mixed with $\frac{1}{30}$ th sulphuric acid; this combination raises the electromotive force from 1.6 to 2.0 Daniell. To render the current constant an addition of $\frac{1}{30}$ th to $\frac{1}{15}$ th of strong sulphuric acid is necessary. This acid decomposes the permanganate into oxygen which passes over to the zinc, potash which remains dissolved in the liquid as sulphate, and manganic hydrate which gradually settles to the bottom as a black powder. As an atom of potash is set free for each atom of zinc galvanically dissolved, the quantity of sulphuric acid consumed is double of that in any other battery; hence the large excess of sulphuric acid required. The use of charcoal instead of platinum in this form of battery, is not found advantageous.

Laclanché's Battery.—This zinc-carbon battery, in which the porous cell containing the gas-coke cylinder is filled up with a mixture of coarsely pounded manganese dioxide and gas-coke, and the exciting liquid is a solution of sal-ammoniac (*1st Suppl.* 555) has, according to J. Müller (*Pogg. Ann.* cxl. 308), an electromotive force equal to 0.896 of that of a Daniell's element, whereas Laclanché himself estimates it at 1.38. The difference between the two estimations is probably due, at least in part, to differences in the degrees of polarisation of the elements experimented on; this polarisation, according to Müller's experiments, being only partially removed by the manganese peroxide. In fact, this oxide, by giving up part of its oxygen to oxidise the electrolytically separated hydrogen, becomes inactive after prolonged use.

The loss of power in this battery is also partly due to the formation of a crystalline compound of ammonia and zinc chloride, $(\text{NH}_4)_2\text{ZnCl}_4$, which is deposited in the cells and on the zinc-plate, and obstructs the action. The formation of this compound arises from the liberation of ammonia by the action of the manganese dioxide on the sal-ammoniac:

The ammonia is at first set free, and combines slowly with the zinc chloride when the two are present in the liquid in considerable quantity. The frequent addition of hydrochloric acid to neutralise the ammonia prevents the formation of the crystalline compound, and to a great extent the diminution of power of the battery (*Priwoznik, Pogg. Ann.* cxlii. 467).

Air-Battery (Gladstone n. Tribe, *Proc. Roy. Soc.* xx. 290; xxi. 247).—When pieces of silver and copper, touching or connected by a wire, are immersed in an aerated solution of pure copper nitrate, a decomposition of the salt ensues, accompanied by a deposition of cuprous oxide on the silver, with a corresponding dissolution of the copper, and a flow of electricity through the liquid from the positive to the negative metal.

The reaction may be represented by the following formulæ:—

Before contact:

After contact:

This decomposition takes place only when the oxygenised solution of copper nitrate is in contact with the silver, and it is independent of any action of free oxygen on the copper; and if free oxygen can be supplied to the solution at the same rate as it combines to form cuprous oxide, the action will go on at about the same rate as long as any metallic copper remains.

To facilitate this as much as possible, the silver plate is placed in a horizontal position just under the surface of the liquid in the cell, and, in fact, converted into a small silver tray full of crystals of the same metal, which rise in projections above the surface. The copper plate lies horizontally under it, separated, if necessary, by a piece of muslin, and connection is made by a wire. Holes are made in the silver tray to facilitate the movements of the salt in solution. The solution itself may be contained in a shallow trough or saucer, and the whole arrangement put upon a wooden stand, the plates being attached to two uprights fixed in the stand.

An increase in area of the silver plates causes almost a proportionate increase in the current. Heat greatly increases the activity of this combination, a cell giving a deflection of 40° at 20° , gave one of 250° at 50° ; and the increase in the higher degrees of this range of temperature was much greater in the lower. The strength of copper nitrate which gives about the maximum effect is 6 p.c.

From the nature of the reaction it might be expected that the current would gradually diminish, on account of the using up of the oxygen in the neighbourhood of the silver. Such a diminution always does take place at first, and consequently agitation of the liquid has the effect of increasing the action. On breaking contact for some time, so as to allow of the absorption of oxygen from the air, the current, upon again making contact, is as strong, or nearly so, as originally.

On placing a cell, with plates connected by a wire, under a bell-jar full of air over mercury, the mercury rose from absorption of oxygen, and the oxygen was so completely removed that a lighted taper was immediately extinguished in the remaining gas.

Comparative experiments with aerated and deaerated solution of copper nitrate showed that the amount of action in the latter case was small, a result clearly attributable to the difficulty of completely excluding air. Two experiments were made alike in all respects, except that in one case the cell used was filled with a solution simply deprived of oxygen, while the other cell was filled with a solution through which a current of carbonic anhydride had been passed for some time. The first was placed in the air, and gave a deflection of 110 rising to 115, but the second was placed in a vessel full of carbonic anhydride and gave a deflection of 20, which gradually fell to 3.

The cuprous oxide deposited on the silver is compensated by an equivalent dissolution of the copper-plate. The cuprous oxide is sometimes deposited in crystals visible to the naked eye, and shown by a lens to be regular octahedrons.

One cell having plates two inches in diameter was found sufficient to decompose such metallic salts as the nitrates of copper, silver, and lead, platinum being used for the negative electrode, and for the positive the same metal as existed in the salt experimented on. Six cells were sufficient to decompose dilute sulphuric acid, and dilute hydrochloric acid pretty quickly, copper electrodes being employed.

The theoretical interest of this battery lies in the fact that it differs from all other galvanic arrangements, inasmuch as the binary compound in solution is incapable of being decomposed either by the positive metal alone, or by the two metals in conjunction, without the presence of another body ready to combine with one of its elements when set free.

Grove's gas battery is essentially different from this, if the oxygen and hydrogen condensed on the platinum plates play the part of the two metals; but it closely resembles this battery, if hydrogen acts the part of the positive metal, and platinum that of the negative; the dilute sulphuric acid will then be decomposed on account of the simultaneous presence of the oxygen which can combine with the liberated hydrogen. Viewed in this manner, Grove's gas-battery is only a special case of the reaction above mentioned, and the formulæ will be:—

Before contact:

After contact:

Electro-capillary action. (Becquerel, *Compt. rend.* lxiv. 919, 1211; lxx. 51, 720, 752; lxxi. 77, 245, 766, 1066; lxxiii. 1285; lxxix. 1037; lxx. 68. *Jahresb. f. Chem.* 1867, 111.; 1868, 82; 1869, 155; 1870, 143).

When a tube closed at one end and having a crack in the direction of its length, is filled with a moderately strong solution of cupric nitrate, and placed within another tube containing an equally concentrated solution of sodium monosulphide, the inner and outer liquids being at the same level, no copper sulphide is formed, but after a short time, there is deposited within the crack, and on the adjacent inner surface of the tube, metallic copper of crystalline aspect, which gradually increases in quantity, widening the crack, and ultimately breaking the tube. With dilute solutions, the action is the same, but takes place more slowly.

To obtain capillary spaces of uniform width, two plates of glass or rock-crystal were laid one on the other, and held together by threads, or by means of ebonite provided with screws. When the plates were placed in the upright position, a small glass vessel, containing the liquid to be introduced into the capillary spaces, was cemented on to their upper ends. When they were to be placed horizontally, the upper plate, at least a centimeter thick, was perforated in the centre by a cylindrical hole of 4 or 5 mm. diameter for introducing the liquid. Sometimes also this aperture was surmounted by a glass tube several centimeters long, so that the column of liquid might exert a certain pressure on the liquid in the capillary space, which is especially necessary when the entrance of the liquid is rendered difficult by very close approximation of the plates. Sometimes also a strip of filter-paper is interposed between the plates, whereby the distribution of the liquid is rendered more uniform. The width of the

2nd Sup.

G G

capillary spaces, both of the cracked tubes and of the glass-plate apparatus, was very exactly determined by means of an apparatus devised by E. Becquerel for measuring the electric resistance of the liquids contained in them, this resistance being compared with that of the same liquid in a capillary tube of known diameter; by this means the width of a capillary space may be estimated down to a few thousandths of a millimeter.

By means of these apparatus, reductions may be effected of copper, silver, gold, nickel, lead and tin. The result appears to be due to the combined action of chemical affinity, molecular attraction and electricity. The two liquids acting on one another through the capillary space form a galvanic couple, the circuit being completed in the first instance by certain parts of the walls of that space, and afterwards by the separated metallic particles. The correctness of this view may be shown by dipping the ends of a bent copper-wire into the tube-apparatus above described, so as to form an ordinary galvanic circuit of two liquids and a metal. The end of the wire dipping into the alkaline solution is then attacked and forms the positive pole, while that which dips into the copper solution forms the negative pole, and becomes covered with metallic copper; at the same time thiosulphate and nitrate of sodium are formed, and the copper nitrate is decomposed, but no trace of metallic copper is formed, either on the crack or on the adjacent portions of the tube. As soon, however, as the wire is removed, the crack and the inner surface of the tube become covered with metallic copper. This shows that, in the absence of the wire, its conducting function is discharged by certain parts of the walls of the capillary space.

Effects similar to the above are also produced by placing the metallic solution in a tube closed at the bottom with parchment-paper, and immersing this tube in the solution of the alkaline sulphide. With this arrangement, metallic deposits are obtained on the inner surface of the tube, sometimes of the thickness of several millimeters; but the reactions are more violent than with the previously described arrangement, and the products alter more quickly. Ordinary paper and other porous bodies are altogether unfit for the production of this phenomenon. On the other hand, the separation of the liquids may be effected by means of a tube tied round at bottom, with linen, and filled to the height of 4 or 5 centimeters with pounded glass or quartz, fine sand or gypsum, the interstices of which form the capillary spaces.

By means of E. Becquerel's apparatus above mentioned, it was found that the reduction of most metals may be effected in capillary spaces, not exceeding a few hundredths of a millimeter in width; but when the width is reduced to a few thousandths of a millimeter, gold and silver are easily reduced, but other metals very slowly. The metallic precipitates formed in the plate apparatus, exert so strong a pressure, that if the bands do not burst, plates of 2 mm. thick are sometimes broken. This action may explain the splitting of rocks in which capillary actions take place in consequence of infiltration.

Metallic reductions likewise take place when the two solutions (the alkaline sulphide and the metallic salt) are separated by salt water, or by water acidulated with sulphuric or nitric acid; but if the alkaline sulphide or sulphhydrate be replaced by other liquids, as caustic potash or soda, or a solution of glycerin in caustic soda, or a concentrated solution of sodium chloride, the reduction either does not take place at all, or it is indistinct and not easily recognisable.

Electro-capillary actions may also be applied to the separation of silver or gold from copper, copper from iron, &c. A solution containing equal parts of silver nitrate and copper nitrate placed in a tube closed at bottom with parchment-paper, and immersed in solution of sodium sulphide, first yields metallic silver in dendrites or laminae, the copper not being reduced till after a considerable time. If a strip of paper saturated with a very strong acid solution of ferrous sulphate containing only a few thousandths of copper be placed between two glass plates, and the whole immersed in a solution of sodium sulphide, black ferrous sulphide is gradually deposited on the paper, and upon it an extremely thin film of metallic copper, which is then completely separated. The copper does not proceed from the paper, for the same results are obtained with asbestos. In like manner copper may be completely separated from a solution of chromous chloride, or from solutions of nickel or cobalt. From the latter, the nickel and cobalt may likewise be precipitated, and nickel separated from cobalt.

Electro-capillary phenomena are also produced when, instead of a strip of paper, a metallic plate covered with a moistened insoluble metallic compound is placed between two glass plates. When moistened iron pyrites is spread on a clean copper plate placed between two glass plates, and the edges cemented to prevent access of air, the iron sulphide is gradually decomposed, metallic iron is deposited here and there upon the copper, and copper sulphide is formed. In like manner with a zinc plate and recently prepared copper sulphide moistened with distilled water, zinc hydrate and

cuprous sulphide are deposited on the zinc plate in about a year, provided the water does not evaporate. With an iron plate and green cupric carbonate, crystallised ferric oxide is obtained and sometimes ferrous carbonate and metallic copper.

The preceding methods may also be applied to the preparation of various insoluble carbonates, aluminates, silicates, &c. in the crystallised state. When a tube closed at the bottom with parchment-paper, or with a double layer of Swedish filter-paper, and containing a moderately concentrated solution of calcium chloride, is immersed in a solution of sodium bicarbonate, the latter penetrates the paper, and forms rhombohedral crystals of calc spar. In like manner, aluminium silicate, lead chromate, barium sulphate, and barium carbonate may be obtained in the crystallised state.

In the following experiments, the alkaline solution was placed in the tube, and the metallic salt in the outer vessel. Concentrated solutions of potassium aluminate and chromic chloride yield on the surface of the diaphragm touching the alkaline solution (the positive surface) small hard nodules or laminae of aluminium monohydrate, $Al_2O_3 \cdot H_2O$, and on the opposite or negative surface green translucent laminae of chromic hydrate having a crystalline aspect. The aluminium hydrate appears under the polarising microscope to consist of double refracting prisms running out into pyramids. If the chromic chloride be replaced by hydrochloric acid diluted with an equal volume of water, the trihydrate $Al_2O_3 \cdot 3H_2O$ is deposited on the positive surface in translucent crystalline crusts resembling diaspor. With cupric nitrate instead of chromic chloride, similar results are obtained in a short time, but the crystals of blue cupric hydrate often contain cupric silicate. These products are formed with peculiar facility when both solutions are concentrated, and there is no excess of acid on the one side or of alkali on the other. To obtain slow action, the tube must be closed with several layers of parchment-paper. With potassium aluminate and solutions of metallic salts, no reduction of metal takes place, the electromotive force being smaller than when an alkaline sulphide is used. Similar results are obtained with cupric nitrate, and a solution of zinc oxide or lead oxide in potash; also with solutions of antimonious chloride and potassium aluminate; the oxides separate in the crystalline state, the one dissolve in potash on the positive side, the one combine with acid on the negative side. With silicate instead of aluminate of potassium, there are deposited on the positive surface, very hard, transparent, single-refracting laminae of silicic hydrate, above this is formed a deposit of transparent gelatinous silica, which gradually acquires an opaline aspect, but becomes transparent again when immersed in water, and resembles hydropneum.

By the simultaneous use of cupric nitrate, there is deposited on the negative side a hard blue crust, not however hard enough to scratch glass, from which by trituration and washing with a large quantity of water, crystalline fragments are obtained, having the form and composition of diopase. With a solution of free alkali, instead of an alkaline salt, crystallised cupric hydrate is deposited on the negative side. The reactions above described, alter as the diaphragm is more or less covered with deposits, and cease altogether when the crust has acquired a certain thickness.

If the same experiments are performed at a temperature of 50° – 80° , the form of the deposits is somewhat different. If the negative plate of a battery of five Daniell's elements be dipped into the solution of potassium aluminate and the positive plate into that of chromic chloride, no precipitate is produced in the former, but in the latter chromic hydrate is deposited not only on the positive plate, but likewise on the diaphragm. On reversing the poles, no precipitate is formed in the chrome-solution, but aluminium hydrate is deposited in the alkaline solution.

If a solution of potassium carbonate be allowed to flow slowly on to a plate of gypsum placed between two glass plates, the surface of the gypsum gradually becomes covered with radiate groups of needles with truncated summits, having the physical and chemical characters of apophyllite, a double silicate of potassium and calcium.

If a tube closed with a double thickness of parchment-paper, and containing carbon sulphide, be immersed in a solution of potassium aluminate to such a depth that the two liquids stand at the same level, the alkaline solution gradually passes through the diaphragm, and forms, with the carbon sulphide, a sulphocarbonate, which floats on the surface of the latter, whilst the alumina is deposited as crystalline monohydrate on the diaphragm, and on the sides of the vessel. The same products are obtained when the diaphragm is omitted, and the one liquid is made to form a layer on the surface of the other.

The electromotive forces developed by two liquids separated by a capillary fissure, are usually very weak. Neutral solutions of potassium sulphate, ammonium sulphide, sodium chloride and sodium nitrate are negative in contact with distilled water. Sulphates give an evolution three times as strong as solutions of potassium nitrate or sodium chloride. The electromotive force varies with the concentration of the solution. If that of a nitric acid battery (Hansen's) = 100, that of a solution of caustic potash

of sp. gr. 1.215 in contact with water is 9.40; if the potash-solution be diluted with three times its bulk of water, the electromotive force will be reduced to 3.

The intensity of the electrochemical action in capillary spaces depends on the electromotive force, and the conducting power of the two liquids which are in capillary connection. The electromotive force is independent of the density of the liquids; but this is not the case with the chemical action, inasmuch as this action is in direct proportion to the conducting power of the circuit.

When nitric acid and solution of caustic potash are placed in the electro-capillary apparatus above described (p. 449), the nitric acid is decomposed, the oxygen, however, not separating at the positive side of the diaphragm, but apparently remaining in solution or combining with the potash to form potassium peroxide. If the potash be replaced by a solution of potassium plumbate, the electromotive force remains nearly the same ($= 0.29$ of the zinc-carbon element); but the chemical actions change if a metallic solution, such as copper or silver nitrate, or gold chloride, be substituted for the nitric acid. The copper salt then yields, on the negative surface of the diaphragm, a thick deposit of anhydrous peroxide of copper. With a solution of silver nitrate or gold chloride, the metal is reduced, and peroxide of lead of considerable hardness is deposited on the positive side. Pure potash-solution is not capable of effecting a reduction of the metals on the opposite side of the capillary partition, the presence of an oxidisable body in the alkali being necessary to depolarise the positive side on which the oxygen collects, and prevent the development of the contrary current which interferes with the reduction (*Compt. rend.* lxxi. 197).

Electro-capillary Actions in the Animal Organism.—Bequerel has endeavoured to show that electrocapillary currents come into play in the conversion of arterial into venous blood, and in the accompanying chemical reactions. For the explanation of respiration and the nutrition of the tissue he sets out from the supposition that when two differently constituted liquids separated by a tissue with capillary pores, act on one another through the medium of these pores, the walls of which act as solid conductors, they give rise to electro-capillary currents, the direction of which is such, that the surface in contact with the liquid which plays the part of an acid forms the negative pole, the other the positive pole. These currents not only produce chemical combinations and decompositions, but likewise act as mechanical forces in transporting substances from one pole to the other (*Compt. rend.* lxxviii. 1285; lxxix. 1037).

Bequerel has also examined the electromotive force of the liquids which is contained in the bone-tissue of animals. When a platinum electrode is introduced into the marrow, and another applied to the surface of a bone of a freshly-killed animal, an electromotive force is exhibited about half as great as that of a Daniell's element. The liquid which penetrates all the pores and channels of the bones, develops, where it comes in contact with the liquid contents of the neighbouring tissues, an abundance of negative electricity, which, when platinum plates are introduced as above, unites with the positive electricity developed at the surface of the bone. When the metal plates are removed electro-capillary actions at once set in, the function of the conductor being then discharged by the solid substance of the bone. The current developed in muscular contraction, is attributed by Bequerel, in accordance with Dubois-Reymond, to the circumstance that the muscular juice in the interior becomes somewhat less alkaline during contraction than in the state of rest. The main result of the investigation is that the muscle-bone and nerve-currents have a purely chemical origin, and are not due to any peculiar electrical organisation of these tissues. In the functions of the muscles and nerves, electro-capillary currents play the principal part (*Compt. rend.* lxx. 68).

In the substance of the nerves and brain, a large number of currents are developed, in such a direction that the inner walls of the vessels and nerves exhibit reduction-phenomena, and their outer walls phenomena of oxidation. Between the grey substance of the brain which forms the outer, and the white substance which forms the inner part of the brain, there is produced a contact-current $= \frac{1}{10}$ of the electromotive force of the nitric acid (zinc-carbon) element. The direction of the current is governed by the law above explained (*Bequerel, Compt. rend.* lxx. 345).

Electro-capillary Actions in the Vegetable Organism.—The development of electric currents in the interior of growing plants was observed several years ago by Bequerel (*Compt. rend.* xxxi. 40), and by Wartmann (*Arch. Phys. nat.* xv. 301), the strength of these currents increasing with the vigour of the plant, and the quantity of juice present in the several parts. Regarding these phenomena from the electro-capillary point of view, Bequerel now infers from his experiments that the pith and the cellular tissue in general are always positive at their contact with the other tissues. He finds, also, that the soil is always positive with regard to the roots, stem and leaves, i.e., to the liquids which moisten those organs or are contained in them. He considers that

the positive tissues, positive liquids, and the substances dissolved in the latter, are richer in oxygen than the rest (*Compt. rend.* lxxv. 752).

Explanation of the preceding Phenomena without the aid of the Electro-capillary Hypothesis.—O. Loew (*J. pr. Chem.* [2] iv. 271) is of opinion that the so-called electro-capillary phenomena may be explained without calling in the aid of electric currents, and proposes to designate the mode of action by the name *chemosmosis*.

When a moderate-sized crystal of cupric sulphate is immersed in a concentrated solution of potassium sulphide contained in a test-tube, the formation of a black crust of cupric sulphide is observed, and soon after a dark yellow coloration is seen to ascend from the crystals, indicating the formation of potassium disulphide. After twelve hours' standing, the black lump formed at the bottom, under the crust of cupric sulphide, is found to consist of metallic copper. Silver nitrate furnishes, under the same conditions, only a small quantity of metallic silver, whilst by far the greater part of the salt is not acted upon at all. Crystals of cupric sulphate covered with a concentrated solution of potassium hydrate yield a loose mixture of the black oxide and the hydrate of copper, and a blue solution of cupric oxide in potassium hydrate, whilst crystals of silver nitrate under the same conditions remain, as in the other case, unaltered below a thin crust of silver oxide.

Now as for every molecule of cupric sulphate a molecule of cupric sulphide is formed, whilst the water of crystallisation, having been solid before, passes into the liquid state, it follows that the crust of cupric sulphide must contain a great many more molecular gaps than that of silver sulphide, for this reason, that silver nitrate contains no water of crystallisation. A crust of sulphide once formed, the process of decomposition will go on in the same manner as before, only when the molecular gaps are large enough to allow of the passage of more molecules of potassium sulphide, whilst when the gaps are too small, chemosmotic decomposition, or electro-capillary phenomena, will be produced. The potassium unites with the group SO_4 , metallic copper being separated, whilst the sulphur previously combined with the potassium remains outside the crust, forming potassium disulphide. The crust of silver sulphide, on the other hand, having no gaps, soon puts a more or less complete stop to the chemical action.

Loew is of the opinion that many of those chemical processes which take place in animal and vegetable organisms may be explained in a similar manner by supposing that the cellular membranes are provided with gaps, and possess a different molecular structure for each species of cells.

Electrolysis. General Laws.—G. Quincke (*Pogg. Ann.* cxliv. 1, 161) has developed a new theory of electrolysis, and of the conduction of electricity in liquids, based on the assumption that to each of the two component molecules which make up the entire molecule of an electrolyte, there is attached a certain quantity of free electricity, these quantities ϵ and ϵ' , which belong to the two component molecules, being either the same or different in sign and quantity. The separation of the component molecules arises from the different attraction which the several atoms composing the molecules exert on the two electric fluids.

The accelerating forces acting upon ϵ and ϵ' at a certain point are expressed by—

$$-\frac{dV}{dx}\epsilon \text{ and } -\frac{dV}{dx}\epsilon',$$

where V denotes the potential of the free electricity at this point and the force is reckoned as positive in the direction of the positive x . The charges ϵ and ϵ' carrying, as a rule, the particles to which they are attached along with them, soon attain, on account of the friction of the moving particles against one another, the constant velocities

$$v = -C\frac{dV}{dx}\epsilon, \text{ and } v' = -C'\frac{dV}{dx}\epsilon',$$

where C and C' are constants depending upon the quantity of mass to be moved, upon the friction between the particles, and upon the force with which ϵ and ϵ' are retained by the moving atoms. The force separating the ions is proportional to their mean relative velocity, and is expressed by

$$K = A(v - v') = -\frac{dV}{dx}(B\epsilon - B'\epsilon'),$$

where A and $B = AC$ are constants.

If q represent the section of the electrolysed liquid, λ its conductivity, and i the current intensity, we get—

$$\frac{dV}{dx} = -\frac{i}{\lambda q}; \text{ and } K = \frac{i}{q} \frac{B\epsilon - B'\epsilon'}{\lambda};$$

from which it appears that the force tending to separate the constituents of an electrolyte is proportional to the density of the current, that is the strength of the current per unit of sectional area of the electrolyte. As long as this force is too small to overcome the chemical affinity, the liquid will behave as an insulator, but it may become conducting by an increase of the density of the current.

From these equations, the following general conclusions are deduced:—

1. The force tending to separate the ions increases with the electromotive force of the battery used, and is inversely proportional to the length, but independent of the section and of the conductivity of the liquid, supposing the resistance of the rest of the circuit to be negligible in comparison with that of the electrolyte.

2. The quantity of the ions separated is proportional to the mean relative velocity with which they pass one another.

3. According as the constituents of an electrolyte both approach to or recede from an electrode, or as they move with different velocities in opposite directions, the concentration of the liquid at this electrode will increase or decrease.

Quincke's formulae show further that the conducting power of a liquid increases with its temperature and condensation, and that, under certain circumstances, a maximum of conductivity may occur. They also show, in accordance with the results of experiment, that the quantities of different substances separated at the electrodes, and the ratios of these quantities when several chemical compounds contained in the same liquid are decomposed simultaneously, are independent of the density of the current. Further, that in a unit of time, different numbers of component molecules may pass through the same transverse section to the anode and cathode, these numbers being proportional to the density of the current and to a constant peculiar to each liquid, and therefore independent of the density of the current.

In most salts the passage of the electric current is attended with a decrease of concentration at both electrodes, whence it follows that the component molecules move in opposite directions, and ϵ and ϵ' have different signs. In solutions of CdI_2 , CdCl_2 , ZnCl_2 , ZnI_2 , however, Hittorff (*Pogg. Ann.* c. 542) observed concentration to take place at the anode, whence it follows that ϵ and ϵ' are in these cases both of negative sign.

Conduction in Liquids without Electrolysis.—The power of liquids to conduct electricity without at the same time undergoing decomposition being still somewhat doubted, though the experiments of Faraday and of Foucault afford strong arguments in favour of its existence, Favre (*Compt. rend.* lxxiii. 1463) has endeavoured to settle the question by experiments made under conditions in which electrolysis was impossible.

A Smee's battery of two cells which, so long as its two poles were unconnected, did not evolve a single bubble of gas, gave off, when its poles were connected through a voltmeter, 20 c.c. of hydrogen in 24 hours, showing that the circuit was complete, and therefore that conduction took place through the acidulated water in the voltmeter. No gas, however, was evolved from the voltmeter, whether the acid liquid contained in it had been previously saturated with the electrolytic gases, or had been previously boiled so as to expel dissolved gas. On replacing one of the Smee's elements by a Daniell's cell, a quantity of copper was deposited in the latter, equivalent to the gas given off by the Smee's cell, but no gas came from the voltmeter; and when solution of cupric sulphate was substituted as an electrolyte for the dilute sulphuric acid it was found that, after four days, though a deposit of copper had occurred in the Daniell's cell, the negative plate of the voltmeter did not exhibit a trace of it.

These facts indicate a true conduction in liquids distinct from electrolytic transference. In fact, according to previous experiments by Favre (p. 460), not less than three Smee's cells, whose voltaic energy is expressed by the number 15,000 per cell in units of heat for a certain amount of chemical decomposition, would be required to effect the electrolysis of the acid liquor of the voltmeter, in which, for a similar amount of decomposition, about 45,000 units of heat are required.

Electrolysis of Water.—Gladstone and Tribe (*Br. Assoc. Reports*, 1872, *Transactions of the Sections*, p. 75) find that pure water may be decomposed by zinc in conjunction with a more negative metal, the connection being made either within the liquid, or outside by a wire. With zinc and copper the effect increases slowly as the plates are approximated till they are within about an inch of each other, and on further diminishing the distance, the action increases at a rapidly accelerating rate. The decomposition is also accelerated by heat. With two plates $1\frac{1}{2}$ inch distant from one another, the deflection of the galvanometer showed that the effect of raising the temperature from 40° to 80° was more than double of that between 20° and 40° . In an experiment with a 'copper-zinc couple,' that is to say, zinc-foil coated with finely divided copper by immersion in a dilute solution of copper sulphate, the following quantities of hydrogen were obtained:—

Mean temperature	Duration of experiment	Hydrogen collected	Hydrogen per hour
22.2	3 hours	3.1 c.c.	1.1 c.c.
31.4	2 "	11.1	5.5
55.0	45 minutes	10.4	13.0
74.1	15 "	15.5	62.0
93.0	10 "	20.1	74.6
	5 "	44.0	528.0

The last column shows the very great acceleration due to heat.

Five other experiments with the copper-zinc couple in which the gas was collected and measured at the end of every 24 or 48 hours yielded the following results:—

In experiment A, 33.4 grams of zinc-foil were employed, 2.6 meters long and 0.05 wide. The coils were kept apart by muslin. In experiment B there was used one meter of similar foil crumpled up. The two experiments continued almost *pari passu* for months, the amount of hydrogen gradually diminishing. Subjoined are the results of the first and last observations:—

	Mean temp.	Expt. A	Expt. B
Day	C°.	c.c.	c.c.
1	12.8	117.1	49.6
84	10.0	14.0	5.1

Under the microscope the bubbles of gas are seen to form, not on the zinc, but among the copper crystals, and sometimes to make their appearance on the glass at some distance off.

From the position of platinum in the electro-chemical series, it was anticipated that the effect would be still more marked with that metal in a spongy state on the zinc. The metal was deposited from the tetrachloride, and thoroughly washed. With 0.6 meter of foil the following quantities of hydrogen were obtained:—

Day	Mean temp.	Vol. in c.c.
	C°.	
1	11.7	113.6
8	7.7	12.3

Similar effects were obtained with water previously freed from air by boiling.

Iron and lead, similarly coated with copper, also decompose pure water, and the action of magnesium is greatly increased by conjunction with copper (*Proc. Roy. Soc.* xx, 218).

A metal less capable than zinc of decomposing water, likewise produces a deflection of the galvanometer if it be united with a metal still more negative. The order for pure water seems to be: platinum, silver, copper, iron, tin, lead, zinc, magnesium.

When the current of a single Daniell's cell is passed through pure water, the electrolysis is more easily effected between poles of a metal which has a considerable affinity for oxygen than between poles of a metal which has but little affinity for that element; with zinc poles, for example, the action is more than double of that between platinum poles of the same size and at the same distance. The order of efficiency for poles in the electrolysis of water seems to be: platinum, tin, silver, copper, iron, lead, zinc, magnesium. After a few minutes the power of tin was found to rise above that of copper. The other metals stand in the same order as in the previous list, where they are arranged according to the facility with which they produce electricity by their joint action on water.

Heating the liquid between the poles accelerates the action. With zinc poles the deflection increases about fourfold between 5° and 80°, and the action increases nearly *pari passu* with the temperature.

When the poles are formed of dissimilar metals, a current is established in the electrolytic cell which, according to its direction, either adds to or subtracts from the current originating in the Daniell's cell. Thus, if two poles of platinum be used, the effect with water is very minute; but if the negative platinum pole be replaced by one of zinc, pure water is decomposed by one cell of Daniell's battery with visible evolution of hydrogen. With poles of silver and zinc the following deflections were obtained:—

Positive	Negative	Deflection
Silver	Silver	27
Zinc	Silver	52
Silver	Zinc	7
Zinc	Zinc	33

When, therefore, the dissimilar metals were employed as poles, the decomposition of the water was not the mean of that producible by silver and by zinc, viz. 30, but 30 + 22 when the forces acted in the same direction, and 30 - 23 when they acted against one another (*Br. Assoc. Reports, loc. cit.*)

Electrolysis of Alcoholic Iodides by the Copper-Zinc Couple.—When zinc-foil coated with copper, as above, is heated to 100° with ethyl iodide, a decomposition takes place similar to that which is produced by zinc alone at higher temperatures, a small quantity of gas being given off, and ethiodide of zinc $\text{Zn}(\text{C}^2\text{H}_5)\text{I}$ produced, which, when gently heated, is resolved into zinc iodide and zinc ethyl. When the couple acts on ethyl iodide in presence of water or alcohol, ethane C^2H_6 is given off, and zinc iodohydrate $\text{Zn}(\text{OH})\text{I}$ or iodethylate $\text{Zn}(\text{OC}^2\text{H}_5)\text{I}$ remains behind.

The iodides of methyl, propyl, and amyl are decomposed in a similar manner (see the several ALCOHOL REACTIONS).

Relations between Electricity and Heat. F. Guthrie finds that the reaction between an electrified body and a neighbouring neutral body, whereby the electricity in the latter is inductively decomposed and attraction produced, undergoes a modification when the neutral body is considerably heated.

Under many circumstances the electrified body is rapidly and completely discharged, the action of discharge depending mainly upon the following conditions:—(1) the temperature of the discharging body, and its distance from the electrified one; (2) the nature (+ or -) of the latter's electricity.

With regard to (1) it is found that the discharging power of a hot body diminishes as its distance increases, and increases with its temperature, depending, however, not upon the quantity of heat radiated from the hot body to the electrified body, but chiefly upon its quality. Thus a white-hot platinum wire connected with the earth may exercise an indefinitely greater discharging power, at the same distance, than a large mass of iron at 100°, though the latter may impart more heat to the electrified body.

Neither the mere reception of heat, however intense, by the electrified body, unless the latter has such small capacity as to be itself intensely heated, discharges the electricity if the source of heat be distant; nor is discharge effected when the electrified body and a neighbouring cold one are surrounded by air through which intense heat is passing. But, for the discharge, it is necessary that heat of intensity pass to the electrified body from a neutral body, within inductive range.

White- and red-hot metallic neutral bodies exercise this discharging power even when isolated from the earth, but always with less facility than when earth-connected.

The hotter the discharging body, whether isolated or earth-connected, the more nearly alike do + and - electricities behave in being discharged; but at certain temperatures distinct differences are noticed. The - electricity, in all cases of difference, is discharged with greater facility than the +.

Various flames, both earth-connected and isolated, have an exceedingly great power of discharging both kinds of electricity.

The effects in regard to discharge are similar when platinum wire, rendered hot by a galvanic current, is used, and also when the condensed electricity of a Leyden jar is experimented on.

As hot iron shows a preferential power of discharging - over + electricity, so it is found that white-hot but isolated iron refuses to be charged either with + or - electricity. As the iron cools, it acquires first the power of receiving -, and afterwards of receiving +. Further, while white-hot iron in contact with an electrified body prevents that body from retaining a charge of either kind of electricity, as it cools it permits a + charge to be received, and subsequently a - one.

Many of these effects may, perhaps, be attributed to the existence of an electrical coercive force which, like the magnetic coercive of steel, is diminished by heat (*Phil. Mag.* [4] xvi. 257; *Proc. Roy. Soc.* xxi. 168).

Thermic Equivalent of Electricity.—F. Kiechl (*Wien. Acad. Ber.* lx. [2] 121), has re-determined the thermic equivalent of electricity, that is to say, the number of heat-units producible by the expenditure of a quantity of electricity capable of eliminating 1 gram of hydrogen at 0°C, and 760 mm. from water at 0°. This quantity of heat is the same as that which is developed by the combustion of 1 gram of hydrogen at 0°, and 760 mm. in oxygen under the condition that the resulting aqueous vapour is converted into water at 0°. The principle of the determination is as follows:—A voltmeter and a rheostat whose water-equivalent is exactly known, are enclosed in a calorimeter and traversed for equal times by a current of constant strength. When the voltmeter is placed in the circuit, the action is: evolution of N grams of detonating gas, and production of a quantity of heat Q; when the rheostat is inserted, the

effect is simply the production of another quantity of heat Q_1 . The difference $Q_1 - Q$ is therefore equivalent to the decomposition of N grams of water, or to the elimination of $\frac{1}{2}$ N gram of hydrogen. The simplicity of the principle is somewhat disturbed by the polarisation of the electrodes, and by the circumstance that, under the most favourable circumstances, the evolved detonating gas leaves the calorimeter at the temperature of the latter, which is not exactly 0° , and under a pressure more or less different from 760 mm. Nine experiments gave, as the mean value of the thermic equivalent of electricity, as above defined, the number 33591. The experiments of Andrews on the direct combination of hydrogen with oxygen give 33808; those of Favre and Silbermann 34462.

Thermo-electric Action of Liquids and Metals.—Gore (Proc. Roy. Soc. xix, 324) has examined the relations of the temperature and chemical action of metals to their electrical state. Two shallow copper dishes connected by wires with a galvanometer, were so arranged in a U-shaped glass vessel with vase-like terminations, that the under surfaces of both could be placed in contact with any liquid contained in the glass vessel. One of the copper dishes was heated by pouring hot water into it, the other remaining at the temperature of the atmosphere. The general results are as follows:—The hot copper dish was *positive* to the cold one, when the active liquids were: hydrochloric, hydrocyanic, boric, and orthophosphoric acids; cupric chloride (weak solution); cobalt chloride; manganous chloride; chromic acid; chromic chloride; zinc sulphate (weak solution); magnesium sulphate; calcium chloride; strontium nitrate and chloride; barium chloride; sodium nitrate (strong solution); sodium chloride, iodide, carbonate, and diborate; sodium sulphate (strong solution); trisodic phosphate; potassium nitrate, chloride, and chlorate; potassium bromide (strong solution); potassium iodide (strong solution); potassium carbonate, hydrocarbonate and dichromate; ammonium hydrate and chloride; potassium cyanide and ferro-cyanide; zinc acetate; and sodium acetate. *Negative* in the following: nitric, chloric, hydrobromic, hydrofluosilicic, and sulphuric acids; ferrous sulphate; cupric chloride (strong solution); cupric sulphate; zinc sulphate (strong solution); sodium nitrate and iodide (weak solutions); potassium iodate; chrome alum; ammonium nitrate; oxalic, acetic, tartaric, and citric acids. In several instances where the hot metal was negative with a weak solution, it became positive in a strong one. The direction of the current appeared to be more influenced by the nature of the acid in a salt than by that of the base. The currents appear to be due either (1) to the direct influence of heat, the effect of which would be to make the hot copper negative in acid, and positive in alkaline liquids; (2) to chemical action, which sometimes overpowers the direct influence of heat and reverses the effect; or, (3) to both these influences combined. The action of air in promoting oxidation at the line where the liquid and metal come in contact with it, no doubt influences the amount of current, as also perhaps the direction. When the air-line is long, the metal becomes electro-negative in all cases, and gives stronger indications when the liquid has a powerful chemical action.

To ascertain whether the quantity of current was due to the difference in number of the molecules of liquid touching the hot and cold plates respectively, and also what amount of difference of strength of liquid was equivalent to the difference of temperature employed, experiments were made with liquids of unequal strength, instead of unequal temperature. The results show, that heat does not act simply by causing a greater number of molecules of each substance to touch the hot plate.

Following the suggestions of these researches, Gore has constructed a thermo-electric battery consisting of twelve bent glass tubes (fig. 15), closed at one end, and having a platinum wire sealed into that end, each tube being filled with a conducting liquid and having its outer end closed by a cork, in which was fixed a second platinum wire dipping into the liquid. The upper ends of the tubes are heated by hot water contained in an oblong tin box, having in its lower surface a long semi-cylindrical cavity to receive them. The tubes 1, 3, 5, 7, 9, 11 are filled with a dilute sulphuric acid, the alternate ones with aqueous solution of potash. The platinum wires are connected alternately at top and bottom, 3 and 4 at top, and so on. The battery produces a current very small in quantity, but of considerable intensity. By employing electrodes of larger surface, such as spirals of platinum, and more concentrated liquids, the quantity of the current might be considerably increased.

Gore has also shown that the currents produced by the friction of a liquid against

Fig. 15.

a polar plate rotating in its own plane, have no direct connection with those which are excited in the same liquids by heating; further, that the thermo-electric properties of liquids are not dependent on the molecular structure by virtue of which liquids, under the influence of magnetism, polarise light circularly.

Noë's Thermo-electric Battery.—In this battery the negative metal, an alloy similar to German silver, is drawn into wire; the positive alloy,* which is very brittle and somewhat less fusible than antimony, is cast into cylinders. The metals are joined together by casting the cylinder round the thickened end of the wire, in such a manner that the wire is in the prolongation of the axis of the cylinder. Over the wire a short copper cylinder is passed, and pushed up against the positive metal, but it is prevented from coming in actual contact with it by the interposition of a piece of mica. Against these copper cylinders the flames of either gas or spirit lamps impinge, and are thereby prevented from fusing the positive alloy or burning through the wire. The elements are placed in double parallel series, which, in the larger batteries, are so mounted that they may be used in various combinations, either for quantity or intensity.

The electromotive power of one of these elements was found to be from 1.24 to 1.36 of the Jacobi-Siemens' unit, while the electromotive power of a Daniell's cell was found to be equal to 12 of these units. It requires, therefore, 9 to 10 Noë's elements to equal 1 Daniell. With larger batteries the electromotive power cannot, however, safely be raised above 1, otherwise superheating of parts is not to be avoided.

The larger battery examined consisted of 72 elements, which could be combined so as to form either, I. one series of 72 pairs, or II. one of 36 pairs, or, III. 18 of four pairs each. With each combination, the electromotive power, per element, was found to be one of the above units; the resistance of a single element was 0.05. A Bunsen's element, charged with concentrated nitric acid and with sulphuric acid of 1 in 10, has an electromotive power of 20, and with a good porous cell a resistance of about 0.3 in elements of the usual size. With a great external resistance, 20 of Noë's elements will therefore be equal to one of Bunsen's. With a small external resistance, 20 quadruple elements are somewhat stronger than one of Bunsen's. One Noë's element is about equal to 11 ordinary bismuth-antimony elements (temperature 0° and 100° C.). Even a single Noë's element produces considerable physiological effects when used with an induction apparatus.

The above-mentioned battery of 72 elements effects, with combination I. a copious decomposition of water; with combination II. it sets in action middle-sized Ruhmkorff's coils; and with combination III. and spirals of thick wire, it produces powerful electro-magnets.

In subsequent experiments it was found that the battery could be safely heated higher than was found expedient on the former series: it then gave a mean electromotive power of 1.14 per element, with a resistance of 0.054 (v. Waltenhofen, *Pogg. Ann.* cxliii. 113).

A new form of this battery has been devised by v. Waltenhofen, in which the negative wire fused to the positive metal is bent back from the point of contact at an acute angle. A small metallic rod is fused to the two elements at this same point. Twenty elements are arranged in a circle, the metallic rods just mentioned being in the centre. The space in the centre is covered with a plate of mica, and the metallic rods are then heated by means of a circular gas flame.

The electromotive power of twenty such elements is equal to 19.4, one Bunsen cell being equal to 20. If a Daniell cell be equal to 12, then one of these cells is about equal to 1. The resistance of each element = 0.056 (*Chem. Centr.* 1872, 530).

Thermic Phenomena in the Voltaic Circuit.—Favre (*Compt. rend.* lxxii. 369) has examined the heat-phenomena accompanying decompositions in the voltaic circuit, by means of an apparatus consisting of two mercury-calorimeters, one of which served to measure the internal work of a 5-pair battery (zinc, platinum, dilute sulphuric acid) enclosed within it, the other to measure the external work. Into this second calorimeter were successively introduced: (1) A sixth couple, identical with those of the first calorimeter; (2) a voltmeter consisting of a pair of platinum-plates of the same surface as the zinc-platinum pairs; (3) a voltmeter with two copper plates, likewise of the same surface, but immersed in a solution of cupric sulphate.

In the following table, A denotes the heat (in units or gram-degrees) taken up by the first calorimeter; B, the heat which is withdrawn from the battery, and represents its external work, also in gram-degrees, both reckoned for 1 equivalent of zinc (33) dissolved in the battery; θ , the tangent of the angles of deflection of the galvanometer; C, the heat, also in gram-degrees, taken up by the voltmeter from the battery. The

* The composition of these alloys is at present kept secret.

dilute sulphuric acid used in all the experiments contained in 1,000 cub. cent. 89.21 grams of sulphuric anhydride.

	A	B	δ	C
1. Battery alone	19,572	382	—	—
2. Battery with Galvanometer in the circuit	18,474	1,480	3.1880	—
3. Battery, Galvanometer and sixth couple	18,402	1,552	3.6069	—
4. Battery, Galvanometer and Voltmeter (platinum with dilute sulphuric acid)	7,975	11,979	0.1095	59,895
5. Battery, Galvanometer, Voltmeter (platinum with nitric acid)	8,888	11,066	0.0969	55,330
6. Battery, Galvanometer, Voltmeter (platinum with cupric sulphate)	8,573	11,381	0.7623	56,905
7. Battery, Galvanometer, Voltmeter (platinum with cupric nitrate)	8,424	11,530	0.8278	57,650
8. Battery, Galvanometer, Voltmeter (copper with cupric sulphate)	11,091	5,863	1.8611	29,315
9. Battery, Galvanometer, Voltmeter (copper with cupric sulphate)*.	10,557	9,397	0.5658	46,985

*Without the current, 1 eq. sulphuric acid (49) of the dilution above stated, and 1 eq. zinc (63) evolved 19,574 gram-degrees of heat; moreover, 1 eq. cupric sulphate, and 1 eq. zinc evolved 27,388 gram-degrees.

When a sixth couple is enclosed in the second calorimeter, the development of heat thereby is exactly one-fifth of that developed by the 5-pair battery in the first calorimeter, inasmuch as it proceeds exclusively from this one couple. When the second calorimeter contains the platinum voltameter, which evolves no heat, the entire quantity of heat proceeds from the battery, and the heat of the first calorimeter is diminished by a corresponding amount (*i.e.* by the fifth part of C). If the voltameter is fitted with copper plates, the heat developed within the second calorimeter proceeds partly from the battery, partly from the voltameter, the processes which take place separately in the zinc-platinum couple and the platinum voltameter here going on simultaneously (decomposition of cupric sulphate, with assumption of heat from the battery, and formation of an equivalent quantity of cupric sulphate with development of heat, which is added to that product by the current). Whereas therefore (in 3), the sixth couple in the second calorimeter develops 19.954 units of heat for each equivalent of sulphuric acid decomposed, the voltameter (in 4) consumes, for the same effect, 59,895 units which it abstracts from the current. Nearly the same values may be deduced from the decomposition of the copper salt in (6) and (7). After deduction of 7.975 heat-units (which Favre regards as required to overcome the resistance in the voltameter), there remain therefore 51,920 units, and these express the quantity of heat required for the decomposition of 49 grams of hydrogen sulphate (into SO^4 and H, or, on the other hand, for the combination of SO^4 with H).

The further consequences from the results obtained may be summarised as follows: The battery yields to the compounds which it decomposes, the quantity of heat required for their decomposition, and this quantity of heat is larger than that which the same elements in their ordinary free state evolve in combining, because, in the form of isolated atoms, they contain an excess of heat, which they give up on passing into their ordinary condition of molecules. The alterations which the elementary bodies experience before entering into true chemical combination, or after separation from that state, are therefore characterised by heat-phenomena which have no connection with those accompanying actual combination and decomposition. Hence the stability of a compound affords no measure of the magnitude of the affinity of its elements. Compounds whose elementary constituents require for their separation equal quantities of heat, will be decomposed with greater facility, the greater the amount of heat which these elements evolve in passing from the nascent state (*i.e.* the state in which they exist in combination and separate from it) into the ordinary state.

A considerable portion of the heat evolved by the chemical action in the battery remains in the calorimeter, and is not available for the performance of useful work in the external part of the circuit. This quantity of heat (= 6,000 units in the experi-

* In this experiment the distance of the plates was 30 mm., in all the others 5 mm.

ments above described) is that which is due to the passage of the hydrogen from the nascent to the ordinary state.

The quantity of heat which might be supposed to be equivalent to the work expended in the orientation of the molecules of the electrolyte is so small that it may be neglected. The concentration and nature of the liquid, and the distance between the immersed metal plates, likewise exert no appreciable influence on the distribution of heat in the circuit, and therefore, also, do not perceptibly alter its resistance. A greater influence appears to be due to the size of the immersed plates.

The remaining portion of the heat developed by the battery, that is to say the quantity which is transferable to the connecting wire, and capable of doing work outside the battery, may be regarded as the measure of the voltaic energy of the battery.

In another series of experiments (*Compt. rend.* lxxiii. 890, 936) Favre has determined the voltaic energy, E , of several battery-combinations. That of a Smee's couple was found to be equal to 15,000 heat units. For a Grove's battery, in which the ordinary nitric acid is replaced by fuming nitric acid, $E = 49,847$ heat-units. A zinc-platinum pair excited by a mixture of permanganic and sulphuric acids, gave $E = 39,234$ heat-units. The same with hypochlorous acid gave $E = 50,806$. A combination, one pole of which was formed of a plate of hydrogenised palladium immersed in dilute sulphuric acid, while the other pole consisted of a platinum plate in solution of cupric sulphate, gave $E =$ about 4,000 units.

The results obtained in the electrolysis of the principal oxygen-acids are given in the following table, in which column I. indicates the voltaic energy of these acids as directly determined (in the battery); column II. the same as calculated from the number of heat-units transferred from the battery to the acid when the acid is electrolysed in an ordinary non-partitioned voltameter; and column III. the same as determined by electrolysis in a voltameter divided into two cells by a porous diaphragm, so that the separated elements cannot recombine.

	I.	II.	III.
Chromic acid	30,225	31,279	34,176
Permanganic acid	39,234	42,617	45,304
Fuming Nitric acid	49,848	52,822	47,646
Concentrated Nitric acid	46,447	46,786	44,190
Hypochlorous acid	50,807	55,754	51,908.

For the hydrogen-acids electrolysed in a partitioned voltameter, the following results were obtained:

Hydrochloric acid	173,468 heat-units
Hydrobromic acid	177,108 "
Hydriodic acid	173,629 "

The difference between the first and second of these numbers is equal to that between the second and third.

A Smee's battery in which the sulphuric acid is replaced by one of these three haloid acids, exhibits the following degrees of voltaic energy:

With Hydrochloric acid	16,738 heat-units
,, Hydrobromic acid	14,967 "
,, Hydriodic acid	14,584 "

Electrolysis of the Oxides and Sulphates of the Alkali-metals.—These compounds can be decomposed by batteries whose energy is smaller than that which is required to produce the same compounds from their constituents, because the energy of the battery is strengthened by that which is brought into play by the oxidation of the metal. This oxidation is a synelectrolytic effect, *i.e.*, one which takes place in connection with and during the electrolysis. The quantity of heat abstracted from the battery by an alkali subjected to electrolysis is the same for all the alkalis. This quantity of heat (about 50,000 units on the average) is made up of two portions, namely the heat of combination of the water = 34,500 units, and the quantity, equal to rather more than 1,400 units, which is developed by the passage of the liberated constituents of the water from the active into the ordinary state; this last change, which takes place after the electrolysis, is called meta-electrolytic.

The process of decomposition in the salts is exactly similar. If the voltameter containing the salt be divided by a porous diaphragm, so as to prevent the recombination of the acid and base, the quantity of heat evolved is diminished by the heat of combination, and amounts, on the average, to 14,000 units. If the continuous reproduction of the oxide be prevented by pouring mercury into a porous cell, placing the cell in the solution, and surrounding it with a platinum plate forming the positive

pole, so that the metal may be immediately amalgamated at the negative quicksilver surface, the decomposition does not become rapid unless the energy of the battery be considerably increased. A very weak, slow decomposition does indeed take place, because the amalgamated metal undergoes gradual oxidation; from the same cause, also, the strengthened battery attains its full decomposing power at a degree of energy somewhat below that which is indicated by theory (Favre, *Compt. rend.* lxxiii. 767, 1036).

Electrolysis of various Acids and Salts.—Experiments on the electrolysis of acetic acid, zinc acetate, formic acid, cupric formate, oxalic acid, sulphuric acid, monohydric phosphate and aqueous phosphoric acid, have led to the following conclusions: When the electrolysis is difficult, as in the case of acetic acid, and the voltaic energy of the battery is small, the secondary reactions, which usually take place after the true electrolysis, and produce heat not transferable to the circuit, always tend to strengthen the energy of the battery. On the other hand, the more the energy of the battery is increased by using a greater number of cells, the less does it appear to be strengthened by the secondary reactions in the voltameter. It is, therefore, very difficult to determine exactly the quantity of heat which is due to the battery and transmissible or not transmissible to the circuit. The secondary actions above spoken of are such as are produced by the hydrogen and oxygen set free during the electrolysis, the first being burned, the second oxidising any combustible substances present (*Compt. rend.* lxxiii. 1186).

In the electrolysis of the sulphates of zinc and copper, and of copper nitrate, in the voltameter, the following quantities of heat were found to be transferred to the voltameter from the battery:

Zinc sulphate	65,510	heat-units
Cupric sulphate	39,415	"
Cupric nitrate	37,770	"

When mixed saline solutions are electrolysed, very different results are obtained, according to the proportions of the mixture, the voltaic energy of the battery, the electric resistance of the salts, and the more or less rapid course of the operation. Sulphuric acid behaves like a salt, SO_4H^2 , and its gradual liberation during the electrolysis of zinc or copper sulphate, consequently exerts a continually increasing influence on the amount of heat developed in the decomposition. In fact, a great part of the sulphuric acid set free during the electrolysis of zinc sulphate is electrolysed instead of the zinc salt, because it offers less resistance to decomposition, and consequently less heat is withdrawn from the battery than would be required for the decomposition of the zinc salt. This electrolysis of the sulphuric acid instead of the metallic salt, is greatly augmented when the resistance is increased, as, for instance, by inserting the thermorheostat. The disturbing influence of the sulphuric acid can be avoided by employing a large quantity of zinc solution, about 2 litres, in the voltameter, because when the sulphuric acid formed during the operation is immediately diluted to such an extent, that its electrolysis, in comparison with that of the zinc salt, may be neglected.

When, on the other hand, cupric sulphate is electrolysed, which offers less resistance to its decomposition than sulphuric acid, the quantity of the latter increases rapidly, and it becomes necessary to employ the thermorheostat—(1) in order to render the resistance of the voltameter small compared with the total resistance of the circuit; (2) to retard the electrolysis so far that the cupric sulphate may have time to approach the negative electrode in the same proportion in which it is decomposed, as otherwise the sulphuric acid would be electrolysed in the place of copper-salt.

In electrolysing a mixture of the three sulphates of zinc, cadmium, and copper, Favre has succeeded, by altering the condition of the experiments, in obtaining at will, one metal or two metals at the same time, or all three metals in certain proportions. The results of the operations vary, 1st, with the voltaic energy of the battery; 2d, with the electrolytic resistance of the salts employed; 3rd, with the relative quantity of each salt; 4th, with the more or less rapid progress of the operation, which can be regulated by means of a rheostat.

Voltameters in which the whole of the hydrogen evolved by decomposition of hydrochloric or hydriodic acid is taken up by free iodine or bromine dissolved in the acid, according to Favre, the only ones in which the quantity of heat consumed in the decomposition is equal to that which is liberated in recombination. In the electrolysis of cupric sulphate between copper plates this is not the case, although here, also, the heat decomposed is immediately reproduced, but a certain quantity of the voltaic energy transmitted from the battery to the voltameter is converted into heat, and remains in the voltameter as heat not transmissible to the circuit. The conversion of voltaic energy into heat, probably takes place whilst the metal passes from the state

in which it is present in the saline solution into its elementary state, resuming its metallic properties. On the other hand, the copper of the plates, in order to pass from its truly metallic state into that modification in which it exists in its solutions, consumes heat derived from the battery. On making this experiment, first with plates of rolled copper, then with plates covered with electrolytically deposited copper, it is found that the rolled copper possesses less heat than that which is deposited by electrolysis.

If from the 10,500 heat-units evolved during the electrolysis of cupric sulphate between platinum-plates, we subtract 1,000 units due to the separation of copper, we obtain 9,500 units as the thermic expression of the change of state which the oxygen undergoes during its liberation.

The analogous expression for the liberation of 1 equivalent hydrogen is 4,000 heat-units, obtained by subtracting 9,500 from the 13,500 units evolved during the electrolysis of one equivalent of hydrogen sulphate between platinum plates (Favre, *Compt. rend.* lxxiii. 1258).

ELEMENTS. The relations between the atomic weights of the elementary bodies and their physical and chemical characters, already explained in the article 'Metals, Atomic Weights, and Classification of' (vol. iii. p. 275, second edition of this Dictionary), have been further developed by Mendelejeff in an elaborate paper (*Ann. Ch. Pharm. Suppl.* viii. 133-229).

Mendelejeff points out that when the elements are arranged according to the order of their atomic weights, from H = 1 to U = 240, the relations between their properties and their atomic weights, exhibit the form of a periodic function. If, for example, the fourteen elements whose atomic weights lie between 7 and 36 be thus arranged:

Li = 7; G = 9.4; B = 11; C = 12; N = 14; O = 16; F = 19.
Na = 23; Mg = 24; Al = 27.3; Si = 28; P = 31; S = 32; Cl = 35.5.

it is seen at once that the characters of these elements vary gradually and regularly as their atomic weights increase, and that this variation is periodical, i.e. varies in the two series in the same manner, so that the corresponding members of these series are analogous to one another; Na and Li; Mg and G; Al and B; Si and C; S and O, &c. forming similarly constituted compounds, or, in other words, possessing equal atomicity or combining capacity. Moreover the combining capacity of the elements in each series increases regularly with the atomic weight, the first members forming monochlorides, the second dichlorides, the third trichlorides, &c., or corresponding oxides or oxychlorides.

The physical characters of the elements and their corresponding compounds likewise exhibit remarkable regularity when thus arranged, as may be seen with regard to the specific gravities and atomic volumes of the elements in the second series above given:—

	Na	Mg	Al	Si	P	S	Cl
Sp. gr. . .	0.97	1.75	2.67	2.40	1.84	2.06	1.33
At. volume	24	14	10	11	16	16	27
	Na ² O	Mg ² O ²	Al ³ O ³	Si ² O ⁴	P ² O ⁵	S ² O ⁸	Cl ³ O ⁷
Sp. gr. . .	2.8	3.7	4.0	2.6	2.7	1.9	(?)
At. volume	22	22	25	45	55	82	(?)

Most of the other elements may likewise be arranged in groups of seven, the members of which exhibit similar relations, e.g. :—

	Ag	Cd	In	Sb	Te	I
At. weight .	108	112	113	118	125?	127
Sp. gr. . .	10.5	8.6	7.4	7.2	6.7	4.0

Such a group of seven elements is called by Mendelejeff, a *small period or series*.

The elements which can be thus seriated are contained in the first seven columns of the table on p. 463, those in the same column having equal combining capacity, and therefore forming oxides of corresponding composition.

On comparing the several series in this table, it will be observed that the corresponding members of an even, and of the following uneven series (the fourth and fifth for example) differ from one another in character much more than the corresponding members of two even or two uneven series (e.g. the fourth and sixth or the fifth and seventh); thus calcium resembles strontium much more than it resembles zinc. The members of the even series are not so distinctly metalloidal as those of the uneven series; and the last members of the even series resemble in many respects (in their lower oxides, &c.) the first members of the uneven series. Thus chromium and manganese in their basic oxides are analogous to copper and zinc. On the other hand, strongly marked differences exist between the last members of the uneven series (haloids) and the first members of the following even series (alkali-metals). Now

TABLE I.

Series	Group I. RH RO	Group II. RO	Group III. RO	Group IV. RH RO	Group V. RH RO	Group VI. RH RO	Group VII. RH RO	Group VIII. RO
1. .	H = 1							
2. .	Li = 7	G = 9.4		C = 12	N = 14	O = 16	F = 19	
3. .	Na = 23	Mg = 24	Al = 27.3	Si = 28	P = 31	S = 32	Cl = 35.5	
4. .	K = 39	Ca = 40	— = 44	Ti = 48	V = 51	Cr = 52	Mn = 55	Fe = 56, Co = 59 Ni = 59, Cu = 63
5. .	(Cu = 63)	Zn = 65	— = 68	— = 72	As = 75	Se = 78	Br = 80	
6. .	Rb = 85	Sr = 87	?Yt = 88	Zr = 90	Nb = 94	Mo = 96	— = 100	Ru = 104, Rh = 104, Pd = 106, Ag = 108
7. .	(Ag = 108)	Cd = 112	In = 113	Su = 118	Sb = 122	Te = 125	J = 127	
8. .	Cs = 133	Ba = 137	?Di = 138	?Ce = 140	—	—	—	
9. .	(—)	—	—	—	—	—	—	
10. .	—	—	?Er = 175	?La = 180	Ta = 182	W = 184	—	Os = 195, Ir = 197, Pt = 198, Au = 199
11. .	(Au = 199)	Hg = 200	Tl = 204	Pb = 207	Pi = 205	—	—	
12. .	—	—	—	Th = 231	—	U = 240	—	

between the last members of the even series and the first members of the uneven series there occur, according to the order of the atomic weights, *all* those elements which cannot be included in the small periods. Thus, between Cr and Mn on the one hand, and Cu and Zn on the other, there come the elements Fe, Co, Ni, forming the following transition series:

Cr = 52; Mn = 55; Fe = 56; Co = 59; Ni = 59; Cu = 63; Zn = 65.

In like manner after the sixth series follow the metals Ru, Rh, Pd; and after the tenth, Os, Ir, Pt. These two series of seven terms each, together with the three intervening members, form a *long period* of seventeen members.

As these intermediate members are not included in either of the seven groups of short period, they form a group of themselves (the eighth), some of the numbers of which, viz. Os and Ru, are capable of forming oxides of the form RO^+ or R^2O^+ . This group contains nine metals, viz.:—

Fe = 56;	Ni = 59;	Cu = 59.
Ru = 101;	Rh = 104;	Pd = 106.
Os = 193?	Ir = 195?	Pt = 197.

These metals resemble one another in many respects: (1) They are all of grey colour and difficult of fusion: the fusibility increases from Fe to Co and Ni, just as in the following series Ru, Rh, Pd, and Os, Ir, Pt. (2) They possess in a high degree the power of condensing and giving passage to gases, as seen especially in nickel, palladium, iron, and platinum. (3) Their highest oxides are bases, or acids of little energy, which are easily reduced to lower oxides of more decided basic character. (4) They form stable double cyanides with the alkali-metals. Fe, Ru, and Os, form analogous compounds K^2RCy^2 ; Co, Rh, Ir, form salts having the general formula K^2RCy^2 ; Ni, Pd, Pt, form salts having the composition K^2RCy^2 . (5) All these metals form stable metallammonium salts resembling one another in many of their characters. Thus rhodium and iridium form salts analogous in composition to the rosecobaltic salts $RX^2 \cdot 5NH^2$. (6) Some of the compounds of these metals, especially those of the higher degrees of combination, are distinguished by characteristic colours.

The metals Cu, Ag, Au, are also, on account of analogous behaviour, included in the eighth group; although, according to the constitution of their lower oxides, they may also be included in the first group.

The arrangement of the elements in the order of their atomic weights and the composition of the short and long periods, is more clearly seen in Table II., in which the periods form vertical columns:—

TABLE II.

Typical Elements.	H = 1	Li = 7 G = 9.4 B = 11 C = 12 N = 14 O = 16 F = 19	Na = 23 Mg = 24 Al = 27.3 Si = 28 P = 31 S = 32 Cl = 35.5	K = 39	Rb = 85	Cs = 133	—	—
				Ca = 40	Sr = 87	Ba = 137	—	—
				—	?Yt = 88?	?Di = 138?	Er = 178?	Th = 231
				Ti = 48?	Zr = 90	Ce = 140?	?La = 180?	—
				V = 51	Nb = 94	—	Ta = 182	U = 210
				Cr = 52	Mo = 96	—	W = 184	—
				Mn = 55	—	—	—	—
				Fe = 56	Ru = 104	—	Os = 195?	—
				Co = 59	Rh = 104	—	Ir = 197	—
				Ni = 59	Pd = 106	—	Pt = 198?	—
				Cu = 63	Ag = 108	—	Au = 199?	—
				Zn = 65	Cd = 112	—	Hg = 200	—
				—	In = 113	—	Tl = 204	—
				—	Sn = 118	—	Pb = 207	—
				As = 75	Sb = 122	—	Bi = 208	—
				Se = 78	Te = 125?	—	—	—
				Br = 80	J = 127	—	—	—

In the members of the even series (Table I.), the metallic or basic character predominates, whereas the corresponding members of the uneven series rather exhibit acid properties. Thus there is a decided difference between V, Nb, Ta, from the even series of the fifth group, and P, As, Sb, Bi, from the uneven series whose highest oxides have a similar constitution R^2O^3 , the former yielding less powerful acids than the latter. The members of the even series do not, so far as is known, yield volatile compounds with hydrogen or the alcohol-radicals, like the corresponding members of the uneven

series; thus all attempts to prepare the compound $Ti(C^2H^3)^4$ from $TiCl^4$ have been unsuccessful, in spite of the great resemblance between $TiCl^4$, $SiCl^4$ and $SnCl^4$.

The position of the second series seems at first sight to be inconsistent with the general division of the elements into even and uneven series; for most of the members of this series possess acid properties, form compounds with hydrogen and the alcohol-radicles, and some of them are gaseous—in all which characters they rather resemble the elements of the uneven series. It must, however, be observed, with regard to this series: (1) That it does not include an eighth group like the other uneven series; (2) That the atomic weights of the elements included in it differ from those of the corresponding elements of the following series by only 16, whereas in all the other series this difference ranges from 24 to 28. The difference between the atomic weights of successive even series is generally about 46, but in the elements of the second and fourth series it is only 32–36.

	Li.	G.	B.	C.	N.	O.	F.	Na.	Mg.	Al.	Si.	P.	S.	C.
	K	Ca	—	Ti	V	Cr	Mn	Cu	Zn	—	—	As	Se	Br
Diff.	32	31	—	36	37	36	36	40	41	—	—	44	46	45

These peculiarities explain the apparent anomalies above mentioned, and, moreover, afford additional evidence of the dependence of the properties of the elements on their atomic weights. To make the elements of the second series analogous in character to those of the fourth, their atomic weights should indeed be smaller than they actually are. Similar anomalies may also be observed in comparison of Na with Ca and of Mg with Zn, but they disappear in cases of P and As, S and Se, Cl and Br, where the differences in the atomic weights conform to the general rule.

In consequence of the peculiar properties of the elements of the second series, Mendelejeff designates them as typical elements, to which category, also, belong hydrogen, and likewise sodium and magnesium for the reason just stated. These typical elements may indeed be regarded as analogous to the lowest members of homologous series (H^2O and CH^4O for example), which, as is well known, do not exhibit all the properties of the higher homologues.

The preceding considerations likewise explain the isolated position of hydrogen, the element possessing the lowest atomic weight. According to the form of its salifiable oxide H^2O , and of the salts HX , it belongs to the first group; its nearest analogue is Na, which likewise belongs to an uneven series of the first group. More remote analogues of hydrogen are Cu, Ag and Au.

Mendelejeff also develops several applications of the law of periodicity: viz. (1) To the classification of the elements. (2) To the determination of the atomic weights of elements whose properties are but little known. (3) To the determination of the properties of hitherto unknown elements, those, namely, which might be expected to occupy the blank spaces in the preceding tables. (4) To the correction of the values of atomic weights. (5) To the completion of our knowledge of the combination-forms of chemical compounds.

For the details of these applications we must refer to the original paper. The proposed corrections of atomic weights will be noticed in connection with the several elements. (See CERIUM, DIDYMIUM, ERBIUM, LANTHANUM, TELLURIUM, YTTRIUM.)

ELLAGIC ACID. For Schiff's view of the constitution of this acid, see TANNIC ACID.

ELVANITE. Analyses of this rock from Knockmalon, Waterfordshire, and of the clay slate in which it is imbedded, have been made by J. A. Phillips (*Phil. Mag.* [4], xxxix. 12). The elvanite consists of a bluish-grey ground-mass containing crystals of quartz and oligoclase, together with a little hornblende. 1. Elvanite, sp. gr. 2.66. 2. Felsite, sp. gr. = 2.64. 3. Slate, sp. gr. 2.66. 4. Altered state, sp. gr. = 2.65.

SiO^2	AlO^2	Fe^2O^2	FeO	CaO	MgO	K^2O	Na^2O	H^2O	X^*
72.33	9.02	6.34	1.06	1.92	trace	1.46	5.83	1.33	0.35
80.50	8.33	3.44	0.96	1.21	trace	1.89	2.12	1.38	0.37
74.28	7.78	7.10	0.90	1.08	0.46	2.05	5.05	0.80	0.34
52.66	18.33	10.43	9.00	1.76	trace	0.73	2.12	5.50	0.50

EMBRITHITE. A. Frenzel (*J. pr. Chem.* [2], ii. 360) has analysed the two species of lead sulphantimonite from the Algaitschinski mine, near Nertschinsk, described by Breithaupt under the names plumbostilb (A), and embrithite (B), and finds them both to agree with the formula $10PbS.3Sb^2S^2$. (C):—

* Loss in the water-bath. No. 2 contains a trace of manganous oxide.
2nd Sup. II H

	Pb	Cu	Sb	S		Sp. gr.
A (found) (1).	59.64	0.88	19.49	18.04	= 98.05	6.12
(2).	59.44	0.88	21.48	18.14	= 99.94	6.12
(3).	not determined	—	21.34 not determined	—	—	6.22
B (found) (1).	59.30	0.80	21.47	18.08	= 99.65	6.32
(2).	59.43	not determined	—	—	—	—
C (calc.)	60.59	—	21.53	17.88	= 100.00	—

In spite of the difference in specific gravity, colour (A is lead-grey to steel-grey, B, pure blue-grey), tenacity (B is softer), and cleavage (A in two directions, B only in one), Frenzel is inclined to regard plumbostib as the cauliform and fibrous, embrittle as the fine-grained aggregation of one and the same species. The hardness of both = 2.5.

EMETINE. According to Pander (*Chem. Centralblatt*, 1872, 440), sulphuric acid containing molybdic acid gives, even with only $\frac{1}{100}$ of a milligram of emetine, a reddish colour quickly changing to green, and with $\frac{1}{100}$ mgm. a reddish iridescence. Potassium-bismuth iodide and potassium-cadmium iodide give precipitates with $\frac{1}{10}$ mgm. of this alkaloid in solutions diluted 25,000 times.

ENAMEL. The following preparation is recommended in Dingler's *Polytechnic Journal* (cciii, 499) for enamelling the insides of copper vessels used for cooking fruit or vegetables:—12 parts of white fluorspar, 12 parts unburnt gypsum, and 1 part borax are finely powdered, intimately mixed and fused in a crucible. The fused mass is then poured out, and after cooling is rubbed up to a paste. The copper vessel is then coated inside with this preparation, which is applied by means of a brush, and the vessel is left in a moderately warm place, so that the coating may dry uniformly; it is then subjected to a gradually increasing heat, till the preparation melts. On cooling, the vessel is found to be coated internally with a white, opaque enamel, adhering very firmly to the copper, not chipping off by ordinary knocking and rubbing, and impervious to vegetable acids.

ENNEACHLORDINAPHTHALENE, C²⁰H¹²Cl⁸. This, according to Faust, (*Zeitschr. f. Chem.* [2] vi. 297) is the final product of the action of chlorine gas on heated chloronaphthalenes. After repeated crystallisation from alcohol, it forms soft white needles, melting at 156°–158° (Faust & Saume, *Ann. Ch. Pharm.* clx, 65).

EOSITE. A vanadio-molybdate of lead from Leadhills in Scotland. See VANADATES OF LEAD.

EPIBOULANGERITE. A sulphantimonite of lead occurring on veins in the Bergmannstrost mine at Altenberg in Silesia, in dark gray needles, of sp. gr. 6.309. Analysis gave, for fine levigated needles, the values A; for coarser material, the values B; and for a boulangerite of sp. gr. 6.825, on which the epiboulangerite rests, the values C:—

	S	Sb	Pb	Ni	Fe	Zn
A.	21.31	20.23	54.88	0.30	0.84	1.32 = 98.88
B.	21.89	20.77	56.11	0.20	0.60	0.20 = 99.86
C.	18.51	20.96	58.73	—	2.13	— = 100.33

Supposing the epiboulangerite to be mixed with a small quantity of zinc blende, analyses A and B lead to the formula 3PbS.Sb²S³ + 3(3PbS.Sb²S³). (Websky *Jahrbuch für Mineralogie*, 1870, 351).

EPICHLORHYDRIN. See CHLORHYDRINS. (P. 320.)

EPICYANHYDRIN, (C²H³)₂NCN.—For the preparation of this compound, discovered by Puzschke (*1st Suppl.* 580), he now recommends the following process: 20 grams of epichlorhydrin are added to a solution of 15 grams of potassium cyanide in 60 grams of water, the violent reaction which immediately takes place being moderated by dipping the vessel into cold water. The epicyanhydrin which separates on cooling from the brown solution may be purified by recrystallisation from alcohol or water. From water it crystallises in broad prisms, often united in rows, which melt at 162°.

When epicyanhydrin is boiled with potash-ley, a large quantity of ammonia is given off, but the solution turns black, and does not yield the corresponding carbon-acid. Better results are obtained with baryta; but a still more definite reaction takes place on heating the epicyanhydrin for some time to 130° (in a sealed tube) with dilute sulphuric acid. The liquid on cooling deposits shining colourless needles, which, when purified by recrystallisation from hot water, with addition of animal charcoal, and then dried at 100°, exhibit the composition of the acid, C²H²O.CO²H. This acid melts at 225°; its silver salt, C²H²O.CO²Ag, obtained by precipitating the

ammonium salt with silver nitrate, blackens but slightly on exposure to the air, and may be dried without decomposition at 50°-60°.

On mixing the solution of the ammonium salt with lead acetate, the lead salt is precipitated after a while in broad, colourless, transparent laminae.

When epichlorhydrin is added to a solution of potassium sulphocyanate mixed with sulphuric acid, and the liquid is warmed, a fetid oil separates, which solidifies after a while and may be crystallised from alcohol. This compound is probably an addition-product, $C^3H^2ClO.CNS = C^3H^2ClO + NCSH$ (Pazschko *J. pr. Chem.* [2], i. 82).

EPIDOTE. The formula given for this mineral in vol. ii. p. 490, on the authority of Rammelsberg, is $Si^2Al^2Ca^2O^{36}$ or $3(2CaO.SiO^2) + 2(2Al^2O^3.3SiO^2)$, the alumina being more or less replaced by ferric oxide. This formula Rammelsberg has lately sought to confirm by an analysis of the epidote of Sulzbach (*Zeitschr. d. deutsch. geolog. Gesellsch.* 1872. 69). Tschermak, on the other hand, in his memoir on felspars (*Wien. Akad. Ber.* i. 585) first represented the composition of epidote by the formula :

and Kenngott (*Jahrbuch für Mineralogie.* 1871, 449), by a comparison of all the published analysis of epidote, concludes that, with the exception of a few of doubtful character, they may all be concluded in the latter formula, the alumina being more or less replaced by ferric oxide, and the lime to a small extent by magnesia; the presence of the magnesia appears, however, to be due, in many cases at least, to foreign minerals imbedded in the epidote. In some of the analyses, the iron is calculated partly as ferrous oxide; this, however, Kenngott reckons also as ferric oxide, and regards it as taking the place of an equivalent quantity of alumina.

To decide between the two formulae above given, C. Ludwig (*Ann. Ch. Pharm.* clxv. 217) has made a series of analyses of perfectly pure specimens of epidote, free from foreign enclosed minerals, as it occurs in the beautiful transparent crystals from Sulzbach.

This epidote contains silica, alumina, ferric oxide, ferrous oxide, lime, water, and traces of manganous oxide, magnesia, and chlorine. The quantitative analysis was carried out by the processes usually adopted for silicates, excepting that the ferrous oxide was determined by decomposing the mineral with sulphuric acid in a sealed glass tube, and acting upon it with a standard solution of dilute potassium permanganate. Especial care was bestowed on the estimation of the water, as it is chiefly on this point that previous analyses are at variance. Epidote loses about 0.25 per cent. of its weight by ignition in a platinum crucible over a Bunsen's burner, and nearly 2 per cent. when heated in a gas flame fed by a blast of air; after this strong ignition it is reduced to a sintered mass easily attacked by acids. To avoid errors which might arise from reduction of ferric to ferrous oxide by the flame-gases, and obtain a direct demonstration of the presence of water in epidote, the mineral previously dried at 150° was enclosed, in Ludwig's experiments, in a platinum tube through which a slow stream of dry air was passed, and heated to whiteness over a gas-flame urged by a blast, the water evolved being condensed in a calcium chloride tube connected with the platinum tube. The mean of eleven experiments made in this manner, gave from 1.78 to 2.35 per cent. of water, the mean being 2.05.

The mean result of several analyses of the mineral is as follows:—

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	H ² O	MnO, MgO, Cl	
or,	37.83	22.63	14.02	0.93	23.27	2.05	traces	= 100.73
	Si	Al	Fe		Ca	H	O	
			as Fe ² O ³	as FeO				
	17.65	12.06	9.81	0.72	16.62	0.23	43.64	
The atomic proportions of the elements are therefore—								
	Si	Al	Fe		Ca	H	O	
			as Fe ² O ³	as FeO				
	0.630	0.440	0.175	0.013	0.415	0.230	2.727	
		0.615		0.428				
or,	6	5.86		4.07		2.2	25.07	
Tschermak and Kenngott's formula requires—								
	6	6		4		2	26	

The result of the analysis of perfectly pure epidote is therefore to confirm the formula $Si^2Al^2Ca^2H^2O^{28}$.

Epidotes may accordingly be regarded as mixtures of two isomorphous constituents $\text{Si}^2\text{Al}^2\text{Ca}^2\text{H}^2\text{O}^{22}$ (aluminium epidote) and $\text{Si}^2\text{Fe}^2\text{Ca}^2\text{H}^2\text{O}^{22}$ (iron epidote).

The percentage composition of these two varieties in the pure state is as follows:—

	Aluminium Epidote	Iron Epidote
Silica	39.543	33.272
Alumina	33.875	—
Ferrie oxide	—	44.362
Lime	24.605	20.702
Water	1.977	1.664

Ludwig's paper contains a table of the percentage composition of such mixtures calculated for 1, 2, 3 up to 45 p.c. of iron epidote, and a comparison of these calculated numbers with all the actual analyses of epidote hitherto published,—excluding, however, as inaccurate, those which take no account of the water, and in which nevertheless the sum of the other constituents is equal to or greater than 100, also those which indicate a considerable amount of magnesia or alkalis, these having been made upon impure material.

The result of this comparison is to show that the older analyses of epidote also lead to the formula $\text{Si}^2\text{Al}^2\text{Ca}^2\text{H}^2\text{O}^{22}$.

Epidote from the Untersulzbach valley in Salzburg (sp. gr. 3.51), has been analysed by F. Kottal, in Lieben's laboratory, with the following mean results:—

SiO^2	Al^2O^2	Fe^2O^2	Fe^2O	CaO	MgO	H^2O
37.00	22.10	13.80	0.33	25.15	0.03	0.26 = 98.67

These numbers do not differ much from those obtained by Ludwig, excepting in the water, which was determined by igniting the substance, previously dried at 100° , in a stream of carbon dioxide. Probably the degree of heat applied was not sufficient to expel the whole of the water (*Ann. Ch. Pharm.* clxv. 360).

The most highly ferruginous epidotes are those from Switzerland and the Fornazza valley; in these the ratio of alumina to ferrie oxide is $5\text{Al}^2\text{O}^2 : 1\text{Fe}^2\text{O}^2$; in the epidotes from Bourg d'Oisans in Dauphiny, Traversella in Piedmont, Arendal in Norway, and Penig in Saxony, the ratio is $2\text{Al}^2\text{O}^2 : 1\text{Fe}^2\text{O}^2$.

EPIGENITE. A cuproso-ferrous sulphide from the Neuglück mine near Wittichen in Baden, where it is found in short prismatic rhombic crystals exhibiting the combination $\infty\text{P} . m\text{P}\infty . m\text{P}\infty$, and having the angle $\infty\text{P} : \infty\text{P} = 110^\circ 50'$ nearly. Colour steel-grey with black streak and black and blue tarnish. Hardness = 3.5. When heated in a tube, it yields a sublimate, first of sulphur, then of sulphide of arsenic, a reaction which is likewise exhibited by enargite, and indicates the presence of arsenic pentasulphide. It dissolves in nitric acid without separation of sulphur.

Analysis A is by Petersen (*Pogg. Ann.* cxxxvi. 502). As perfectly pure crystals are free from bismuth, and, on the other hand, wittichenite (copper-bismuth sulphide) is imbedded in the baryta of the gangue, the bismuth, together with corresponding quantities of copper and sulphur, has been deducted, giving the corrected result B, which leads to the formula $6\text{RS}.\text{As}^2\text{S}^2$, in which $6\text{RS} = 3\text{Cu}^2\text{S} + 3\text{FeS}$. The calculated numbers according to this formula are given under C. Silver and zinc were found only in traces.

	S	As	Bi	Fe	Cu
A (found)	31.57	12.09	2.12	13.43	40.32 = 99.53
B (corr.)	32.34	12.78	—	14.20	40.68 = 100.00
C (calc.)	33.58	14.32	—	16.03	36.07 = 100.00

(Sandborger *Jahrbuch f. Mineralogie*, 1869, 205, 862).

formed by heating epichlorhydrin with a solution of potassium phenate in absolute alcohol. On addition of water it separates as an oil which solidifies after being heated to 200° , and may be purified by pressure and recrystallisation from alcohol. The crystals are rhombic, exhibiting the combination $0\text{P} . \infty\text{P}$, and having the axes $a : b$ in the ratio of 0.64076 : 1 and the angle $\infty\text{P} : \infty\text{P} = 65^\circ 20'$ (Lippmann, *Wien. Akad. Ber.* lxii. [2], 605).

EPISTILBITE. The crystals of this mineral from the almond-stone of the Finkenhübel near Glatz in Silesia—where it occurs with other zeolites, viz. laumontite, heulandite, desmin, harmotome, and chabasite—have been measured by Websky (*Zeitschr. d. deutsch. geolog. Gesellsch.* xxi. 100), whose angular measurements agree

essentially with those of G. Rose. He regards epistilbite as a mineral species distinct from heulandite.

ERBIUM. The compounds of this metal have lately been examined by Clève and Hoeglund (*Bull. Soc. Chim.* [2], xix. 193). They will be described in connection with the yttrium compounds.

ERGOT. The constituents of ergot have been examined by J. C. Herrmann (*N. Rep. Pharm.* xx. 283) and by J. B. Gausser, *ibid.* 301). Herrmann, by thoroughly exhausting finely powdered ergot with ether, ultimately obtained six ounces of a fatty oil which, when saponified with soda-ley, yielded a distillate containing ammonia, trimethylamine, and a liquid from which common salt separated a soap, the aqueous portion containing glycerin. This soap, treated with sulphuric acid, yielded a semi-solid oil, and the aqueous liquid from this operation yielded, on distillation, traces of butyric and acetic acid. By pressing this semi-fluid oil between bibulous paper, a solid fat was obtained which, after several recrystallisations from alcohol, melted constantly at 62° , solidified at 57° – 58° , and exhibited the composition of palmitic acid. The oil was not a drying oil, and the fluid portion treated with nitric acid yielded claidic acid, whence the presence of oleic acid was inferred.

By treating a portion of the extracted oil with alcoholic ammonia, separating the alcoholic liquor from the oily portion and evaporating, a dark-brown aromatic-smelling residue was obtained, agreeing in properties (excepting its solubility in ether) with the ergotine of Wiggers (*ii.* 499.)

Contrary to the statements of Manassewitz, the oil was found to be saponifiable with caustic potash, the soap being softer than that obtained with soda.

By exhausting ergot with water, precipitating with lead acetate, and treating the filtrate with mercuric chloride, a precipitate was obtained from which the cecolino of Wenzell was separated, either by treatment with lead oxide or basic lead carbonate or by Wenzell's process, viz., treatment with hydrogen sulphide, and then successively with freshly precipitated silver phosphate, milk of lime, and ammonia carbonate. The product, freed by heat from excess of ammonia carbonate, had an alkaline reaction, and gave white precipitates with mercuric chloride, tannic acid, and potassium cyanide; yellow with phosphomolybdic acid; orange with platonic chloride; red-brown with iodised potassium iodide; and brownish with gold chloride.

The ashes of ergot were found to have the following composition:—

NaCl	K ₂ O	Na ₂ O	CaO	MgO	Al ₂ O ₃	Fe ₂ O ₃	MnO	P ₂ O ₅	SiO ₂
1.51	30.06	0.65	1.38	4.88	0.59	0.86	0.26	45.12	14.67 = 99.98

According to Gausser, finely powdered ergot yields, by extraction with ether, 30 p.c. of its weight of fatty oil, containing a resin separable from the fats by nearly absolute alcohol, and giving to them a peculiar bitter rough taste and brownish tint. With lead oxide these fats form a plaster from which ether extracts lead oleate; with soda-ley of 1.3 sp. gr. a soap is obtained; no free ammonia distils over during the operation, the distillate being neutral; on the addition of hydrochloric acid, however, thick white clouds are formed, and the colourless distillate becomes reddish.

The oil readily yields claidic acid with nitric acid. A dose of 10 grams, given in two portions of 6 and 4 grams each, only produced a sensation of nausea, without actual vomiting; the last 4 grams increased the pulse and produced a slight faintness and perspiration, all symptoms ceasing in five hours. The oil extracted with alcohol yielded a resin and a small quantity of crystals, giving the cholesterol reactions; this resin possesses the same physiological properties as the oil, but in a much more marked degree.

Pulverised ergot heated, *per se*, in a water-bath in a retort, gave no volatile bases; and the same was found on heating 250 grams of ergot with 150 of calcium carbonate and 500 of water; but the residue from the ether-extract of the fatty acids had a strong smell of horring-pickle (trimethylamine), and, on distillation with oxalic ether, yielded a distillate containing ammonia and emitting the smell of animal oils; the residue in the retort from this operation, distilled with water, gave ammonia and a smell of animal oils. Hence neither ammonia nor trimethylamine pre-exists in ergot, but these bodies are formed by decomposition of other substances by the re-agents employed.

By boiling with water the residue left after extraction of ergot with ether, precipitation with lead acetate, and of the filtrate with mercuric chloride, a precipitate is obtained which, when treated successively with freshly precipitated silver phosphate, milk of lime, and carbonic acid, yields finally, after evaporation, a brown, hygroscopic, amorphous powder of cecolino; this is soluble in water and alcohol, insoluble in ether and chloroform; on boiling it with potash, ammonia is evolved; it has a bitter taste with sweet after-taste, and, in small doses, produces nausea and

vomiting. The filtrate from the mercury precipitate of ecboiline, on precipitation with phosphomolybdic acid, and digestion of the precipitate with barium carbonate, and evaporation, furnishes ergotine as a greenish-yellow, glistening, amorphous, hygroscopic powder. This base forms deliquescent salts, the hydrochloride crystallising in long slender needles; given to a young dog in small doses, it produced symptoms of nausea without actual vomiting.

On distilling with sulphuric acid the aqueous extract from the ergot deprived of fats by ether, an acid of peculiar odour was obtained which reduced silver nitrate (ergotic acid); on distilling it with alcohol and sulphuric acid, formic ether was found in the distillate.

On extracting the residue deprived of fats by ether, with alcohol of 80 p.c., a cherry-red tincture is obtained, which deposits flocks of a sugar which reduces a potassium-cupric solution (identical with mycose?).

3.2 p.c. of albumin was found in the infusion of ergot, also potash, lime, and magnesia, together with hydrochloric, sulphuric, and phosphoric acids (Ganser).

ERICACEÆ. *Gaultheria procumbens* and *Epigaea repens* contain arbutin, ursone, ericolin, tannic acid, a principle analogous to gallic acid, formic acid (in *Epigaea*), glucose, gum and colouring matter. Arbutin, ursone and ericolin have previously been found in *Uva ursi* and *Chimaphila umbellata*, and may, therefore, be regarded as common to plants of the ericaceous order (J. Oxley, *Pharm. J. Trans.* [3], ii. 1050).

ERSBYITE. This mineral occurs at Pargas in Finland, intergrown with blackish-green augite (in small quantity) and brown titanite, in some parts, also, with laminar calcspar. It is colourless when quite fresh, and does not exhibit any crystalline faces. Its specific gravity is 1.723.

Considerable uncertainty has hitherto existed respecting the constitution of this mineral. A. E. Nordenskjöld described it as a triclinic feldspar, cleavable in two directions inclined to one another at an angle of $90^{\circ} 22'$, and, according to an analysis made by N. A. Nordenskjöld (54.13 SiO_2 , $29.23 \text{ Al}_2\text{O}_3$, 15.16 CaO , 1.07 water), as a true labradorite free from soda. But according to the theory of Tschermak, which regards the triclinic feldspars as isomorphous mixtures of albite and anorthite there should be no such thing as an oligoclase free from lime or a labradorite free from soda. (See FELSPAR.)

To clear up this doubt, G. vom Rath has subjected the mineral to a fresh examination. He finds that it cleaves very distinctly and with equal precision in two directions at right angles to each other, has a specific gravity of 1.723, loses by ignition 0.58 p.c. and gives by analysis—

SiO_2	Al_2O_3	CaO	MgO	K_2O	Na_2O	
44.26	30.37	20.17	0.15	1.15	2.75	= 98.85

If the loss in the analysis be attributed to lime and the alkalis, these numbers agree very nearly with the formula of scapolite, $3\left(\frac{2}{3}\text{CaO} + \frac{1}{3}\text{Na}_2\text{O}\right) \cdot 2\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$ (calc. 44.39 SiO_2 , 30.4 Al_2O_3 , 21.75 CaO , and 3.44 Na_2O).

Both the cleavage and the chemical composition of ersbyite show, therefore, that it belongs, not to the calcio-sodic feldspars, but to the scapolites (*Pogg. Ann.* cxliv. 375).

ERUCIC ACID, $\text{C}^{22}\text{H}^{42}\text{O}_2$. This acid has been obtained by Fitz (*Dent. Chem. Ges. Ber.* iv. 442), from the fat oil of grape-seeds, which exists in them to the amount of 15 to 18 p.c. This oil was saponified with potash, and the acids were separated by the partial precipitation of their alcoholic solution with lead acetate, the first fractions being flocculent, the latter semifluid. The flocculent precipitate, on being treated with warm ether, left a small portion undissolved, the acid from which, by its melting point and analysis, proved to be a mixture of palmitic and stearic acids. The acid contained in the soluble lead salt crystallised from alcohol in lustrous needles, and on analysis was found to be erucic acid. The solubility of its lead salt varies extremely with the temperature, as it is very soluble in ether, benzene, or acetone when hot, and but slightly when cold. One half of the mixed acid contained in the oil was found to be erucic acid, and the remainder an acid yielding a semi-fluid lead-salt, together with a very small quantity of palmitic and stearic acids. By treatment with nitrous acid, the erucic acid was converted into the corresponding clausic acid (brassicic acid), which melts at 56° (at 60° according to Haussknecht, *1st Suppl.* 367). The lead salt is almost insoluble in warm ether.

Erucic acid is resolved by fusion with potash into arachidic and acetic acids:

This is the usual mode of decomposition of the acids of the acrylic series.

ERYTHRITE, $\text{C}_4\text{H}^{10}\text{O}_4 = (\text{C}_2\text{H}_5)_2(\text{OH})_2$. Some of the haloïd ethers of this alcohol have been prepared and examined by P. Champion (*Compt. rend.* lxxiii. 114).

Erythritic Dibromhydrin, $C^4H^6Br^2O^2 = (C^4H^5)^2Br^2(OH)^2$.—When erythrito is treated with a saturated solution of hydrobromic acid in a sealed tube at the temperature of 110° for three hours, a brown liquid is obtained, which, when evaporated on the water-bath and redissolved in boiling ether, deposits crystals of erythritic dibromhydrin. This body is insoluble in water, slightly volatile at 100° , melts at 130° , and forms a crystalline mass on cooling. In its composition and properties it resembles the erythritic dichlorhydrin prepared by De Luyne (1st Suppl. 583).

Erythritic Dinitrodibromhydrin, $C^4H^6Br^2(NO^2)^2O^2$.—When erythritic dibromhydrin in powder is introduced into a cold mixture of 1 part fuming nitric acid, and 2 parts concentrated sulphuric acid, the temperature slowly rises, and if, after a contact of some minutes, the whole be poured into cold water, a white flaky precipitate is formed, which, after being washed and dissolved in boiling alcohol, deposits the dinitrobromhydrin in long white flexible needles. This body is insoluble in water; melts at 75° ; does not detonate when struck, like nitroerythrite; is decomposed by heat, producing yellow fumes. A boiling solution of potash changes it, the liquid becoming brown, and a nitrate being formed.

Erythritic Dinitrodichlorhydrin, $C^4H^6Cl^2(NO^2)^2O^2$.—This body, like the preceding, is obtained by the action of a mixture of nitric and sulphuric acids on erythritic dichlorhydrin. It crystallises easily from alcohol, melts at 60° , and resembles the preceding compound in its properties.

ERYTHROCENTAURIN. Méhu has demonstrated the identity of the erythrocentaurin prepared from *Erythraea Centaurium* (1st Suppl. 584), with the preparation obtained from *Erythraea chilensis*. The two preparations agree in their solubilities in various liquids, their melting point (136°) and in the change of colour from white to red produced by the action of the sun's rays (*J. Pharm.* [4], xi. 454).

ESENBECKIA. The bark of *Esenbeckia febrifuga* (Martius) contains, together with much chlorophyll, sugar, gum, and pectous substances (no starch), two very closely allied resinous substances, namely, an acid called esenbeckic acid, resembling quinic acid, and a nitrogenous base, esenbeckine, which crystallises in octohedrons (*C. am Ende, Arch. Pharm.* [2], cxliii. 112).

ESERINE. To prepare the neutral sulphate of this base, the hydro-alcoholic extract of the Calabar bean (*Physostigma venenosum*) is dissolved in a small quantity of distilled water, and filtered. To the filtrate is added 1 gram of potassium bicarbonate for every 20 grams of extract dissolved, and the solution is agitated with a considerable quantity of ether. After allowing the ether to separate, it is decanted, and the aqueous liquid again treated with ether, until the whole of the alkaloid is completely removed. The ethereal solution, after the addition of a little distilled water, is carefully neutralised with dilute sulphuric acid containing 40 grams of the monohydrated acid per litre, the point of saturation being ascertained by the aid of good litmus paper. The ether is then gently evaporated or decanted, and the solution of eserine sulphate concentrated to crystallisation. The first crop of crystals is sufficiently pure for medicinal use, but it is preferable to treat the alkaloid again with alkali and ether, which, after a second crystallisation, will render the salt perfectly white and pure.

In preparing a solution of the alkaloid, if as many grams of liquid are obtained as it was found necessary to employ drops of the standard sulphuric acid, 1.0 gram of the solution will contain 0.01 gram of eserine. For general purposes, one part of the above solution may be diluted with 4 or 5 parts of distilled water (*A. Petit, J. Pharm.* [4], xiv. 255).

Blue Colouring Matter from Eserine.—Eserine, exactly neutralised with dilute sulphuric acid, then treated with excess of ammonia and evaporated to dryness in a water-bath, yields a residue of magnificent blue colour, soluble in water and alcohol, and crystallising in the form of elongated prisms. This residue stains the skin, nails, &c., and strongly dyes silk blue without the aid of a mordant; acids change the colour to a fine violet purple.

Eserine treated with ammonia, without previous saturation with sulphuric acid, yields, on evaporation, a greenish residue, much less soluble, and turned red by acids (*A. Petit, Compt. rend.*, lxxii. 669).

ESSENTIAL OILS. See OILS, VOLATILE.

ETHANE, C^2H^6 . On the nitro-derivatives of this hydrocarbon, see NITRO-COMPOUNDS.

ETHENE, C^2H^4 . See ETHYLENE.

ETHYL ALCOHOL, C^2H^5O . *Formation from Acetic Acid* (Saytzeff, *J. pr. Chem.* [2] iii. 76. Acetic acid cannot be directly converted into ethyl alcohol by the action of reducing agents, but by first converting it into acetyl chloride by distillation with phosphorus pentachloride, and subjecting this chloride to the action of nascent hydrogen, ethyl alcohol is produced. The reduction is effected by the action of sodium amalgam on a mixture of acetyl chloride and glacial acetic acid, the sodium amalgam decomposing the acetic acid and evolving hydrogen, which then acts on the acetyl chloride, apparently changing it first into aldehyde: $C^2H^3OCl + H^2 = HCl + C^2H^4O$, which, by the further action of hydrogen, is converted into alcohol; a fresh quantity of acetyl chloride then converts this alcohol into acetic ether, which is the final product of the reaction. Simultaneously with this process another reaction occurs, whereby, at the expense of the acetyl chloride and the sodium acetate, acetic anhydride is formed, and this by the nascent hydrogen is also converted into alcohol, which, as in the first case, is obtained as acetic ether. This is shown by treating a mixture of either propionyl chloride or butyryl chloride and acetic hydrate with sodium amalgam, when, besides the particular alcohol, ethyl alcohol is also obtained, which can only be formed from the mixed anhydrides generated by the reaction, since acetic acid cannot be directly changed into ethyl alcohol by deoxidising agents. The details of the process are as follows:

Solid sodium amalgam, finely divided, and consisting of 100 parts mercury and 3 parts sodium, was placed in a flask fitted to the lower end of a condenser, and immersed in ice-water. To $1\frac{1}{2}$ molecules of the sodium a mixture of 1 molecule of acetyl chloride and 2 molecules of acetic hydrate was taken, and gradually poured upon the amalgam, keeping the flask constantly agitated, or stirring its contents briskly with a glass rod passing through the cork. After running in all the mixture, the flask was still kept in motion until its contents had become a solid mass, and the whole was then set aside till the next day. Water was then added, and the mixture distilled until oily drops ceased to come over with the water. The distillate consisted of two layers, the upper of which had a strong odour of acetic ether, and when distilled with potash yielded ethyl alcohol. In this way, 8 grams of alcohol were obtained from 60 grams of acetyl chloride.

On the formation of Ethyl Alcohol from Acetic Anhydride, see 1st Suppl. 592.

Preparation from Lichens.—The large quantity of amylaceous matter contained in certain lichens, renders them available for the preparation of spirit, the starch being first converted into glucose by the action of hydrochloric or sulphuric acid, and the glucose fermented in the ordinary way. S. Stenborg (*J. pr. Chem.* civ. 441) prepares alcohol in this manner from reindeer moss (*Cladonia rangiferina*). The lichen, if impure, is treated with 7 p.c., if pure and dry, with 10 p.c. of hydrochloric acid of sp. gr. 1.165, to convert it into sugar; the acid is neutralised with chalk, or better with sodium carbonate (so that the refuse of the operation may be used as fodder for cattle); and the mash is diluted till it contains only 5 p.c. of sugar, which is found to be a good strength for fermentation. By this latter process, $\frac{1}{10}$ to $\frac{1}{15}$ of the glucose present, which amounts to 60.68 p.c. of the dry lichen, is converted into alcohol. The spirit obtained by distilling the fermented liquor, has a faint taste of almonds, unless the lichen used is contaminated with pine cones and needles, in which case it has a flavour of gin. The fusel oil, which is quite different from that of corn or potatoes, may be easily removed with charcoal, and the spirit obtained yields by oxidation very good acetic acid. Observations on this process have been published by Stahlschmidt (*Dingl. polyt. J.* cxvii. 177; *Jahresb. f. Chem.* 1870, 1212).

Defuselation of Spirit.—W. Artus (*Dingl. polyt. J.* xcxi. 175) removes the fusel oil from spirit, without distillation, by repeated treatment with lumps of charcoal of the size of peas, previously impregnated with pure alumina (by soaking them in solution of alum and sodium carbonate) and then ignited.

On the composition of the 'first runnings' of crude spirit, see ALDEHYDES (p. 82).

Preparation of Absolute Alcohol.—Mendelejeff (*Zeitschr. f. Chem.* 1865, 260), who has found quick lime superior to all the other substances in use for dehydrating alcohol, states that, to obtain the alcohol absolute, spirit of sp. gr. not above 0.792 must be taken, and its digestion over the quick lime continued for not less than two days, or else for a few hours at 50°–60°. Even then, on distilling, only the middle portions are found to be anhydrous.

Erlenmeyer (*Ann. Ch. Pharm.* clix. 249) finds that when the spirit is boiled with the lime in a vessel fitted with inverted condenser, for $\frac{1}{2}$ –1 hour and then distilled, the whole product obtained is anhydrous. If the spirit contains more than 5 per cent. of water, it is only necessary to repeat the treatment with lime two or more times. But with weak spirit, care must be taken at first not to fill more than half the space occupied by the spirit with lime, as otherwise the vessel may be broken by the sinking of

the time. In this way several litres of spirit may be converted in a few hours into absolute alcohol.

Reactions.—1. *With Sulphuric Acid.*—Erlenmeyer (*Ann. Ch. Pharm.* clxii. 373) has examined the action of sulphuric acid on alcohol and ether, with results agreeing in the main with those of former experimenters (ii. 437), though differing in certain particulars.

(a). *Formation of Ether from Alcohol, and vice versa, in presence of dilute Sulphuric acid, at high temperatures.* Ether, heated in a sealed tube to 180° with 4 volumes of water and 1 c.c. dilute sulphuric acid, gave a considerable quantity of alcohol. Alcohol heated in sealed tubes with water only, gave no ether. Alcohol heated with dilute sulphuric acid (1 : 3, 1 : 5, and 1 : 10) to 226°–230° yielded ether, ethylene, and, under certain conditions, ethylsulphuric acid.

Hence Erlenmeyer concludes that—

- (1). Alcohol or ether heated with sulphuric acid and water at a high temperature, forms ethylsulphuric acid.
- (2). At a certain temperature, and with a given proportion of alcohol in the solution, ethylsulphuric acid is decomposed into sulphuric acid and alcohol.
- (3). At a higher temperature, or by having a larger proportion of alcohol in the solution, ethylsulphuric acid and alcohol react so as to form ether.
- (4). A part of the ethylsulphuric acid is decomposed, forming ethylene and sulphuric acid, another part forming ethylene, sulphur dioxide and water.

(b). *Formation of Ether from Alcohol under the influence of Neutral Ethylic Sulphate and Ethylsulphuric acid.* Ethylic sulphate heated with the proper proportion of alcohol yields ether when distilled, and ethylsulphuric acid together with free sulphuric acid in the residue; this residue heated to 140°, alcohol being allowed to flow on it, yields ether. Erlenmeyer therefore thought that the formation of ethylic sulphate might probably precede that of ether. But by experiment it was found that alcohol distilled with sulphuric acid, at a temperature at which ethylic sulphate could not form (96°), gave a large percentage of ether in the distillate, no ethylene or sulphurous acid being produced. The formation of ether at this temperature was, however, much slower than at 140°.

2. *With Salts* (Krant, *Ann. Ch. Pharm.* clvi. 323). Zinc acetate acts on alcohol, in the absence of water, at ordinary temperatures, but very slowly; on leaving together for $7\frac{1}{2}$ months a mixture of 1 mol. zinc acetate with 25 mols. alcohol, about 8 per cent. of the zinc acetate was decomposed. A mixture of 1 mol. of the acetate with 10 mols. alcohol, heated for 10 hours to 100°, showed a separation of 64.75 per cent. of the ZnO employed. From a similar mixture heated for 10 hours to 200°–220°, 97.1 per cent. ZnO had separated.

1 mol. zinc acetate heated with 10 equivs. alcohol to 100°, gave in

5	10	15	20	50 hours.
52.2	61.75	77.4	90.2	93.5 per cent. ZnO.

1 mol. zinc valerate heated with 10 equivs. alcohol to 100°, gave in

10	20	30	50 hours.
36.4	61.1	71.2	78.9
37.8	62.4	71.8	79.6

The formation of ethyl formate was observed in the action of alcohol on zinc formate, but the difficulty of drying the zinc salt completely, without some decomposition, rendered it unsuitable for comparative experiments.

Alcohol was found to act on the acetates of ammonium, magnesium, mercurous, and silver, with formation of ethyl acetate. At 100°, it had no action on sodium acetate.

3. *With the Chlorides of Sulphur.*—Absolute alcohol treated with either of the chlorides S^2Cl^2 or SCl^2 , is converted into ethylsulphuric acid. The product, diluted with water, and saturated with barium hydrate, yields barium ethylsulphate $(C^2H^5)_2Ba/S^2O^8 + 2H^2O$ (W. Housser, *Ann. Ch. Pharm.* cli. 249).

4. *With Carbon Tetrabromide.*—Alcohol heated with carbon tetrabromide to 100° for twelve hours, yields bromoform amounting to about three-fourths of the carbon tetrabromide, together with aldehyde and hydrobromic acid.

(Bols a. Groves, *Chem. Soc. J.* [2], ix. 784).

Detection of Alcohol.—The presence of alcohol when mixed with a large quantity of water may be detected by means of benzoyl chloride, which is very slowly decomposed

by water either cold or lukewarm, but is immediately converted into ethyl benzoate by any alcohol that may be present. The ethyl benzoate remains mixed with the excess of benzoyl chloride, but may be detected by heating a drop of the chloride with aqueous potash, which dissolves the chloride almost immediately, without at first acting on the ethyl benzoate, which may then be recognised by its odour. The reaction is very distinct in working with 20 to 25 c.c. of water containing a hundredth part of alcohol. Even with a thousandth part, the smell of the benzoic ether is very apparent when several cubic centimeters of liquid are used (Berthelot, *Compt. rend.*, lxxiii. 496).

For the detection of alcohol by Lieben's method of converting it into iodoform (1st Suppl. 593), the following mode of proceeding is recommended by H. Hager, (*Zeitschr. anal. Chem.* ix. 492). The reagents used are a solution of potassium iodide in five or six times its weight of water supersaturated with iodine, and a solution of potassium hydrate of the strength of 10 per cent. The clear liquid is heated to 40°-50° with five or six drops of the potash-solution, and the iodine-solution is then added, with gentle agitation, till the liquid becomes somewhat yellowish-brown. If this colour does not disappear on agitation, a drop or more of the potash-solution is added with a glass rod till complete decoloration takes place. The resulting iodoform is then deposited at the bottom of the test-tube in yellow crystals.

If the body to be tested is not soluble in water, it must be shaken up with 5 to 10 times its volume of lukewarm water, the liquid filtered, and the filtrate tested as above.

To detect alcohol in chloroform, the latter is briskly shaken with about 5 times its volume of water, then warmed to 30° or 40°, again shaken till the liquid appears milky from finely divided chloroform, and the chloroform is separated from the watery liquid by filtration through a wet filter.

A. Blachez (*J. Pharm.* [4], ix. 289) detects alcohol in chloroform by introducing a few grams of the liquid into a test-tube, adding a stick of potash as dry as possible, agitating for five minutes, then removing the potash, shaking the chloroform with an equal volume of water, and adding a small quantity of solution of cupric sulphate. If alcohol is present, a precipitate of cupric hydrate is formed by the potash, which the alcohol dissolves. Pure chloroform does not give this reaction, inasmuch as potash is not dissolved by it. A. Vogel (*Zeitschr. anal. Chem.* viii. 473) adds pyrogallie acid to the potash-solution decanted from the chloroform; if a yellowish or brownish colour is then produced on exposure to the air, the presence of alcohol may be inferred. A simpler, though perhaps less delicate method, is to place a few drops of the chloroform, after agitation with potash, on red litmus-paper, the presence of alcohol being then indicated by the production of a blue spot.

Mixtures of Alcohol and Water.—The specific heats, heat of combination, boiling point, capillarity, expansion by heat, and compressibility, of mixtures of water and absolute alcohol in various proportions, have been determined by Dupré a. Page (*Phil. Trans.* 1869, 591-614; *Proc. Roy. Soc.* xvii. 333; *Phil. Mag.* [4], xxxviii. 158; *Pogg. Ergänzungsband*, v. 221; *Jahresb.* 1869, 95).

The results are given in the following tables, in which the 'calculated values' of the several physical properties are determined on the supposition that the effect of each constituent of the mixture on the property in question is proportional to its weight.

The greatest differences between the observed and calculated values take place in mixtures containing between 30 and 45 p.c. of alcohol; 30 p.c. corresponds nearly with the formula $C^2H^6O + 6H^2O$ (= 29.87 p.c.); 45 p.c. nearly with $C^2H^6O + 3H^2O$ (= 46 p.c.). The excess of the specific heat of any mixture above its calculated amount is approximately equal to the quotient obtained by dividing the number of heat-units evolved in the formation of the same mixture by 3.411, and the depression of the boiling point is approximately equal to the quotient obtained by dividing the coefficient of capillary elevation by 3.6.

Heat of Mixture of Alcohol and Water.

Weight per cent. of Absolute Alcohol	Heat-units for 5 grams of Mixture
90	7.7025
80	12.4775
70	18.8200
60	27.2620
50	35.5850
45	38.8095
40	44.8630
30	47.0800
20	43.9545
10	28.6850

Determinations of the specific gravity of mixtures of alcohol and water at different temperatures have also been made by Mendelejeff (*Pogg. Ann.* cxxxviii. 103, 230), from which he infers that between the temperatures of 0° and 30°, the maximum of contraction takes place in mixtures corresponding with the formula $C^2H^6O + 3H^2O$.

The specific heats of mixtures of alcohol with water, carbon bisulphide, chloroform and benzene, have been determined by J. H. Schüller (*Pogg. Ann. Ergänzungsband*, v. 116, 192). The specific heats of these several liquids in the pure state were first determined with the following results:

Alcohol		Carbon Bisulphide		Chloroform		Benzene	
Temp.	Sp. Heat	Temp.	Sp. Heat	Temp.	Sp. Heat	Temp.	Sp. Heat
16-30°	0.6019	14-29.5°	0.2468	16-35°	0.2337	19.5-30.5°	0.4518
16-35°	0.6067			18-30°	0.2331	19.5-35.5°	0.4194
16-40.5°	0.6120					20-41°	0.4237

From the observed specific heats of absolute alcohol and benzene above given, the specific heats for other temperatures may be calculated by the formulae:

$$\text{for alcohol, } c = 0.5585 + 0.00093195 t + 0.0000003463 t^2$$

$$\text{for benzene, } c = 0.3798 + 0.00072 t$$

The specific heat of the carbon bisulphide actually used for the mixtures was 0.2442 for an interval of temperature 15° to 30°.

In the following tables, c denotes the observed specific heat of the mixtures, c_1 the mean specific heat of the mixture calculated from those of its constituents:—

80.15	0.5862	0.5712	1.0271

In all these alcoholic mixtures the observed specific heat is greater than the mean value obtained by calculation from the specific heats of the constituents, and it may even exceed the specific heat of that constituent which has the greater specific heat. As the proportion of alcohol becomes greater, the ratio of the true to the mean specific heat increases also, rapidly at first till it attains a maximum, then diminishes somewhat quickly at first, afterwards more slowly, and gradually approximates to the first value.

In the case of mixtures of alcohol and water, the excess of the observed over the calculated mean specific heat is confirmed by the experiments of Dupré and Page already cited, also by those of Jamin a. Amaury (*Compt. rend.* lxx. 1237), who explain it on the hypothesis that the specific heat of a body increases as its density diminishes, and must, therefore, be greater in a mixture in which each of the constituents is diffused through the entire volume.

ETHYL BROMIDE, C^2H^5Br . *Decomposition by the Copper-Zinc Couple* (p. 454).—The action of zinc coated by precipitation with finely divided copper on ethyl bromide at 100° is in the main similar to that which it exerts on the iodide (p. 479), giving rise to zinc ethylbromide, $Zn \begin{Bmatrix} C^2H^5 \\ Br \end{Bmatrix}$ or $Zn(C^2H^5)^2.ZnBr^2$. It varies, however, greatly in different experiments, apparently depending on small differences in the conditions, the nature of which has not yet been determined; in some experiments no action took place, even when the ethyl bromide was heated with the dry couple for thirty-six hours. When the ethyl bromide is mixed with a little ethyl iodide, the reaction always takes place, and with comparative facility, the ethiodide at first formed appearing to facilitate the formation of the ethylbromide.

Zinc ethylbromide melts at 62° and crystallises on cooling in white pearly scales. When heated it yields zinc-ethyl, a great part of which, however, is decomposed, yielding ethane, ethylene, and metallic zinc, $Zn(C^2H^5)^2 = Zn + C^2H^4 + C^2H^6$, apparently in consequence of the high temperature required, so that the quantity of zinc-ethyl obtained is only about a third of that which is theoretically producible.

The action of the couple on ethyl bromide in presence of water or alcohol is very slow at ordinary temperatures, but proceeds much more rapidly on application of heat, ethane being evolved and bromhydrate or bromethylate of zinc remaining in the flask:—

(Gladstone a. Tribe, *Chem. Soc. J.* [2], xii. 410–415).

Bromethyl bromide, $C^2H^4Br^2$ (obtained by the action of bromine on ethyl bromide at 170°) treated with sodium ethylate yields sodium bromide and bromethylene (together with alcohol: $C^2H^4Br^2 + C^2H^5NaO = NaBr + C^2H^4O + C^2H^5Br$).—The same products are obtained by the action of sodium ethylate on the addition-product of monobromethylene and dilute hydrobromic acid, $C^2H^4Br.HBr$, which agrees also in its other properties with bromethyl bromide, and is therefore probably identical therewith (Reboul, *Ann. Ch. Pharm.* clv. 29).

Ethyl bromide treated with bromine yields monobromethyl bromide $C^2H^4Br.Br$, ethylene bromide $C^2H^4.Br^2$, and dibromethyl bromide $C^2H^5Br^2.Br$. The two former may be separated by treatment with an alcoholic solution of potassium sulphhydrate, which converts the ethylene bromide into the compound $C^2H^4S^2$. *Monobromethyl bromide* treated with ammonia yields collidine, C^2H^4N , boiling at 181° . *Monobromethyl bromide* and potassium acetate, heated together in alcoholic solution, yield

aldehyde and acetal. Oxidation of monobromethyl bromide by means of lead dioxide and water, leads to the production of aldehyde.

Dibromethyl bromide may be produced by the action of bromine on ethylene bromide, and when the product thus obtained is treated with sodium ethylate, two substances having the composition $C^2H^2Br^2$ are produced, one boiling at 91° the other at 161° . The products of the action of bromine on ethylene bromide contain a small proportion of a substance containing $C^2H^2Br^1$, and boiling, with partial decomposition, at 209° . This substance remains fluid at -20° , but the isomeric body obtained by the action of bromine on acetylene forms crystals melting at 185° (Tawildarow, *Deut. Chem. Ges. Ber.* vi. 1459).

ETHYL CHLORIDE, C^2H^5Cl . The easiest method of preparing this compound is to pass hydrochloric acid gas into a boiling solution of zinc chloride in $1\frac{1}{2}$ times its weight of alcohol of 95 p.c., contained in a flask connected with an inverted condenser and a wash-bottle containing water. Nearly the whole of the alcohol is thus converted into ethyl chloride (Groves, *Chem. Soc. J.* [2] xii. 637).

Chlorinated Derivatives.—It has hitherto been supposed that of the various bodies $C^2H^4Cl^2$ produced by passing chlorine into ethyl chloride, only the final product C^2Cl^4 is identical with the similarly composed product formed by the action of chlorine on ethylene chloride. According to Geuther a. Stapff, however (*Jenaische Zeitschrift*, vi. 228), this view is not correct, the two series from $C^2H^2Cl^4$ (inclusive) to C^2Cl^4 uniting into one. According to Regnault, the chlorination of ethyl chloride yields the bodies—

	$C^2H^4Cl^2$	$C^2H^3Cl^3$	$C^2H^2Cl^4$	C^2HCl^5
boiling at	64°	75°	102°	145° .

On the other hand, according to Geuther, the action of chlorine on chloride of ethylene yields the compounds—

	$C^2H^4Cl^2$	$C^2H^3Cl^3$	$C^2H^2Cl^4$	C^2Cl^4
boiling at	82.5°	116°	135°	153.5° .

Geuther a. Stapff, by fractionally distilling a large quantity of crude chlorinated ethyl chloride (the portions boiling at 62° – 72° and at 75° being subjected, after further chlorination, to the same treatment) obtained, of products not further alterable by fractionation, and in addition to the constantly occurring C^2Cl^4 , only bodies boiling respectively at:

II.	IIa.	III.	IIIa.	IV.	V.
58° – 64°	81° – 84°	75°	115°	135°	153° .

The portion which originally passed over at 102° or 146° , always split up into bodies of this series (and C^2Cl^4). A portion of III a. boiling at 115.6° (corr.), gave, on analysis, numbers agreeing with the formula $C^2H^2Cl^4$. The product II a. was obtained, in small quantity only, by very careful fractional distillation of a product boiling between 75° and 100° ; it exhibited the composition of a mixture of $C^2H^4Cl^2$ and $C^2H^3Cl^3$. If, then, we admit with Geuther that in the group $C^2H^2Cl^4$ —equality of boiling point and elementary composition indicate chemical identity, the preceding facts must be regarded as establishing the proposition above stated, viz., that the corresponding bodies produced by chlorination of ethyl chloride and of ethylene chloride belong to the same series. According to Stapff, the body above designated as II. yields, by further distillation, a liquid having exactly the composition $C^2H^4Cl^2$, and boiling between 57° and 59° ; identical, therefore, with ethylidene chloride.

Stadel, by submitting 5000 grams of the crude product of the action of chlorine on ethyl chloride to a very large number of fractional distillations, found that ultimately only 3 or 4 grams were obtainable boiling between 80° and 90° ; whence he infers that ethylene chloride does not occur amongst the products of the reaction, the small quantity which Geuther obtained being probably formed—as, indeed, Geuther also supposes—from alcohol contained in the ethyl chloride. Small quantities of pure mono- and di-chlorinated ethyl chloride were separated, boiling respectively at 62° and 74.6° .

Regnault found the boiling point of monochlorethyl chloride (ethylidene chloride, $ClP.ClHCl^2$) to be 64° , Geuther 57° – 59° , Beilstein, and also Krämer, 60° . Of these results Krämer's is perhaps the most trustworthy, as he operated on larger quantities of liquid.

ETHYL IODIDE, C^2H^5I . This compound, treated with *sulphuric anhydride*, yields, with separation of iodine, an acid isomeric with ethyl-sulphuric acid, $(C^2H^5)HSO^4$. *Sulphuric chlorhydrate*, $SO^2(HO)Cl$, acts strongly on ethyl iodide, converting it into ethyl-sulphuric acid (Wroblewsky, *Zeitschr. f. Chem.* [2], iv. 563; v. 280).

When a solution of *phosphine* in ethyl iodide is heated, either alone or mixed with an ethereal solution of zinc iodide, the iodides of triethyl- and tetraethyl-phosphonium are produced (Hofmann, *Deut. Chem. Ges. Ber.* iv. 372).

Decomposition by the Copper-Zinc Couple.—Zinc-foil coated with metallic copper by immersing it in a 1 p.c. solution of cupric sulphate, decomposes ethyl iodide at 100°, yielding white crystalline ethiodide of zinc, $\text{Zn}(\text{C}^2\text{H}^5)_2\text{I}$ or $\text{Zn}(\text{C}^2\text{H}^5)_2\cdot\text{ZnI}_2$, which, when gently heated, is resolved into zinc-ethyl and zinc iodide, together with more or less of combustible gas consisting of ethane and ethylene, resulting from decomposition of the ethyl. The reaction is, in fact, the same as that which takes place when ethyl iodide is strongly heated with zinc alone in sealed tubes (ii. 524). At ordinary temperatures, or at 100°, pure zinc has no action on ethyl iodide. The ethiodide of zinc is resolved by gentle heating into zinc iodide and zinc-ethyl, $\text{Zn}(\text{C}^2\text{H}^5)_2$, the quantity of the latter obtained being about two-thirds of the total quantity theoretically producible from the materials employed; this reaction affords, therefore, an easy method of obtaining zinc-ethyl in considerable quantity.

Ethiodide of zinc may be viewed either as $\text{Zn} \begin{Bmatrix} \text{C}^2\text{H}^5 \\ \text{I} \end{Bmatrix}$, formed by direct combination, or as a compound of zinc-ethyl with zinc iodide, $\text{Zn}(\text{C}^2\text{H}^5)_2\cdot\text{ZnI}_2$. The latter view is perhaps the more probable, inasmuch as the especial function of a galvanic couple appears to be the resolution of a binary compound into its elements.

When the couple acts on ethyl iodide in presence of water, ethane is abundantly given off, and zinc iodhydrate remains in the flask; in presence of alcohol the products are ethane and zinc iodethylate;

(Gladstone & Tribe, *Chem. Soc. J.* [2], xi. 445).

ETHYL OXIDE or **ETHYLIC ETHER** $(\text{C}^2\text{H}^5)_2\text{O}$. Pure ether, when shaken with water, does not communicate to the water anything capable of yielding the iodoform reaction (indicating the presence of alcohol) when treated with iodine and potash; such ether can be obtained by distilling purified ether two or three times over sodium, the entrance of moisture being prevented by means of a chloride of calcium tube. Ether thus purified does not give the iodoform reaction even after standing 1½ year in well closed vessels; if, however, it be mixed with water or dilute sulphuric acid, and heated to 100° for a day, a strong iodoform reaction is obtained, and when it is kept in contact with water at the ordinary temperature for three or four months, the same result ensues.

Pure ether sealed up with fragments of sodium, caustic potash, or potassium carbonate, was unaffected even after many months; but in contact with calcium chloride, sodium chloride, or copper sulphate (anhydrous), decomposition took place, and a body which yielded the iodoform reaction was produced.

It appears therefore that bases do not cause this change in ether, while neutral salts and acids do; possibly ethylates are formed thus:

or possibly the ether splits into alcohol and ethylene (Lieben, *Ann. Ch. Pharm.* clxv. 134).

On the formation of alcohol from ether, and of ether from alcohol, by the action of water and dilute sulphuric acid, see p. 473.

Action of Ether on Iodides.—When a concentrated solution of an iodide is mixed with starch-paste and then shaken with ether, part of the iodine is separated, and the starch is turned blue. If the solution is dilute, the blueing does not appear till after two or three hours, and in extremely dilute solutions not till after two or three days. On filtering from the blue starch and adding more ether, a blue colour is again produced, and so on, till at length all the iodine is removed from the compound. Mineral waters containing iodides exhibit, when thus treated, the same reactions as artificially prepared solutions (E. Ferriero, *J. Pharm. Chim.* [4], xvi. 107).

Chlorinated Derivatives of Ethyl Oxide.

Monochlorethyl oxide, $\text{C}^4\text{H}^9\text{ClO}$, the first product of the action of chlorine on ether, is identical with the body which Wurtz & Frapollé obtained (i. 3, 107) by the action of hydrochloric acid on an alcoholic solution of aldehyde. Pure monochlor-

ethyl oxide boils at 97° – 98° . With sodium ethylate it forms acetal; sulphuric acid decomposes it, with formation of ethyl-sulphuric acid, hydrochloric acid, and aldehyde. These reactions show that its constitutional formula is $\text{CH}_3\text{CH} \begin{Bmatrix} \text{Cl} \\ \text{OC}^2\text{H}^3 \end{Bmatrix}$. When treated with water it yields, besides hydrochloric acid, a liquid which boils a little below 50° , has the composition $\text{CH}_3\text{CH} \begin{Bmatrix} \text{OH} \\ \text{OC}^2\text{H}^3 \end{Bmatrix}$, and from its analogy to chloral alcoholate may be called aldehyde alcoholate. Condensation-products are formed at the same time, the first of which, boiling between 80° and 84° , appears to have the

Dichlorethyl Oxide, $\text{C}^2\text{H}^3\text{Cl}_2\text{O}$ (Jacobsen, *loc. cit.*; Abeljanz, *Ann. Chem. Pharm.* xiv. 197). Lieben has shown that both the chlorine-atoms of this compound are situated in one ethyl group, as represented by the formula $\text{C}^2\text{H}^3\text{Cl}_2\text{OC}^2\text{H}^3$ (1st Suppl. 596); but he has not determined which of the three following formulæ, included in the preceding, viz.,

must be accepted as the true representative of its constitution, though, for a reason to be mentioned hereafter, he gives the preference to the third. But the reaction of the compound with sulphuric acid, by which it is easily and completely resolved into ethyl-sulphuric acid, hydrochloric acid, and monochloraldehyde, $\text{CH}^2\text{Cl}\cdot\text{CHO}$, and with sodium ethylate, whereby it is converted into monochloroacetal, $\text{CH}^2\text{Cl}\cdot\text{CH}(\text{OC}^2\text{H}^3)^2$, identical with Lieben's ethylchlorinated ethyl oxide (1st Suppl. 597) show that it is correctly represented by the second of the formulæ above given:—

By the action of water, dichlorethyl oxide is converted into the alcoholate of monochloraldehyde, $\text{CH}^2\text{Cl}-\text{CH} \begin{Bmatrix} \text{OC}^2\text{H}^3 \\ \text{OH} \end{Bmatrix}$, boiling at 95° – 96° , together with condensation-products (especially on warming), the first of which distils at about

165° , and has the composition

This body is analogous to Ginsky's monochloraldehyde hydrate, $\text{C}^2\text{H}^3\text{ClO} + \frac{1}{2}\text{H}^2\text{O}$, or $\text{C}^2\text{H}^3\text{ClO}^2 + \text{H}^2\text{O}$ (Deut. Chem. Ges. Ber. iii. 870), the constitution of which

The formula of dichlorethyl oxide deduced from the preceding reactions is corroborated by the experiments of Abeljanz on the action of phosphorus trichloride on this compound.

The two substances brought together in molecular proportion react pretty briskly, the temperature rising to 65° or 70° . The experiment was performed in a retort connected with an upright condenser, and this again with a series of Woulfe's bottles, leading finally to a well-cooled Liebig's condenser, terminating in a U-tube surrounded by ice and salt. A small quantity of hydrochloric acid was collected in the Woulfe's bottles, and in the U-tube a considerable amount of pure ethyl chloride. The residue contained phosphorus trichloride and oxychloride, and when submitted to distillation gave, below 130° , a liquid which, when treated with water, yielded a large quantity of hydrochloric acid and a solution having a peculiar aldehydic smell. To isolate this aldehydic body, the solution was neutralised by boiling with lead oxide, and distilled. A colourless oil was deposited from the distillate, but as it was decomposed by redistillation, the whole was oxidised by heating it with excess of silver oxide. After

removal of the reduced silver and the silver chloride, which had been simultaneously produced, the acid was converted into zinc salt and analysed. The physical properties and composition of this compound showed that it was zinc glycolate, $\text{Zn}(\text{C}^2\text{H}^2\text{O}^2)^2$.

The products of the action of phosphorus pentachloride boiling above 130° consisted chiefly of unchanged dichlorethyl oxide.

The principal reaction between phosphorus pentachloride and dichlorethyl oxide may be represented by the following equation:—

The last body, by boiling with lead oxide, yields monochloraldehyde:—

and this, when oxidised by silver oxide, gives silver chloride, metallic silver, and silver glycolate:—

Reaction of Dichlorethyl Oxide with Water and with Alkalis.—Dichlorethyl oxide heated in sealed tubes, with seven or eight times its volume of water, to 115° – 120° , but not higher, gives a colourless homogeneous solution containing hydrochloric acid, ethyl alcohol, and a mixture of aldehydes, among which chloraldehyde may be identified by treating it with silver oxide, whereby it is converted into glycollic acid. Another portion of the watery solution of the aldehyde, exposed for a week to the air and then evaporated, yielded a mixture of two kinds of crystals which, when separated and recrystallised, proved to be monochloroacetic acid (from the chloraldehyde) and glycollic acid. The latter could only have resulted from the oxidation of the hitherto unknown oxaldehyde, $\begin{Bmatrix} \text{CH}^2\text{OH} \\ \text{CHO} \end{Bmatrix}$, which may be regarded as the aldehyde of glycollic acid.

The oily body which was produced in small quantity by distillation of the original acid solution, is probably a hydroxyl-chlorethyl oxide, $\begin{Bmatrix} \text{C}^2\text{H}^2\text{Cl}(\text{OH}) \\ \text{O.C}^2\text{H}^2 \end{Bmatrix}$.

From these results the principal reaction between water and dichlorethyl oxide may be represented as follows:—

The oxaldehyde results from the subsequent decomposition of the chloraldehyde by water:—

With *alkalis* dichlorethyl oxide yields products similar to those obtained in its decomposition by water, viz., alcohol, chloraldehyde, and two other chlorinated bodies. One of these has the composition of a hydroxyl-chlorethyl oxide, $\begin{Bmatrix} \text{CH}^2\text{Cl} \\ \text{CH}(\text{OH})(\text{OC}^2\text{H}^2) \end{Bmatrix}$, and boils at about 153° ; the other is a condensation-product, $\begin{Bmatrix} \text{C}^2\text{H}^2\text{Cl}.\text{OC}^2\text{H}^2 \\ \text{O} \end{Bmatrix}$, boiling at 163° – 165° , and identical with the body observed by Jacobson as a product of the decomposition of dichlorethyl oxide with water.

Besides the reaction in which the hydroxyl-chlorethyl oxide, just described, is the principal product, another which yields an isomeric of that body occurs at the same time, viz.:—

This latter substance is not susceptible of condensation, but when treated with concentrated sulphuric acid, it yields hydrochloric acid, ethyl-sulphuric acid, and oxaldehyde:—

together with a small quantity of a body, $\text{C}^2\text{H}^3\text{Cl}^2\text{O}^2$, which is the analogue of ethylidene oxychloride, and results from a secondary reaction between the hydrochloric acid and the oxaldehyde:—

The condensation-product, $\text{C}^2\text{H}^{14}\text{Cl}^2\text{O}^2$, obtained from dichlorethyl oxide by the action of potash, gives scarcely any hydrochloric acid when treated with sulphuric acid, but forms chloraldehyde, water, and ethylsulphuric acid.

The chloraldehyde cannot be purified by fractional distillation, but when oxidised by silver oxide it gives glycollic acid; on exposure to the air it leaves crystals of monochloroacetic acid. It unites with bisulphite of soda, and ammonia passed into its ethereal solution produces a compound which crystallises in large pearly tables melting at about 136° .

Lieben, by treating dichlorethyl oxide with potash, obtained indications of the formation of acetic acid, a result which would imply that dichlorethyl oxide should be represented by the third of the preceding formulæ, $\text{CH}^2\text{Cl}^2.\text{OC}^2\text{H}^3$; thus —

or at all events that this modification was present in the substance operated on. But if this were the case, acetic acid should also have been found in the final product of the series of reactions described by Abeljan, who prepared his dichlorethyl oxide exactly according to Lieben's directions, but not a trace of acetic acid could be discovered. Neither could acetic acid be detected in the saline residue obtained by the action of potash on dichlorethyl oxide, that residue consisting of potassium chloride with a small quantity of formate.

Dichlorethyl oxide being then represented by the formula $\begin{Bmatrix} \text{CH}^2\text{Cl} \\ \text{CHCl}.\text{OC}^2\text{H}^3 \end{Bmatrix}$, the compounds formed from it by the action of sodium-ethylate, zinc-ethyl, &c. (*1st Suppl.* 597) must be represented by analogous formulæ, viz. oxethyl-chlorethyl oxide $\text{C}^2\text{H}^3\text{Cl}^2\text{O}^2$, the first product of the action of sodium ethylate, by either of the formulæ

and dioxethyl-ethyl oxide, $\text{C}^2\text{H}^{12}\text{O}^2$, the product obtained by the further action of the same reagent, by the formula

Ethylchloroethyl oxide, $\text{C}^4\text{H}^{13}\text{ClO}$, the first product of the action of zinc-ethyl on dichlorethyl oxide, may be represented by either of the formulæ

more probably however by the former, which is in accordance with the transformation of this compound into secondary butyl iodide or methyl-ethyl-carbonyl iodide by the action of hydriodic acid:

Diethylated ethyl oxide, $\text{C}^6\text{H}^{16}\text{O}$, the second product of the action of zinc-ethyl on dichlorethyl oxide, has the constitution

and the hexyl alcohol obtained by treating it with hydriodic acid and saponifying the resulting iodide, is represented by the formula

that is to say, it is ethyl-butyl carbinol.

Trichlorethyl Oxide, $\text{C}_2\text{H}_3\text{Cl}_3\text{O}$, is also formed by the action of chlorine on ether, but it cannot be separated in the pure state by fractional distillation, dichlorethyl oxide being the most highly chlorinated product that distills unchanged. The presence of the trichlorinated ether may however be proved indirectly, namely, by the action of sodium ethylate on the residue obtained in the distillation of the crude dichlorethyl oxide after the temperature has risen above 155° . A mixture of chlorinated acetals is thus obtained, which, when submitted to fractional distillation, yields moderately pure dichloroacetal. This reaction establishes the constitution of trichlorethyl oxide, as shown by the equation

Tetrachlorethyl Oxide, $\text{C}_2\text{H}_2\text{Cl}_4\text{O}$ = $\text{CCl}^2\text{CH} \left\{ \begin{array}{l} \text{Cl} \\ \text{OC}^2\text{H}^5 \end{array} \right.$. This compound, prepared by the action of phosphorus pentachloride on chloral alcoholate (Henry's process, p. 313),

boils at 189.7° under the pressure of (reduced to 0°) 857.5 mm. and has a density of 1.4370 at 0° , 1.4182 at 15.2° , 1.3055 at 99.9° . Heated with alcohol for several hours in a bath of salt water, it yields the trichloroacetal, $\text{CCl}^2\text{CH} \left\{ \begin{array}{l} \text{OC}^2\text{H}^5 \\ \text{OC}^2\text{H}^5 \end{array} \right.$, discovered by Wurtz a. Frapolli (p. 2),

The same transformation is effected, though less sharply, by sodium ethylate, or by a very strong alcoholic solution of potash. If, however, the tetrachlorinated ether be treated with a 10 p.c. solution of potassium hydrate in absolute alcohol, a totally different reaction takes place, a molecule of hydrochloric acid being eliminated, and a compound formed, which appears to have the composition $\text{CCl}^2 = \text{CCl} - \text{OC}^2\text{H}^5$ (Paternò a. Pisati, *Gazzetta chimica italiana*, ii. 333).

Tetrachlorethyl oxide is likewise formed, together with lower chlorinated products, by the action of chlorine on ether at 90° . If the action be not pushed too far, a liquid is obtained which, when treated with sulphuric acid, yields a considerable quantity of chloral CCl^2CHO , and therefore contains trichlorethyl oxide (Jacobsen).

Pentachlorethyl Oxide, $\text{C}_2\text{HCl}_5\text{O}$, is the end-product of the action of chlorine on ethyl oxide in diffused daylight. It is a rather thick colourless liquid of sp. gr. 1.646. Its reactions show that it still retains one of the ethyl-groups of ethylic oxide intact, and therefore that its constitution is represented by the formula $\text{CCl}^2\text{OC}^2\text{H}^5$ (OC^2H^5).

To extend the chlorination to the second ethyl group, the influence of sunshine is necessary. In that case, perchlorinated ether $\text{C}_2\text{Cl}_6\text{O} = \text{CCl}^2\text{CCl}^2\text{O.CCP.CCl}^2$ is produced (ii. 541).

The order in which the hydrogen atoms in the first ethyl group are successively replaced by chlorine, may be represented by the formula $\text{CH}_3\text{H.CHH.O.CCl}^2$ 2, 3, 4, 1, 5 (Jacobsen, *loc. cit.*)

ETHYL SULPHIDES. (M. Müller, *J. pr. Chem.* [2], iv. 89). Mercaptan heated in a sealed tube for six hours to 150° with sulphur in the proportion of 2 molecules to 1 atom of the latter, is decomposed according to the equation,—

Selenium is without action on mercaptan. Ethyl monosulphide, $(C^2H^5)^2S$, is entirely unacted on by sulphur, and may, when mixed with mercaptan, be readily obtained pure, by heating the mixture with sulphur, whereby the mercaptan is converted into ethyl bisulphide and hydrogen sulphide.

Ethyl disulphide, $(C^2H^5)^2S_2$, heated with sulphur, yields the trisulphide $(C^2H^5)^2S_3$, as a yellow oil, heavier than water, which cannot be distilled alone but may be obtained pure by slowly distilling it in a current of steam. This compound may also be prepared by distilling liver of sulphur and potassium sulphovinate from a retort, with frequent addition of water, so long as oily drops pass over. The oil thus obtained is a mixture of ethyl di- and tri-sulphides, and to convert it entirely into the latter, it is heated with sulphur in sealed tubes for some hours at 150° . The contents of the tubes are then carefully distilled in a current of steam.

On shaking ethyl trisulphide with *mercury*, the third sulphur-atom is slowly removed; also on heating with copper turnings in a sealed tube to 150° for a day. When the product is suspended in water and carefully oxidised by fuming nitric acid, an amount of sulphuric acid is produced exactly equivalent to the third sulphur-atom, two molecules of ethylsulphurous acid being formed at the same time. The above-mentioned mixture of di- and tri-sulphides may therefore be employed with advantage for the preparation of ethylsulphurous acid, $C^2H^5 \cdot SO_2 \cdot OH$. *Aqueous potash*, shaken for a long time with ethyl trisulphide, removes the third sulphur-atom; alcoholic potash seems to act differently. The trisulphide heated with potassium cyanide yields potassium sulphocyanate and ethyl disulphide. Many *metallic salts* remove the third sulphur atom, with simultaneous formation of metallic sulphide. *Silver oxide* forms silver sulphide and ethylsulphurous acid; *silver acetate* acts similarly, acetic acid being set free.

ETHYLAMINES. The volatile by-products rich in ethyl chloride, obtained in the manufacture of chloral, have been applied by A. W. Hofmann (*Deut. Chem. Ges. Ber.* 1870, 109 and 776) to the preparation of ethyl-bases on the large scale. These products are heated to 100° for an hour in a wrought-iron digester with three times their volume of 95 p.c. alcohol previously saturated with ammonia at 0° ; the liquid is filtered from the separated sal-ammoniac; the alcohol distilled off; and the residue evaporated to dryness. This residue, which contains the hydrochlorides of the three ethyl-bases, is decomposed by a concentrated solution of caustic soda, and the bases which separate are removed and separated from one another by treatment with oxalic ether (ii. 551). With reference to this method of separation, Hofmann observes that the diethyloxamide and ethylic diethyloxamate must be separated by filtration at 0° , and not by treatment with hot water, since ethylic diethyloxamate is resolved by boiling with water into alcohol and diethyloxamic acid. The chief product of the action of ammonia on ethyl chloride is diethylamine.

Tetraphylammonium bromide, $(C^2H^5)^4NBr$, unites very easily with bromine, forming polybromides, among which the tribromide is the most stable. When an aqueous solution of tetraphylammonium bromide is mixed with bromine-water, a light red-precipitate of the tribromide is immediately formed, which, on further addition of bromine, turns crimson-red and is converted into the pentabromide. The latter, however, on exposure to the air, gives off 1 mol. bromine, and is reconverted into the tribromide. The same result is obtained when alcohol or chloroform is used as the solvent, the red crystalline mass which separates quickly losing bromine, and yielding the tribromide.

Tetraphylammonium tribromide, $(C^2H^5)^3NBr_3$, crystallises from alcohol in beautiful light orange-red needles which melt at 78° . It dissolves easily in alcohol and carbon sulphide; in chloroform only in certain proportions, an excess of chloroform floating in the solution without becoming coloured. On mixing a saturated alcoholic solution of the tribromide with an alcoholic solution of iodine, small crystals, resembling iodine, and probably consisting of the tri-iodide, separate at first, together with the tribromide. On adding a solution of iodine in potassium iodide to the alcoholic solution of the tribromide, a brown precipitate is formed consisting of the tri-iodide $(C^2H^5)^3NI_3$. (Clamor-Marquart, *J. pr. Chem.* [2], i. 429).

ETHYLATE OF SODIUM, C^2H^5ONa . The constitution of this compound may be represented by three different formulæ, viz:

If the first formula be the true one, the action of ethyl iodide on sodium ethylate ought to yield ethyl oxide, $C^2H^5-O-C^2H^5$; if the second is correct, normal butylic alcohol, $CH^3CH^2CH^2-CH^2OH$, should be obtained; and finally, if the third formula correctly expresses the constitution of sodium ethylate, the action of ethyl iodide on it should give secondary butylic alcohol, $CH^3-CH(C^2H^5)-OH$.

Now the action of ethyl iodide on sodium ethylate is well known to yield ethyl oxide, and according to Laubenheimer (*Ann. Ch. Pharm.* clxiv. 280), it yields nothing else, excepting a small quantity of ethylene, probably arising from a secondary reaction according to the equation,

This action is analogous to the decomposition of ethyl iodide by sodium hydrate, and to the formation of butylene by the action of alcoholic potash on butyl iodide.

From these results Laubenheimer concludes that the true formula of sodium ethylate is C^2H^5ONa , and not $C^2H^5Na.OIL$, as proposed by Wanklyn (*1st Suppl.* 244, 1028).

Reactions of Sodium Ethylate with Chlorides.—Geuther u. Brockhoff (*Jenaische Zeitschrift*, vii. 359).

1. With phosphorus pentachloride. When 4 mol. sodium ethylate are acted on by 1 mol. PCl^5 , the products obtained are triethylie phosphato, ethyl chloride, and sodium chloride, together with a little alcohol, the reaction probably taking place in two stages, thus:

2. With perchlorethylene C^2Cl^4 .—The action of sodium ethylate on perchlorethylene has been studied by Fischer and Geuther, who found that, besides sodium chloride, sodium ethylglyoxalate, and ethyl dichloracetate, there were also produced two substances having the composition $C^2H^5Cl^2O$ and $C^2H^5Cl^2O^2$. These substances have since been proved to be trichlorethoxyl-ethylene and triethylie dichloracetate. Geuther u. Brockhoff consider that trichlorethoxyl-ethylene is the primary product of the reaction, and that it is derived from perchlorethylene by the replacement of one atom of chlorine by one atom of ethoxyl:—

The triethylie dichloracetate may be derived from the above compound as follows, the sodium ethylate originally employed having contained alcohol:

The ethyl dichloracetate may arise from the action of water on tribasic ethyl dichloracetate, the water being partly hygroscopic and partly derived from secondary reactions:

The action of sodium ethylate on this ether gives rise to ethyl diethylglyoxalate, this compound being subsequently decomposed by sodium hydrate into alcohol and sodium diethyl-glyoxalate:

The above-mentioned intermediate reactions were confirmed by experiments in which the action of the sodium ethylate was to some extent limited.

The action of sodium ethylate free from alcohol on perchlorethylene gave rise to the products enumerated above, but in smaller quantities, also to a gas burning with a blue flame, and some brown products.

3. With perchlorethane C^2Cl^4 .—When an ethereal solution of perchlorethane.

was heated to 106°–110° with sodium ethylate, an energetic action took place, ethane being evolved as a gas burning with a non-luminous flame. On distilling the products of the reaction, perchlorethylene was found in the distillate, accompanied, as might be expected, by those substances which are formed by the action of sodium ethylate on it. Besides sodium chloride and resinous substances, the residue contained sodium ethylglyoxalate and sodium acetate. The latter appears to be formed by the action of chlorine on sodium ethylate, the chlorine being yielded by the perchlorethane:

4. With trichlorethylene chloride C^2HCl_3 .—These substances act readily on one another, perchlorethylene being produced. Similar results were obtained when the trichlorethylene chloride was dissolved in ether and then treated with sodium ethylate.

5. With dichlorethylene chloride.—This chloride was digested for some time with sufficient alcoholic sodium ethylate to replace all the chlorine by ethoxyl. The product was then distilled, and by the addition of water to the distillate, an oil was obtained which had the composition of dichloroethoxyl-ethylene, $\text{C}^2\text{HCl}(\text{OC}^2\text{H}^5)$. This substance is a colourless liquid having a peculiar aromatic odour. It boils at 128.2 (corr.), and has a specific gravity of 1.08 at 10°. Moisture acts slowly on it, hydrochloric acid and ethyl chloride being formed. Heated in a sealed tube to 180° with excess of water, it is entirely decomposed, with formation of glycollic acid, hydrochloric acid, and ethyl chloride:

Excess of alcoholic sodium ethylate converts dichloroethoxyl-ethylene into the sodium salt of ethyl-glycollic acid, ethyl monochloracetate being probably formed as an intermediate product. A small quantity of the latter was apparently formed during the action of sodium ethylate on dichlorethylene chloride, and it may be also formed, together with ethyl chloride, by the action of sodium ethylate on excess of dichloroethoxyl-ethylene.

6. With monochlorethylene chloride $\text{C}^2\text{H}^2\text{ClCl}_2$.—When this chloride is treated with excess of sodium ethylate, an action takes place, resulting in the formation of dichlorethylene and a small quantity of sodium acetate.

7. With perchloromethane C^2Cl_4 .—One molecule of this compound was diluted with two volumes of ether and treated with 4 molecules of sodium ethylate, the whole being then digested for about 4 hours under a slightly increased pressure. After the reaction, during which no gas was evolved, had terminated, the product was distilled, and the distillate was found not to contain any portion boiling above 75°. The residue in the retort contained a brown substance insoluble in water, which, after washing with hydrochloric acid, contained 63.6 p.c. of carbon, and 72 p.c. of hydrogen. This substance contained no chlorine and yielded no ash.

The alkaline liquor obtained by heating the residue with water yielded, when treated with hydrochloric acid, a brown resinous precipitate, soluble in alkalis and alcohol. It contained 60.8 p.c. C., and 6.2 p.c. H. The alkaline liquor also contained traces of carbonic acid and oxalic acid.

On the reaction of sodium ethylate with *acetamide*, see page 3

ETHYLCYANOPHOSPHIDE. See CYANETHYL-PHOSPHIDE (p. 405).

ETHYL-DIACETIC ACID, $\text{C}^6\text{H}^{10}\text{O}_2$ (Genther, *Jenaische Zeitschrift*, vi. 560, 575; *J. pr. Chem.* [2], iv. 431, 450). In preparing the sodium salt of this acid by the action of sodium on ethyl-acetate (1st Suppl. 601), Genther recommends the use of a large excess of the acetic ether, so that all the sodium may dissolve without any great rise of temperature, which would cause the formation of resinous products, dehydracetic acid, &c. By using 4 pounds of ethyl acetate to 60 grains of sodium, he obtained 165 grams of ethyl-diacetic acid corresponding very nearly with the theoretical amount.

Action of Phosphorus Pentachloride.—When the pentachloride (33 parts) is gradually added to ethyl-diacetic acid (10 parts) it dissolves without much evolution of heat, forming a reddish brown liquid; at the same time large quantities of hydrogen chloride and ethyl chloride are evolved, but no acetyl chloride. The product, which consists of phosphorus oxychloride and the chlorides of several acids, cannot be separated by fractional distillation, and must therefore be gradually added to water kept at a low temperature, in which it readily dissolves. On distilling the aqueous solution, there passes over at first, with the vapour of water, an oil which does not solidify; then a milky liquid which deposits crystals on cooling, after which the distillate becomes clear. The milky liquid contains the monochlorinated derivative of liquid crotonic acid; called by

Gauthier quartenylic acid; the residue in the retort contains the corresponding derivative of solid crotonic acid (Gauthier's tetraerylic acid: *1st Suppl.* 511); and the neutral oil is a mixture of the ethylic ethers of these two chlorinated acids.

Hence it appears that the action of phosphorus pentachloride on ethyl-di-acetic acid gives rise to the chlorides of the two modifications of monochlorocrotonyl, C^2H^3ClO , and the ethers of the corresponding acids, together with ethyl chloride, hydrogen chloride, and phosphorus oxychloride; according to the equations:

Action of Ammonia on Ethylic Ethyl-di-acetate. The action of concentrated ammonia on this ether at ordinary temperatures gives rise to two compounds, a soluble amide, $C^2H^3NO^2$, which is the amide of ethyl-di-acetic acid, $C^2H^3O^2.NH^2$, and an insoluble amide, $C^2H^3NO^2$, which might be regarded either as the amide of diethyl-di-acetic acid $C^2H^3O^2.NH^2$, or as the ethylamide of ethyl-di-acetic acid $C^2H^3O^2.NH(C^2H^3)$.

The insoluble amide is decomposed by moisture, and more quickly by acids, ammonia being liberated and the crystals being converted into an oily liquid which is nearly pure ethylic ethyl-di-acetate, whence it may be inferred that the insoluble amide is the ethyl amide of ethyl-di-acetic acid:

When the insoluble amide is heated with water to 100° in a sealed tube for several days, and the contents, after acidulation with sulphuric acid, are distilled, an oily liquid passes over between 78° and 208° , consisting of methyl-propyl ketone (ethyl-acetone) $C^2H^{10}O$, together with a little alcohol, and afterwards between 200° and 215° , the ethylic ether of diethyl-di-acetic acid, $C^2H^{10}O^2$. The residue from the first distillation contains the soluble amide of ethyldiacetic acid $C^2H^3NO^2$. The insoluble amide is therefore resolved into the soluble amide and alcohol:

and the soluble amide is further resolved into methyl-propyl ketone, carbon dioxide, and ammonia:

Ethylic diethyl-di-acetate $C^2H^{10}O^2$ is more easily obtained by heating ethylic ethyl-di-acetate with four or five times its volume of strong aqueous ammonia for several days to 120° – 130° . The resulting oil, after being carefully dried, yields by fractional distillation, methyl-propyl ketone boiling at about 100° , unaltered ethylic ethyl-di-acetate boiling between 190° and 200° , and ethylic diethyl-di-acetate boiling between 200° and 215° .

From these results it would appear that in the decomposition of ethylic ethyl-di-acetate by ammonia at a high temperature, and also that of the insoluble ethylamide of ethyldiacetic acid by water, the soluble amide of ethyldiacetic acid is obtained together with a small quantity of ethylic ethyl-di-acetate, as represented by the following equations:

ETHYLENE. *Oxidation.*—According to F. Ludwig (*Ann. Ch. Pharm.* clxii. 47), ethylene heated with concentrated solution of *chromic acid* in sealed tubes is completely oxidised to carbonic acid and water; but at ordinary temperatures, intermediate products, viz. formic acid and perhaps also acetic acid, are likewise produced. Berthelot, on the other hand, found that ethylene, heated with concentrated chromic acid, in sealed tubes, was oxidised to aldehyde (*1st Suppl.* 602).

Ethylene is not taken up by *sulphuric acid* at ordinary temperatures, but at 100° , and, still better, between 160° and 175° , the gas is rapidly absorbed, and by subsequently diluting and distilling the acid liquid, a considerable quantity of alcohol may be produced. Elevation of temperature, then, being necessary to the absorption of ethylene by sulphuric acid, it appears not improbable that, in Berthelot's well-known experiment, the violent and continued shaking serves not only to bring the gas into intimate contact with the acid, but to develop the heat necessary.

Contact of ethylene with sulphuric acid at the temperatures above mentioned, does not give rise to condensation of the hydrocarbon. Neither does a still further elevation of temperature, or the employment of fuming sulphuric acid or of fluoride of boron produce signs of polymerisation. This remarkable stability in circumstances under which its higher homologues are easily affected, indicates that the constitution of ethylene is symmetrical, and not analogous to that of propylene, isobutylene, &c. (Gorjainow & Butlerow, *Ann. Ch. Pharm.* clxix. 196).

Ethylene Bromide, $C_2H_4Br_2$. Carius (*ibid.*) by heating this compound with water to 150° - 160° obtained hydrobromic acid and aldehyde; Kriwaxin (*Zeitschr. f. Chem.* [2] vii. 263) obtained no aldehyde and only a doubtful trace of a condensed aldehyde.

Decomposition by the Copper-zinc Couple.—The dry couple has but little action on ethylene bromide, even at its boiling-point, the products being ethylene and zinc bromide. In presence of water, however, the bromide is easily decomposed at ordinary temperatures—zinc alone acts but slowly, the reaction in both cases being the same as with the dry couple:

In presence of alcohol, the couple acts with great violence, the products being still the same. With uncoated zinc-foil in presence of alcohol, no action takes place for half-an-hour, but it then proceeds rapidly and is terminated in about twenty minutes. The nature of the reaction being the same whether the couple is used in the dry state or moistened with water or alcohol, it appeared probable that the sluggishness of the action in the first case might be due to the insolubility of the zinc bromide in ethylene bromide. But when the ethylene bromide was diluted with twice its bulk of ether, the action was found to be much more sluggish than with water or alcohol: hence it appears that the nature of the solvent exerts some influence on the reaction (Gladstone & Tribe, *Chem. Soc. J.* [2], xii.)

Bromethylene, C_2H_3Br .—The reactions of this compound with haloid acids have been examined by Reboul (*Ann. Ch. Pharm.* clv. 29, 212). When aqueous hydrobromic acid saturated at $+6^{\circ}$ acts upon monobromethylene boiling at $+18^{\circ}$ (3 to $\frac{1}{2}$ vols. of the former to 1 vol. of the latter), ethylene bromide, $C_2H_4Br_2$, is formed slowly in the cold, more quickly at 100° ; but if the acid be diluted with $\frac{1}{2}$ vol. water (its density then being 55° Bm.), combination takes place but slowly even at 100° ; and the product is not ethylene bromide, but bromethylene hydrobromide $C_2H_3Br.HBr$, identical with the bromethyl bromide formed by the action of bromine on ethyl bromide (*1st Suppl.* 594).

Hydrobromic acid saturated at $+6^{\circ}$ does not act on this latter compound even at 100° .

Hydriodic acid acts on bromethylene in the same way as hydrobromic acid, excepting that the formation of isomeric compounds by it is determined, not by difference of concentration, but by difference of temperature.

Hydriodic acid saturated at $+4^{\circ}$ combines somewhat rapidly with monobromethylene, the transformation being nearly complete in 6 or 7 days: the product consists of monobromethylene hydriodide $C_2H_3Br.HI$, which boils at 141° - 142° under a pressure of 736 mm. and has a specific gravity of 2.5 at 1° . When treated with alcoholic potash or sodium ethylate, it gives up hydriodic acid and yields bromethylene. When hydriodic acid acts on bromethylene at 100° combination takes place quickly, the products being the hydriodide just mentioned, and the isomeric compounds ethylene iodobromide C_2H_4BrI , which may be separated by fractional distillation. Ethylene iodobromide boils, with partial decomposition, at 160° and has a specific gravity of 2.70 at 1° . If the hydriodic acid be diluted with $\frac{1}{2}$ vol. water, it acts at 100° in the same manner though more slowly.

Hydrochloric acid saturated at 0° , does not appear to act on monobromethylene in the cold, but at 100° reaction takes place, and whether acid of 26.5° or of 22° Bm. be used, the product is the same, namely monobromethylene hydrochloride $C_2H_3Br.HCl$. This compound boils at 81° - 82° and has a specific gravity of 1.61 at 14° . Alcoholic potash or sodium ethylate withdraws the hydrochloric acid, leaving monobromethylene.

Sodium methylate acts on bromethylene (also on iodethylene) at ordinary temperatures, even when shaded from sunlight; the products are the same as when the action takes place at a higher temperature, being acetylene, sodium bromide, methyl alcohol, and a trace of a substance which may be allyl alcohol, as it gives rise to an odour exactly resembling that of acrolein when treated with dilute sulphuric acid and potassium dichromate.

Pure potassium cyanide (prepared by saturating alcoholic potash with gaseous hydrocyanic acid) and silver cyanide have practically no action on bromethylene, even after several hours' heating at 140° - 150° .

When bromethylene is kept in a sealed tube in the dark, no change ensues, even after several weeks; but if exposed to direct sunlight, it becomes changed into an isomeric, solid, non-crystalline, porcelain-like, elastic substance; this change takes place more rapidly with moist bromide than with the perfectly dry substance; the

presence of a small quantity of alcohol neither accelerates nor retards the change. This solid substance has the sp. gr. 2.705, whereas the liquid bromide has the sp. gr. 1.52 (Regnault). It begins to decompose at 125° – 130° , and is but little acted on by boiling alcoholic potash; twelve hours heating to 180° – 200° , with this reagent, however, forms a brown-black substance, insoluble in all menstrua, all bromine being removed from it without any evolution of gas. Sulphuric acid carbonises the substance on being heated with it; boiling nitric acid has but little action on it; bromine dissolves it, forming a loose compound, which splits up into bromine and the original substance on treatment with water, alcohol, or alkalis (E. Baumann, *Ann. Ch. Pharm.* clxiii. 308).

Dibromethylene $C^2H^2Br^2$.—In the preparation of this compound by digesting bromethylene bromide, $C^2H^2Br.Br^2$, with alcoholic potash (ii. 570) the formation of acetylene and bromoacetylene may be completely prevented by keeping the liquid cool, adding the potash to the bromide by drops, and not using more of it than is necessary to keep the mixture permanently alkaline. The resulting dibromethylene is separated by water, and then distilled on the water-bath, whereupon it distils almost wholly at 75° . Dibromethylene heated with alcoholic potash in an open vessel yields large quantities of bromoacetylene, C^2HBr ; but when it is heated with a large excess of alcoholic potash in a digestion tube, the product consists only of acetylene (Fontaine, *Compt. rend.* lxx. 1361).

Ethylene Chloride, $C^2H^4Cl^2$, is not attacked by common sulphuric acid, either at ordinary temperatures or at 100° , but at 130° complete decomposition takes place attended with separation of carbon (Oppenheim, *Deut. Chem. Ges. Ber.* ii. 441).

Ethylene Chloride is obtained in large quantity, together with some of its chlorinated derivatives, from the by-products of the manufacture of chloral. At Schering's factory in Berlin these by-products are collected by causing the vapours which issue from the alcohol retort, together with hydrochloric acid and excess of chlorine, to pass first through water, then through a series of condensers. The crude liquid thus obtained has been examined by Krämer (*Deut. Chem. Ges. Ber.* iii. 257). After a preliminary distillation to separate the ethyl chloride present, the residue (about 5 kilos) was submitted to fractional distillation, and the separate fractions were examined, either by further fractionation, or by first treating them with alcoholic potash (which acts especially, with separation of potassium chloride, on the higher boiling portions), and again separating them by distillation. In this manner the following compounds were isolated:—

1. **Ethylidene Chloride**, $CH^3.CHCl^2$, was obtained in pounds, as a liquid boiling at 60° (according to Regnault it boils at 64°) not decomposed by cold alcoholic potash. Vapour-density, obs. = 49.54; calc. 49.5.

2. **Ethylene-chloride**, $CH^2Cl.CH^2Cl$, was obtained in considerable quantity. Boiling point 85° , vapour-density, obs. = 49.9, and 50.3.

3. **Monochlorethylene Chloride**, $C^2H^3Cl.Cl^2$, boiling at 115° . Vapour-density 66.6 and 68.1 (calc. 66.75). Easily resolved by alcoholic potash in the cold into potassium chloride and the following compounds:

4. **Dichlorethylene**, $C^2H^2Cl^2$.—This compound after purification boiled at 35° (Regnault gives 35° – 40°) and exhibited the characteristic property of changing, after a while, into a solid polymeric modification. On account of this transformation, the vapour-density came out somewhat higher than the calculated value: 49.35 instead of 48.5.

Regnault's chlorinated ethyl chloride, $C^2H^3Cl^2$, and the final product C^2Cl^4 , were not found in the liquid examined by Krämer.

Monochlorethylene is changed by the action of sunshine into an isomeride similar in appearance and properties to the solid modification of bromethylene. Its sp. gr. is 1.406. It bears a heat of 130° without decomposition, but melts to a brown black mass at a higher temperature. It is not dissolved by bromine. Dichlorethylene is also changed by light into a solid isomeride which has been described by Regnault.

Ethylene Cyanide, $C^2H^4.C^2N^2$, or $CH^3CN.CH^3CN$, appears to be formed in the electrolysis of cyanacetic acid (p. 10).

Ethylene Iodide, $C^2H^4I^2$. When this compound is heated to 85° – 95° in sealed tubes for 5 or 6 hours with acetylides of copper suspended in ether, and the ether is evaporated, an iodised compound is obtained, crystallising in broad concentrically grouped prisms and, after recrystallisation from alcohol, in pale yellow glistening prisms. It has an intensely allineous odour, quite different from that of acetylene, is not acted on by a mixture of strong nitric and sulphuric acids in the cold, but dissolves in hot sulphuric acid, forming a colourless liquid. Its composition has not yet been determined (Carstanjen u. Schortel, *J. pr. Chem.* [2], iv. 47).

Iodethylene, C^2H^2I , is formed, though only in small quantity, by the action of alcoholic potash on ethylene iodide; it is not produced by that of potassium iodide on bromethyleno. Sunlight decomposes it, liberating iodine, which probably prevents the isomeric transformation of the unaltered iodethylene (Baumann).

Iodobromethylenes, C^2H^2IBr . Reboni, by treating bromothylene with hydriodic acid, obtained two products having this composition, one boiling at 142° , the other at 162° ; and Lagermark (*Deut. Chem. Ges. Ber.* vi. 1211), by passing ethylene through a mixture of bromine and iodine in equivalent proportions, has obtained a third isomeric melting at 25° and boiling, with partial decomposition, at 150° . Mixed with an alcoholic solution of sodium acetate it yields iodethyl acetate, $\begin{matrix} C^2H^2I \\ C^2H^2O \end{matrix}$. A fourth isomeride appears to be produced by the action of hydrobromic acid on iodethylene.

Sulphethers of Ethylene (Bwerlöf, *Deut. Chem. Ges. Ber.* iv. 716). The following bodies have been obtained by the action of ethylene bromide on sodium mercaptide:—

Ethylene-sulphonethyl, $C^2H^4 \begin{Bmatrix} SCH^3 \\ SCH^3 \end{Bmatrix}$, boiling at 185° ; probably converted by fuming nitric acid into methylethylene-sulphin nitrate.

Ethylene-sulphethyl, $C^2H^4 \begin{Bmatrix} SC^2H^3 \\ SC^2H^3 \end{Bmatrix}$, boiling at 210° – 213° ; oxidised by nitric acid to $C^2H^4 \begin{Bmatrix} SOC^2H^3 \\ SOC^2H^3 \end{Bmatrix}$, which forms glistening, crystalline scales, melting at 170° .

Ethylene-sulphamyl, $C^2H^4 \begin{Bmatrix} SC^2H^3 \\ SC^2H^3 \end{Bmatrix}$, boiling at 245° – 255° , formed in like manner, is converted by oxidation into $C^2H^4 \begin{Bmatrix} SOC^2H^3 \\ SOC^2H^3 \end{Bmatrix}$, which is obtained in thin plates melting at 45° – 150° .

Ethylene-sulphophenyl, $C^2H^4 \begin{Bmatrix} SC^6H^5 \\ SC^6H^5 \end{Bmatrix}$, white needles, insoluble in water, melting at 65° . By oxidation with chromic acid, it yields the compound $C^2H^4 \begin{Bmatrix} SOC^6H^5 \\ SOC^6H^5 \end{Bmatrix}$.

By the action of bromine the compound $C^2H^4 \begin{Bmatrix} SBr^2C^2H^3 \\ SBr^2C^2H^3 \end{Bmatrix}$ is probably formed.

ETHYLENE BASES. The by-products of the manufacture of chloral contain, as already observed, large quantities of the dichlorides of ethylene and ethylidene. Now the latter compound is not attacked by alcoholic ammonia under 160° , and consequently the mixture of the higher boiling chlorides furnishes an excellent material for the preparation of the ethylene bases. On heating the fraction boiling between 70° and 100° for eight or ten hours to 110° with excess of alcoholic ammonia, the ethylene chloride is decomposed; and on filtering to remove sal-ammoniac, distilling and crystallising the residue from water, a large quantity of ethylene-diamine hydrochloride is obtained, crystallising in large shining needles. The mother-liquors, distilled with caustic soda, first yield ethylene-diamine, and the latter fractions contain the higher diamines and triamines (Hofmann, *Deut. Chem. Ges. Ber.* iv. 666).

Ethylene-diamine Sulphate crystallises in the quadratic system, but nevertheless exhibits the property of circular polarisation, a property not hitherto observed in any other body belonging to that system, except sulphate of strychnine. The circular polarisation of the ethylene-diamine salt is about three-fourths that of quartz. The crystals examined were partly dextro, partly levogyrate, but no hemihedral or hemisymmetric forms were observed in them (V. v. Lang, *Chem. Centr.* 1872, 178).

Ethylene-diamine Sulphocyanate.—Ethylene-diamine hydrochloride and silver sulphocyanate have no action on one another, but ethylene-diamine sulphocyanate can be readily prepared by saturating ethylene-diamine with sulphocyanic acid. It crystallises in large transparent prisms, which soon become opaque. It is insoluble in ether, very soluble in alcohol, and still more so in water. Even below its melting point, which is about 145° , it splits up into ammonium sulphocyanate and ethylene sulphocarbamide, no sulphocarbimide being formed. This decomposition is quite analogous to that which aniline sulphocyanate undergoes when heated (Hofmann, *Ann. Ch. Pharm.* lxx. 143).

Tetraethylene-triamine.—A mixture of ethylene bromide and alcoholic ammonia left to itself for several months, deposits considerable quantities of a white substance containing, together with ammonium bromide, an amorphous substance nearly insoluble in water, alcohol, and ether. This body appears, from analysis of the products of several preparations, to consist of the hydrobromides of one and the same ethylene base, probably belonging to the highest order of polyamines. The simplest atomic

relations may be expressed by the formulæ $(C^2H^4)^2HN^2.HBr$, $(C^2H^4)^2HN^2.2HBr$, and $(C^2H^4)^2HN^2.3HBr$, which represent the hydrobromides of tetraethylene-triamine. By prolonged boiling with ammonia the hydrobromic acid is removed and the corresponding hydrides, resembling the hydrobromides in being amorphous and uncrySTALLISABLE, were produced (Hofmann, *Deut. Chem. Ges. Ber.* iii. 141).

ETHYLENE DIAMIDES. A mixture of benzoyl chloride and ethylene-diamine, after it has become cool, solidifies to a crystalline mixture of ethylene-diamine hydrochloride and ethylene-dibenzoyl-diamide, $C^{10}H^{10}N^2O^2 = \left(\begin{smallmatrix} (C^2H^4)^2 \\ (C^2H^4)^2 \end{smallmatrix} \right) N^2$, which crystallises in needles slightly soluble in alcohol, but insoluble in water.

Ethylene-diformyl-diamide, $\left(\begin{smallmatrix} (C^2H^4)^2 \\ (CHO)^2 \end{smallmatrix} \right) N^2$, is formed, with elimination of chloroform, by the action of chloral on ethylene-diamine:

It is a transparent syrup, easily decomposed into ethylene-diamine and formic acid by the action of alkalis or acids. In a similar manner ethyl-formamido, boiling at 199° , may be obtained from chlorine and ethylamine.

A mixture of ethyl oxalate and a strong alcoholic solution of ethylene-diamine becomes almost solid, from deposition of ethylene-oxamide, $(C^2H^4)^2(C^2O^2)^2H^2N^2$, an amorphous substance nearly insoluble in alcohol and in water. The mother-liquors yield, on evaporation, ethylic ethylene-oxamate, $C^{10}H^{10}N^2O^6 = \left(\begin{smallmatrix} (C^2H^4)^2(C^2O^2)^2H^2N^2 \\ (C^2H^3)^2 \end{smallmatrix} \right) O^2$, which crystallises in white scales very soluble in alcohol and water (Hofmann, *Deut. Chem. Ges. Ber.* v. 240).

ETHYLENE-IRIDIUM COMPOUNDS. See IRIDIUM.

ETHYLENE-IRON BROMIDE. See IRON.

ETHYLENE-PLATINUM COMPOUNDS. See PLATINUM.

ETHYLENE-PROTocatechuic Acid. See PROTocatechuic Acid.

ETHYLENE-SULPHOCARBAMIDE or ETHYLENE-SULPHURIA,

$C^2H^4N^2S = \left(\begin{smallmatrix} (C^2H^4)^2 \\ (CS)^2 \end{smallmatrix} \right) N^2$. An alcoholic solution of ethylene-diamine mixed with

carbon bisulphide deposits in a short time a white and nearly amorphous compound, having the composition $C^2H^4N^2S^2 = (C^2H^4)^2H^2N^2.CS^2$. This compound is almost insoluble in alcohol and ether, but dissolves in warm water with partial decomposition, and, provided the solution has not been boiled, is again deposited, on cooling, in prismatic crystals. It does not yield ethylene-diamine when treated with alkalis, and is therefore not the ethylene-sulphocarbonate of ethylene-diamine. On boiling it with water, hydrogen sulphide is given off, and ethylene-sulphocarbamide is formed: $C^2H^4N^2S^2 = C^2H^4N^2S + H^2S$. This amide is soluble in water, and separates from its aqueous solution in prismatic crystals having an extremely bitter taste. It is only slightly soluble in ether, but dissolves readily in alcohol. It melts at 194° , and is decomposed at a higher temperature. It is also formed by the action of dilute acids on solutions of metallic salts. A mercury-compound, $2(C^2H^4)^2N^2S.3HgCl_2$, and a bright yellow amorphous platinum-compound, $2(C^2H^4)^2N^2S.PtCl_4$, have been prepared. On heating the urea with strong sulphuric acid, diluting with water, and adding platinum-chloride, a second salt is obtained, crystallising in long needles, $2(C^2H^4)^2N^2S.HCl.PtCl_4$. When, however, this salt is decomposed by sulphuretted hydrogen and platinum chloride is added to the hydrochloric acid solution, the original amorphous platinum compound is precipitated. Ethylene-sulphocarbamide, which is intermediate between ethylene-diamine and ethylene-disulphocarbamide,

is very stable, not being altered by long digestion at a high temperature with carbon disulphide or with carbon disulphide and lead oxide (Hofmann, *Deut. Chem. Ges. Ber.* v. 240).

ETHYL-GLYCID, $C^2H^4O^2 = C^2H^3 \begin{Bmatrix} OC^2H^3 \\ O \end{Bmatrix}$, is produced by distilling monox-ethyl-chlorhydrin, $C^2H^3HCl(OH)(OC^2H^3)$, the product of the action of cold dilute hypochlorous acid on allyl-ethyl oxide (p. 49) with caustic potash. It is a colourless mobile liquid having an agreeable odour and very pungent taste; soluble in water, and combining readily with the haloid acids. Phosphorus pentachloride converts it into $C^2H^3(OC^2H^3)Cl^2$, a body which is also produced by the action of chlorine on allyl-ethyl oxide (L. Henry, *Deut. Chem. Ges. Ber.* v. 449).

ETHYLIDENE COMPOUNDS. *Bromide*, $CH^3.CHBr^2$.—Chlorinated ethyl chloride is known to be identical with ethylidene chloride (1st Suppl. 606), whereas brominated ethyl bromide differs entirely from the so-called ethylidene bromide which Wurtz and Frapolli (*Ann. Ch. Phys.* lvi. 144) obtained by the action of phosphorus pentabromide on aldehyde. Hence there has existed considerable doubt whether the latter compound is really the bromide of ethylidene. This question has lately been examined by Paternò a. Pisati (*Gazzetta chimica italiana*, i. 596). By treating dichloraldehyde with phosphorus pentachloride, they have obtained results which seem to show that the product of the action of phosphorus pentabromide on aldehyde is an oxybromide of ethylidene analogous to the oxychloride described by Lieben. On adding aldehyde to *phosphorus bromochloride*, PCl^3Br^2 , treating the product with water, and distilling in a current of steam, an oily product is obtained which, by rectification, gives a liquid of the formula $C^2H^3Br^2$, boiling at 110° – 112° . Its mode of formation shows it to be the true ethylidene bromide, and from its boiling point it would seem to be identical with the brominated ethyl bromide obtained by Hofmann and Caventon by the action of bromine on ethyl bromide, and by Reboul (*Compt. rend.* lxx. 399) by that of hydrogen bromide on brominated ethylene. The less volatile portion of the product appears to contain more highly brominated derivatives of ethylidene, an analysis of the portion boiling at about 180° corresponding very nearly with the formula $C^2H^3Br^2$.

Ethylidene Chloride, CH^3-CHCl^2 , is obtained in considerable quantity from the by-products of the manufacture of chloral (p. 490).

Trichlorethylidene Glycol, $CCl^3-CH \begin{Bmatrix} OH \\ OH \end{Bmatrix}$ is identical with chloral hydrate, and its ethylic ether, $CCl^3-CH \begin{Bmatrix} OH \\ OC^2H^5 \end{Bmatrix}$, with chloral alcoholate (p. 314).

ETHYL-METHYL CARBINOL, $(C^2H^5)(CH^3).CHOH$. See BUTYL ALCOHOLS (p. 218).

ETHYLOXY-OXALYL CHLORIDE, $COCl-CO(OC^2H^5)$. See OXALIC ETHERS.

ETHYL-PHOSPHINES }
ETHYL-PHOSPHINIC ACID } . See PHOSPHINES.

ETHYL-PHOSPHOPLATINOUS COMPOUNDS. See PHOSPHOPLATINUM COMPOUNDS.

ETHYL-THIOSULPHURIC ACID, $C^2H^3S^2O^2 = C^2H^3 \begin{Bmatrix} S^2O^2 \\ H \end{Bmatrix}$. *Ethyl-hypo-sulphurous acid*.—This acid is produced by treating ethyl sulphide (boiling at 81°) with an equal volume of strong sulphuric acid. On adding water, saturating with barium carbonate, and concentrating, the liquid deposits colourless rectangular tables with truncated summits, having the composition $C^2H^3BaS^2O^2$ or $(C^2H^3S^2O^2)Ba + 2H^2O$; this salt is easily soluble in water, less soluble in alcohol. The copper salt prepared from it forms small quadratic tables very soluble in water. The silver salt crystallises in small shining laminae. The hydrogen salt or free acid does not appear to have been obtained (R. H. Smith, *Chem. Soc. J.* [2], vii. 302).

EUCALYPTOL, $C^{10}H^{18}O$ (Clocz, *Ann. Ch. Pharm.* cliv. 372).—This compound is contained in large quantity in the volatile oil of *Eucalyptus globulus*, a tree indigenous in Tasmania, and much cultivated in the south-west of Europe. The crude oil contains also a number of products boiling between 188° and 190° , and above 200° , the eucalyptol being contained in the portion which passes over between 170° and 178° , from which it may be obtained pure by contact, first with solid potassium hydrate, then with calcium chloride, and subsequent distillation.

Eucalyptol boils at 175° , has a specific gravity of 0.905 at 8° , and turns the plane of polarisation to the right. Its molecular rotatory power is $+10.42^\circ$ for a length of 100 mm. It is slightly soluble in water and dissolves completely in alcohol; the dilute solution has an odour of roses. Vapour-density, obs. = 5.92, calc. = 6.22.

Ordinary nitric acid slowly attacks eucalyptol, forming, amongst other products, an acid probably analogous to camphoric acid. Strong sulphuric acid blackens eucalyptol,

and water separates from the product a tarry body which yields by distillation a volatile hydrocarbon.

Eucalyptol heated with phosphoric anhydride gives up water, and yields eucalyptone, $C^{12}H^{18}$ (vapour-density = 5.3) which boils at 165° , and has a specific gravity of 0.836 at 12° . At the same time there is formed another liquid, eucalyptolene, which has the same composition, but boils above 300° . Eucalyptol absorbs a large quantity of dry hydrogen chloride, the liquid first solidifying to a crystalline mass, which, however, afterwards liquefies, with separation of water, and formation of a body apparently identical with eucalyptone.

EUDIALYTE and EUKOLITE.—From the analysis of eudialyte from Greenland (A), and of eukolite from the zircon-syenite of Norway (B), Nylander (*Jahrb. f. Mineralogie*, 1870, 488) concludes that both these minerals are included in the formula, $RO.2(SiO_2.ZrO_2)$ given by Rammeisberg for the former.

	SiO ^a	ZrO ^a	CaO	FeO	MnO	CaO	Na ^o O	Cl	X†
A. 51.86	14.67	-	6.5†	1.46	9.82	12.32	1.37	1.43	= 99.47

* Loss by ignition.

† Together with Ta^oO₃.

EUGENOL or EUGENIC ACID, $C^{10}H^{10}O^2$. The formula $C^6H^7 \left\{ \begin{array}{l} OH \\ OCH^3, \text{ as} \\ C^6H^5 \end{array} \right.$

assigned to this body on account of the formation of methyl iodide by heating it with hydriodic acid, and of protocatechuic acid, $C^6H^7(OH)^2.COOH$, by fusing it with potash, (1st Suppl. 609), is further supported by the fact recently observed by Grube and Borgmann (*Ann. Ch. Pharm.* clviii. 282), that methyl eugenate, $C^6H^7(OCH^3)^2.C^6H^5$, when oxidised by chromic acid, is converted into dimethoxybenzoic acid $C^6H^7(OCH^3)^2.CO^2H$. The methylic ether, obtained by heating sodium eugenate with methyl iodide, was dissolved in glacial acetic acid and heated for two or three days on a water-bath with 2 parts of powdered potassium dichromate; the liquid was then diluted with water, and either added to separate any unchanged methyl eugenate; the ethereal solution was shaken with a solution of ammonium carbonate; and the alkaline liquid concentrated. On addition of an acid, a crystalline substance separated, which, after recrystallisation from hot water, exhibited the composition of dimethoxybenzoic acid.

Ethyl eugenate (which boils at 251° and not at 240° , as stated by Cahours) is converted by oxidation into the corresponding diethoxybenzoic acid. Eugenol itself gives by direct oxidation merely a brownish non-crystalline mass, not soluble in water, alcohol, benzene, or any other solvent, and not yielding any definite chemical compound. When heated, it gave off carbonic anhydride and water, while the residue smouldered away on exposure to the air, leaving pure chromic oxide.

EUKOLITE. See EUDIALYTE.

EULYTE and DYSLYTE. These names were given by Baup to two substances which he obtained by the action of strong nitric acid on citraconic acid, the more soluble being called *eulyte*, the less soluble, *dyslyte* (ii. 606). They have lately been more fully examined by Bassett (*Chem. Soc. J.* [2], x. 98).

To prepare them, crystallised citraconic acid was treated with nitric acid of sp. gr. 1.45, using 10 grams of the former to 15 grams of the latter—larger quantities being found to cause a too violent reaction. The mixture was gently heated until action commenced, and the lamp then removed. After completion of the reaction, when most of the nitric acid was decomposed or driven off, the solution deposited an oil, the quantity of which was increased by adding a certain quantity of water. The oil was then washed two or three times with fresh quantities of water. It remains fluid occasionally for days, unless touched with a glass rod, when it crystallises in a short time. The acid mother-liquor contains a large quantity of oxalic, and some mesoconic acid.

The oily product, the quantity of which is very small, consists of a mixture of two neutral crystalline substances, and a small quantity of a yellow oil. The complete separation of these is a matter of considerable difficulty, notwithstanding their great difference in solubility in alcohol, from the fact that the less soluble substance is easily taken up and obstinately held in solution in presence of the more soluble body, which is the main product of the reaction. They may, however, be obtained pure by numerous fractional recrystallisations.

Eulyte, $C^6H^8N^1O^1$, the more soluble substance, agrees perfectly in character with the eulyte of Baup. It is best crystallised from warm chloroform, which deposits it on cooling in large crystals belonging to the quadrate system, with very perfect and brilliant faces. It melts at 99.5° (corr.), but its solidifying point is very uncertain, as

it occasionally remains fluid for hours unless touched with a hard body. By very careful heating, it appears to sublime unchanged, but decomposes at a high temperature with evolution of nitrous fumes, and if in somewhat large quantity, with violent combustion.

Eulyte gives by analysis (mean), 29.26 p.c. carbon, 2.61 hydrogen and 22.60 nitrogen, the formula requiring 29.27 C., 2.52 H., and 22.76 N. Heated with alcoholic potash, it is decomposed, with formation of a nitrite, and a brown resin soluble in alkalis. When moderately heated with tin and hydrochloric acid, it yields ammonia, and a volatile base smelling like picoline. In one experiment a solid base was also obtained, precipitated by ammonia, soluble in potash, and forming an oily hydrochloride almost insoluble in cold water, but soluble in alcohol.

Dyslyte, $C^{10}H^8N^4O^8$, separates from boiling alcohol, in which it is sparingly soluble, in long needles melting at 189° (corr.) On cooling it solidifies suddenly, but at temperatures varying between 135° and 165° . It gives by analysis 37.80 p.c. carbon, 2.50 hydrogen and 21.97 nitrogen, the formula requiring 37.80 C., 2.36 H., and 22.05 N. It is decomposed by alcoholic potash, with formation of brown resinous products.

The fluid product accompanying the two solid substances was precipitated by water from the last mother-liquors of the crude product, and purified as far as possible by distillation in a current of steam (a small quantity of the solid products coming over also), and the distillate shaken up with ether. On evaporation of the clear ethereal solution, a small quantity of a yellow oil remained, having the characteristic smell of volatile nitro-compounds. On the application of a strong heat, it exploded violently. On reduction it gave apparently but ammonia, and some tarry matter.

EUPHORBIA. The flowers of *Euphorbia Cyparissias* yield a yellow colouring matter called luteic acid, which has been prepared and examined by H. Höhn (*Arch. Pharm.* [2] xli. 218). The fresh flowers are exhausted with alcohol of 60 p.c., the greater part of the alcohol distilled off, and the residual liquid filtered and precipitated with basic lead acetate. The well-washed precipitate is suspended in warm water, decomposed by hydrogen sulphide, and the filtrate is evaporated and left to stand over sulphuric acid. Yellowish green crusts then separate, an additional quantity of which may be obtained by evaporating the mother-liquor, dissolving the residue in alcohol, precipitating with ether, and evaporating the filtered solution. A further quantity of the same product may also be obtained in greenish-yellow crusts or warty aggregations by exhausting the precipitated lead sulphide with hot alcohol, and distilling. The colouring matter thus produced may be purified by washing it thoroughly with cold water, then digesting with a little ether, to remove a green soft resin and chlorophyll, dissolving in ether-alcohol, leaving the solution to evaporate slowly, and recrystallising the residue, which is then tolerably pure, several times from hot water mixed with 3 or 4 p.c. of alcohol; five kilos. of fresh flowers yield about 3 grams of pure substance.

The colouring matter is pure yellow, and crystallises in slender needles which appear under the microscope as four-sided, or more rarely as six-sided prisms with perpendicular or less frequently with oblique end-faces. It sometimes separates from a hot aqueous solution in granular, amorphous, or spherical warty groups. It is scentless; has a bitterish, somewhat astringent taste; sublimates at about 220° in yellow flocks made up of shining needles; melts at 273° – 274° ; dissolves in 11,000 parts of cold, and 3,400 parts of boiling water, in 28.7 parts of cold absolute alcohol, and in 27.2 parts of ether. The solutions have an acid reaction, and the body exhibits generally the characters of an acid. The name *luteic acid* has been given to it by Höhn, because it exhibits considerable resemblance to luteolin, and, like the latter, yields protocatechuic acid when fused with potash. It dissolves in caustic and carbonated alkalis with a dark yellow to reddish-yellow colour, the solutions yielding green or yellow-brown precipitates with metallic salts. It reduces silver nitrate, mercurous nitrate, and alkaline cupric solutions, when heated therewith. With ferric chloride, it forms a solution having a fine green colour, changing after a while to red-brown on further addition of the iron solution. Strong sulphuric acid dissolves the colouring matter with yellow colour, and water separates it again in yellow flocks. It is not altered by boiling with dilute sulphuric acid, and is, therefore, not a glucoside. It dissolves easily in acetic and in strong nitric acid, and is oxidised to oxalic acid by boiling with the latter. By distillation with potassium chromate and dilute sulphuric acid, it yields an acid distillate which reduces silver solution and therefore probably contains formic acid. By evaporation of the aqueous solution, the colour becomes continually darker, and a red residue is finally obtained, no longer soluble in water or in alcohol. Höhn assigns to this colouring matter the formula $C^{10}H^{10}O^{10}$, but the analyses from which it is deduced differ considerably from one another.

EUXENITE. The following analyses of this mineral have lately been published:

a. From Hitterö (John, *Pogg. Ann.* clxiv. 594); b. From Alvö near Arendal, sp. gr. 4.984–5 vol. (Rammelsberg, *Chem. Soc. J.* [2], x. 200); c. From the same (Forbes a. Dahll, *ibid.* 293); d. From Morefjär near Arendal, sp. gr. = 4.672 (Rammelsberg, *loc. cit.*); e. From Eydland, Lindernäs, sp. gr. = 5.058–5.103 (Rammelsberg, *loc. cit.*); f. From the same, sp. gr. 5.103 (Behrend, *Deut. Chem. Ges. Ber.* i. 224);

The composition of the euxenite of Hitterö differs considerably from that of all the rest, especially in the predominance of the titanic over the niobic acid, and in the large proportion of the cerum oxide.

EVERNIC ACID, $C^{12}H^{10}O^7$. This acid is obtained, together with usnic acid, by macerating *Evernia prunastri* with milk of lime, and precipitating the filtered solution with hydrochloric acid: it is extracted from the dried precipitate by repeated treatment for a short time with boiling alcohol, precipitated by water, and recrystallised, without further digestion, from strong alcohol. It forms groups of small needles which melt at 164° ; does not decompose solutions of sodium bicarbonate in the cold; its calcium salt is decomposed by carbonic acid. When treated with potash or baryta, it yields, as formerly stated (ii. 611), only one fixed product, viz. overnicnic acid $C^{12}H^{10}O^4$.

Tetrahomevernic acid, $C^{12}H^{12}Br^4O^7$, is obtained by treating perfectly dry finely pulverised evernic acid with a slight excess of anhydrous bromine, washing with carbon sulphide, and repeated crystallisation from boiling alcohol, from which it separates, after long standing, in small colourless prisms. It is insoluble in water and in carbon sulphide, slightly soluble in hot benzene, easily in ether, melts at 161° (Stenhouse, *Proc. Roy. Soc.* xviii. 222).

EXCREMENTS. The excrements of the common bat, and of the Egyptian bat, have been examined by O. Popp (*Ann. Ch. Pharm.* clv. 351; clviii. 115). Those of the Egyptian bat are found in caves in stalactitic masses. They dissolve easily and almost completely in water and in alcohol, have an acid reaction, and yield by analysis 37.2 p.c. nitrogen. They contain 77.80 p.c. urea, 1.25 uric acid, 2.55 creatine, 13.45 sodium phosphate, Na^2HPO^4 , 3.66 water given off at 100° , and 0.575 insoluble residue (= 99.285); they appear also to contain a little xanthine. From this composition it is evident that these excrements consist of the urine of the animal. It is not known what becomes of the faeces, or why the urine should be free from them. The non-decomposition of the urea is due to the dryness and warmth of the climate.

The excrement of the common bat (*Rhinolophus Hipposiderus*) was collected from a locality where it had accumulated to the thickness of three inches. It was in the form of dry, small, long, granular masses, of a dark brown colour, and was obviously composed of the faeces of the animal intermingled with the decomposition-products of the urine, viz., ammonia salts. It contained not a trace of urea, and no uric or oxalic acids. The chief portion seemed to be made up of the undigested wing-cases of insects. Cold solution of soda extracted a brown humus-like body, with abundant evolution of ammonia. Dried at 100° the excrement yielded 8.25 per cent. of nitrogen, and 6.25 per cent. of ash, containing potassium, sodium, calcium, magnesium, ferric oxide, chlorine, sulphuric, silicic, and 36 per cent. of phosphoric acid.

EXCRETIN. Marcet, who discovered this body, assigned to it the formula $C^{12}H^{10}SO^4$ (ii. 614). But, according to Hinterberger (*Ann. Ch. Pharm.* clxvi. 213),

the body thus formulated is a mixture. Pure excretin contains no sulphur, and has the composition $C^{20}H^{16}O$. It is obtained by exhausting fresh excrements with boiling alcohol, and leaving the solution to stand for a week. A black precipitate then separates out, containing excretin and the salt $C^{20}H^{13}MgNO^{11}$. The filtrate is precipitated with milk of lime, and the dried precipitate treated with a hot mixture of ether and alcohol. On exposing the solution during a week to a temperature below 0° , crude excretin crystallises out in semi-globular masses consisting of yellow needles. It is purified by crystallising it repeatedly from alcohol, with addition of blood-charcoal, the temperature being kept below 0° . Bromine converts it into dibrom-excretin, $C^{20}H^{13}Br^2O$, which separates from a mixture of ether and alcohol in hard brittle crystals grouped in globular masses. A crystalline chlorine-compound could not be obtained. 100 pounds of fresh excrements yielded 8 grams of pure excretin.

EXPLOSION. The conditions which determine the explosive force of gun-powder and other detonating substances have been discussed by Berthelot (*Mém. Scientifique*, 1871, 40). He points out that, for the expression of explosive force, four data are necessary, viz. 1st. The composition of the substance. 2nd. The composition of the products of the explosion. 3rd. The quantity of heat disengaged in the reaction. 4th. The volume of gas produced.

The composition of the products of the explosion may be predicted in all cases when the substance contains sufficient oxygen to form stable, completely oxidised compounds. But if the quantity of oxygen is less than this, the nature of the products will vary with the pressure, temperature, work done, &c., and cannot be predicted: in the calculations under consideration, Berthelot adopts the simplest expressions consistent with known facts.

The quantity of heat disengaged may be experimentally determined, and if the reaction be accurately known, it may also be calculated. The maximum work that can be effected by any explosive material is proportional to the heat evolved.

The volume of gas produced may be experimentally determined, and may also be calculated, if the reaction be accurately known.

With these data the pressure produced might easily be calculated if Boyle's law held good under the conditions of the experiment, and if the specific heat of the gases remained constant; but this latter probably varies with the temperature and pressure, and is entirely unknown, whilst the laws of Boyle and Gay-Lussac are wholly inapplicable to gases under a pressure of several thousand atmospheres. As, however, it is necessary to use some comparative expression for the pressure produced by different explosive substances, the product of the volume of the gases (reduced) into the quantity of heat in units is employed for that purpose, not as being an exact measure of the true pressure, but as being obtained from two characteristic and experimental elements.

To gain a complete notion of the reactions occurring at the explosion, it is necessary to bear in mind the phenomena of dissociation, according to which, the products found after cooling do not exist at the high temperature produced by the explosion, but are replaced by more simple compounds. Hence it follows that the quantity of heat corresponding with the actual reactions is less than the quantity calculated from the products found after cooling.

Under the enormous pressure produced by the explosion, it is probable that the pressure varies much more rapidly with the temperature than is admitted by Boyle's law, and as the combinations of elements, other conditions being the same, advance in complexity with the pressure, as shown by Berthelot's experiments on the decomposition of acetylene at various pressures by the electric spark (*Ann. Ch. Phys.* [4], xviii. 196), it will be seen that considerable modifications of the phenomena of dissociation must ensue. This increased influence of pressure may, therefore, be supposed to compensate the decomposing influence of heat.

The phenomena of dissociation doubtless appear at the very commencement of the expansion of the gases; for as the gas expands, it cools, and its elements re-arrange themselves in more complicated compounds; this produces a fresh disengagement of heat, and this action continues during the whole time of expansion. The actual pressure will, therefore, always be higher than the pressure calculated from the quantity of heat disengaged at the moment of maximum temperature, and at first it will be lower than the pressure calculated from the results given by the calorimeter; but as the volume increases, this difference will diminish, and, finally, disappear, the reactions being gradually completed with constant disengagement of heat.

The total quantity of heat, and, consequently, the maximum work done by burning the substance in a known space may be calculated without regard to dissociation, if the final temperature and state of combination of the elements of the products are exactly known.

2nd Sup.

The following table exhibits the heat evolved in the combustion of various explosive compounds, the volume of gas produced, and the product of these two numbers:—

	Quantity of heat evolved by 1 kilo, in units	Volume of gas formed	Product of these two numbers, to serve as a term of comparison of the pressures produced
		cub. cent.	
Sporting powder	644000	0·216	139000

" with nitre	957000	0·337	323000
Picrate with potassium chlorate	1405000	0·337	474000

Ordinary Gunpowder.—On comparing the actual products of the explosion with the results of the theoretical equation, $2\text{NO}^*\text{K} + \text{S} + 3\text{C} = 3\text{CO}^2 + \text{K}^2\text{S} + \text{N}^2$, it appears that the quantity of heat developed in the theoretical reaction is much less than that actually produced: hence it may be inferred that those products are most readily produced, in the formation of which the greatest quantity of heat is evolved, the pressure, represented by 139,000, being the same.

Powder containing sodium nitrate was largely employed in excavating the Suez Canal, and with considerable economy: for experiment shows that the substitution of sodium for potassium in any definite salt occasions a nearly constant disengagement of heat. As the alkaline metal exists as a salt, both before and after the explosion, this influence is eliminated if the quantity of heat be calculated for equivalent weights of sodium and potassium salts; but, with equal weights, the volume of gas and the heat, consequently the total work done, will be greater in the case of sodium nitrate, the equivalent of sodium being lower than that of potassium.

Powder containing potassium chlorate.—The extreme rapidity with which this powder explodes is due to the enormous quantity of heat evolved by the explosion of the particles first ignited, to the low specific heat of the products, and the comparatively low temperatures at which the chlorate decomposes. As the products are the most simple and stable possible, being binary compounds, the progressive effects of dissociation are less marked, and the variations of pressure during the expansion of the gases are not affected by recombinations of the elements successively produced during cooling. Hence the great detonating quality of this powder. Similar remarks are applicable in a still higher degree to *chloride of nitrogen*.

Nitroglycerin combines the properties of chloride of nitrogen and ordinary gunpowder. This is explicable by considering the effects of dissociation. At the first moment the elements of water and carbon dioxide are separated; but as they recombine during expansion, fresh quantities of heat are evolved, and regulate the fall of the pressure; therefore during expansion nitroglycerin behaves as ordinary gunpowder; but the effects of dissociation are less evident, because the products are more simple, and the initial pressure is higher.

Bertholot also discusses, from the thermodynamic point of view the experiments described by Abel (*1st Suppl.* 486), on the detonation of nitroglycerin and gun-cotton. Taking the case of the explosion of nitroglycerin produced by a falling weight, Bertholot calculates that the impact of a weight of several kilos. falling through 0·5m. would raise the temperature of a mass of nitroglycerin but a fraction of a degree, if the heat were distributed equally throughout the mass; but the conversion of motion into heat is too sudden to allow of this distribution; the particles struck may therefore attain the exploding point, 190° ; a large quantity of gas is suddenly produced, and this produces a second and more violent shock on the adjacent particles before they have had time to escape, from the sphere of action. The force so developed is also

converted into heat, and in this way a continuous succession of changes is established throughout the whole mass. The violence of the initial decomposition will increase with the intensity of the first shock, and consequently the pressures produced throughout the entire series of decompositions will rise in equal proportion. Hence one and the same explosive substance will behave in different ways, according to the manner of its inflammation.

These effects are less marked in the case of loose gun-cotton, on account of the large quantity of air interspersed through its bulk. As compressed gun-cotton is less compact than nitroglycerin, it should follow that it is less easily detonated than nitroglycerin; and this is found to be the case. Nitroglycerin may be detonated by the fall of a weight from a moderate height, by a gun-cotton fuse, or by a mixture of potassium chlorate and fulminate of mercury. Gun-cotton detonates only with pure fulminate of mercury, and the best results are not obtained unless the fulminate be enclosed in a rather thick case of sheet-tin, and placed in contact with the gun-cotton, conditions which realise the greatest initial pressure. The quantity of force thus converted depends on the suddenness of the shock, and on the amount of work which it is capable of doing. These elements vary with the detonator, and Abel has found that chloride of nitrogen is not very efficacious, and that iodide of nitrogen, which explodes by the slightest friction, is incapable of exploding gun-cotton. But chloride of nitrogen develops less heat than any other compound here treated of (see table), therefore a larger quantity of it must be employed, and judging by analogies drawn from other iodine substitution-substances, iodide of nitrogen should develop less heat and work than the same weight of chlorido of nitrogen: hence its inactivity in this respect.

Dynamite is found to possess less bursting or breaking power than nitroglycerin; this is explained by the intervention of the inert material, which shares with the nitroglycerin the heat developed by the exploding shock. Thus silica and alumina have nearly the same specific heat as the gaseous products of the explosion of nitroglycerin, the volume being constant; if therefore equal weights of nitroglycerin and either of these substances be fired in a space filled by the mixture, the silica or alumina will absorb half the heat, and proportionally reduce the pressure.

On comparing nitroglycerin with gunpowder, it will be seen that if a given weight of nitro were converted into the exactly equivalent weight of nitroglycerin, it would, in a blast, develop three times as great a pressure as would be produced by the gunpowder made with the same quantity of nitro.

Gun-cotton does not, like nitroglycerin, contain sufficient oxygen for its complete combustion; the products formed on explosion are therefore highly complex. It differs from other explosive substances rather by greater initial pressure than by maximum work; and the empirical results of Piobert [*Traité d'Artillerie, partie théorique*, 196] agree with the calculated result (see table). Theory shows the desirability of causing gun-cotton to explode in the smallest possible space, as practised by Abel in compressing it.

More work may be obtained from gun-cotton by adding to it nitro or potassium chlorate; but as the combustion is then complete, the effects of dissociation during expansion of the products are less evident, and the mixture acquires greater bursting power.

Potassium picrate does not contain sufficient oxygen for its perfect combustion, and is intermediate between gun-cotton and gun-cotton mixed with nitro (see table). Mixed with potassium chlorate it should develop more force than any other solid explosive substance.

Temperature of Explosion.—The temperatures required for the detonation of various explosive compounds have been determined by Leagué and Champion (*Compt. rend.* lxxiii. 1478), with the following results:—

Priming powder for Chassepot	191
Fulminate of mercury	200
Powder formed of potassium chlorate 1 part, sulphur 1 part.	200
Abel's protoxide (paper-pulp)	205
Gun-cotton	220
Powder formed of antimony sulphide 1 part, potassium chlorate 1 part.	280
Shooting powder	283
Gunpowder	295
Picrate of mercury	} detonate at 296
Picrate of lead	
Picrate of iron	
Picrate powder for torpedoes	

Picrate musket-powder	358
Picrate gunpowder	380
Artificial saffron	315
Picric acid, picrate of magnesium, of ammonium, of potassium	336
Nitroglycerin detonates at	256-257
Inflammation of sulphur in the air	246

L. Blekrode (*Phil. Mag.* [4], xvi. 39) finds that a flame may be applied to gun-cotton which has been previously wetted with carbon sulphide, without explosion taking place. Only the latter substance takes fire immediately, the gun-cotton remaining apparently intact amidst the burning sulphide, presenting almost the aspect of a mass of snow slowly melting away. Ether, alcohol, and benzene may be employed with the same result. Blekrode regards this slow combustion, which takes place when the cotton is moistened with carbon sulphide or any other volatile liquid, as a most direct and satisfactory proof in favour of the conclusion to which Abel was led by his researches, viz., that if the gases resulting from the first action of heat on gun-cotton upon its ignition in open air, are impeded from completely enveloping the burning extremity of the gun-cotton twist, their ignition is prevented; and as it is the comparatively high temperature produced by their combustion which effects the rapid combustion of the gun-cotton, the momentary extinction of the gases, and the continuous extraction of heat by them as they escape from the point of combustion, renders it impossible for the cotton to continue to burn otherwise than in a slow and imperfect manner, undergoing a transformation similar in character to destructive distillation. A piece of phosphorus placed in the moistened mass of gun-cotton, is melted and even boils during the combustion, but does not burn, as it is prevented from coming in contact with the oxygen till all the gun-cotton has disappeared. Blekrode suggests that gun-cotton should be preserved under carbon sulphide or benzene, to obviate the danger in case of fire. Should the liquid become ignited the cotton will be only slowly destroyed.

Dependence of Explosion on Vibration.—Transmission of Explosion at a Distance.—Champion A. Pollet (*Compt. rend.* lxxv. 110) have made a series of experiments with the object of following out Abel's theory, that for the explosion of detonating compounds a certain kind of mechanical excitement is necessary, the nature of which depends on the nature of the compound itself (*1st Suppl.* 487). These experiments tend to show that, at least in certain cases, the heat and the shock of an explosion at a distance operate in producing a second explosion, only by producing a certain vibratory motion, which may also be obtained by other means.

The first experiments tried were on explosions produced by means of a previous explosion at a distance. The detonator employed was iodide of nitrogen, which was found particularly suitable for delicate experiments. A tube, at first over two meters, and afterwards seven meters long, was constructed of two lengths joined together by a paper band. Small quantities of the iodide were placed at each end, and it was found that an explosion produced at one end of the tube immediately caused the explosion of the iodide at the other end. A pith-ball pendulum suspended within the tube remained quite motionless, showing that the second explosion was not caused by the pressure of the air in the tube, due to the sudden production of gas by the first explosion. If the tubes are not joined together by the paper band, but separated by an interval of five or six millimeters, the second explosion is not produced, or can be obtained only by using a comparatively large quantity of the iodide for the first explosion.

Experiments were also tried on producing explosion by means of other kinds of excitement. Iodide of nitrogen was fastened by means of a morsel of gold-beater's skin to the strings of a double-bass. It was found, on bowing the strings, that the iodide which was placed on the two lower strings did not explode, while that placed on the string giving the highest note exploded. The lowest number of vibrations that would produce an explosion was found to be about 60* per second.

Experiments on the vibrations of metallic plates and of two small Chinese gongs yielded similar results: vibrations which gave deep sounds had no effect; but those giving the higher sounds readily produced an explosion.

The experiments above described illustrate the effect of vibrations in causing explosion of a detonator. The following show that heat, unless it is accompanied with mechanical vibrations of the proper kind, does not readily produce explosion.

Iodide of nitrogen was placed at the focus of a parabolic-mirror, and at the focus of a second similar mirror, nitroglycerin, fulminate of mercury, and gunpowder were ex-

* According to ordinary English reckoning, 30 per sec. The French count half vibrations instead of complete vibrations from one end of the range to the other, and back again.

ploded. The results showed that, to cause the explosion of the iodide of nitrogen in the other focus, as much gunpowder was required as would produce ten times the heat given out in the burning of the required quantity of nitroglycerin. The mirrors were afterwards covered with lamp-black, and then even this large quantity of powder would not cause the iodide of nitrogen to explode. On the other hand, the lamp-black covering did not in the least prevent the nitroglycerin in one focus from exploding the iodide of nitrogen in the other.

A further set of experiments was made to determine the difference between the vibratory motions excited by various detonants, and thus to account for the difference in their power of causing by means of the intervening air, the explosion of other detonants placed at a distance. For this purpose a series of sensitive flames was arranged corresponding with the complete scale of *g* major, care being taken to tune the flames exactly to the proper pitch. Small quantities of various detonants were then exploded at small distances from the flames. In the case of iodide of nitrogen and mercuric fulminate, 0.03 gram of each being exploded; the former produced no effect upon the flames, while excitement of the flames, *c, c, c, f, g*, was noticed on the explosion of the latter. This seems to show that the vibrations excited by the two explosions are very different, and that the vibrations excited by mercuric fulminate act on the flames belonging to some notes of the scale to the exclusion of others.

Secondly, exploding these bodies at a shorter distance from the flames, it was found that, while the iodide of nitrogen affected the flames corresponding with the higher notes of the scale and those only, the mercuric fulminate acted on all the flames. Two-tenths of a grain of iodide of nitrogen placed at a short distance from the flames was found to influence them all.

The above experiments seem also to indicate, from the difference observed with the same amount of the same detonant placed at different distances, that acute sounds predominate in explosions.

The flames above described were not affected by the explosion of nitroglycerin, nitroethyl, nitroerythrite or nitrodulcitol. It is probable that this negative result was due to the small range of the apparatus, and that by constructing a set of flames graver than those employed in these experiments, the upper sounds of the explosion due to these bodies might be reached (*Compt. rend.* lxxv. 712).

The transmission of detonation through the agency of tubes has lately been made the subject of an elaborate series of experiments by Abel (*Proc. Roy. Soc.* xxii. 160—171), in which the explosive agents used were less highly susceptible, and more uniform and constant in composition than iodide of nitrogen, such as gun-cotton in different mechanical conditions, dynamite, mercuric fulminate, and preparations containing the latter as an ingredient.

The following are some of the points established by these experiments:—

1. The distance to which detonation may be transmitted through the agency of a tube to a distinct mass of explosive substance is regulated by the following conditions:

(a) by the nature and the quantity of the substance employed as the initiative detonator, and by the nature of the substance to be detonated, but not by the quantity of the latter, nor by the *mechanical condition* in which it is exposed to the action of the detonator.

(b) by the relation which the *diameter* of the 'detonator,' and of the charge to be detonated, bear to that of the tube employed;

(c) by the strength of the material composing the tube, and the consequent resistance which it offers to the lateral transmission of the force developed at the instant of detonation;

(d) by the amount of force expended in overcoming the friction between the gas and the sides of the tubes, or other impediments (such as loose tufts of cotton-wool) introduced into the latter;

(e) by the degree of completeness of the channel, and by the positions assigned to the detonator and the charge to be detonated.

2. The nature (apart from strength or power to resist opening up, or disintegration) of the material composing the tube through which detonation is transmitted, generally appears to exert no important influence upon the result obtained. At any rate the differences with respect to smoothness of the interior of the tubes far outweigh those which may prove traceable to differences in the nature of the materials composing them.

In the tube experiments with gun-cotton, many instances occurred in which the mass operated upon was *exploded*, but with comparatively little, if any, destructive effect, portions of the gun-cotton being at the same time dispersed and occasionally inflamed. Similarly, the mercuric fulminate was frequently exploded, through the agency of a transmitted detonation, in a manner quite distinct from the violent detona-

tions at other times developed. Even silver fulminate which, under all ordinary circumstances, detonates violently, and even when only one particle of a mass is subjected to a sufficient disturbing influence, was on one or two occasions exploded by the transmitted effect of a detonation of mercuric fulminate without the usual destructive action.

The dilution of a liquid and of a solid explosive body by inert solid substances produces very different results on the susceptibility of the compound to detonation. If the dilution does not affect the continuity of the explosive body, as when an explosive liquid, like nitroglycerin, is diluted with an inert solid, there appears to be no loss of sensitiveness to detonation; but if the continuity of the explosive be interrupted, as happens when a solid explosive is mixed with an inert body, the susceptibility to detonation is much diminished if the mass is loose and unconfined; but by compressing the diluted explosive, or strongly confining it, detonation may be much more easily produced. Thus mixtures of gun-cotton with potassium chloride, or still better with the chlorate or nitrate of potassium compressed with addition of water and then dried, were found to be more susceptible to detonation by nitroglycerin than undiluted gun-cotton itself.

The dilution of a solid explosive by a liquid greatly reduces its sensitiveness to detonation. Damp gun-cotton can be exploded only by large charges of mercuric fulminate; it is, however, much more easily exploded by an initiative detonator of dry gun-cotton.

Gun-cotton made up into a pulp with water is not susceptible of detonation, even by dry gun-cotton, unless the escape of force be retarded at the instant of the first detonation; but if this condition be fulfilled, either by the resistance of the material of the case, or by the pressure of a considerable column of water, the detonation may be accomplished with certainty. By confining the gun-cotton lightly in sheet-tin cases or bags, or even in fishing nets, and sinking it to a sufficient depth under water, or by placing the pulp in a shell and filling up the interstices with water, the whole can be detonated with a small charge of dry gun-cotton. Remarkable results were likewise obtained by detonating small charges of compressed gun-cotton in shells filled up with water. A quarter of an ounce of compressed gun-cotton detonated in a shell filled with water, broke it up into nearly eight times the number of fragments obtained by exploding a shell of the same kind full of gunpowder (13 oz.)

Velocity of Transmission of Detonation.—A series of experiments, in which the time was measured by Noble's electric chronograph, showed that with dry compressed gun-cotton the rate of transmission is between 17,500 and 20,000 feet per second when the masses are arranged so as to touch one another. The separation of the masses retards the transmission to an extent depending on the size of the masses and the distance between them. When gun-cotton saturated with water was employed, a marked increase in the rate of transmission was observed. Nitrated gun-cotton gave a slower rate, 15,500 to 16,000 feet per second. Dynamite, in continuous masses, gave 19,500 to 21,600 feet per second; but separation of the masses reduced the rate to a greater extent than was the case with gun-cotton. Nitroglycerin, contained in V-shaped troughs, gave a velocity of only 5,500 feet per second.

New Class of Explosives.—A class of explosives which are non-explosive during manufacture and transport has lately been introduced by Dr. Sprengel (*Chem. Soc. J.* [2], xi. 796). These explosives are mixtures of a combustible and an oxidising substance which can be kept separate during transport and mixed only when required for use. The examination of a considerable number of such mixtures showed that the most effective were mixtures of nitric acid, sp. gr. 1.5, and nitro-compounds of the hydrocarbons, fired by a detonating cap. A mixture of nitrobenzene or picric acid with nitric acid explodes with the greatest violence, comparable with that of the explosion of nitroglycerin. Porous cakes of potassium chlorate saturated with a combustible liquid, such as carbon sulphide or nitrobenzene, were found to be five times as effective in open granite quarries as an equal weight of gunpowder.

Experiments on the composition and tension of the products of combustion of gunpowder, when fired in a closed vessel, and in the bore of a gun, have lately been published by Captain Noble and Mr. Abel (*Proc. Roy. Soc.* liii, 1874). See GUNPOWDER.

F.

FAHL-ORE. The separation of copper-pyrites and copper-glance from the fahl-ore of Wohlfach has been observed by F. Sandberger (*Jahrb. f. Mineralogie*, 1869, 301), who shows by calculation how this fahl-ore yields, in addition to the two minerals just mentioned, zinc-blende, brittle silver ore, and stibnite, which also occur at Wohlfach in a manner indicating the probability of their formation from the fahl-ore. The weathering of this same fahl-ore yields antimony-bloom coloured yellow by stibnite, besides a brown-red mass not yet examined.

Bismuth fahl-ore.—Analyses of two specimens of this mineral have been published by Petersen (*Jahrb. f. Mineralogie*, 1870, 464, 590): A. From Neubulach in the Württemberg Schwarzwald, in crude lumps intimately intergrown with the quartz gangue, and only once found crystallised in the form $\frac{O}{2} \cdot \frac{2O_2}{2} \cdot \infty O$; sp. gr. = 4.908; analysed

by R. Senfter. B. Occurring with heavy spar and quartz at Cromez in the Emmenthal (Val d'Auniviers) in the canton Wallis; analysed by Brauns, who names it *Rönite*. The quantities of the metals found by analysis require only 25.13 p.c. sulphur. Petersen found 26.67 p.c., which he regards as too high, because copper pyrites is mixed with the mineral too intimately to allow of complete separation. Petersen is therefore inclined to refer the analysis to the general formula $3RS.RS^3$, which he regards as the typical formula of the fahl-ores:—

	S	As	Sh	H	Cu	Ag	Pb	Zn	Fe	Co	Ni	
A.	24.85	13.63	4.28	6.33	41.13	trace	1.52	3.82	3.74	trace	trace	= 99.50.
B.	29.10	11.44	2.19	13.07	37.52	0.01	—	—	6.51	1.20	—	= 101.07.

FAT. *The Storing up of Fat in the Animal Organism.*—Experiments have been made by F. Hofmann (*Zeitschr. f. Biologie*, viii. 153) to determine in what way fat becomes deposited in the body, whether it is derived directly from the fatty elements of the food, or whether, as Toldt and Subbotin hold, it is derived from the splitting up of albuminoids; or whether, according to the views of Radziejewski, all fats must be first saponified, and again undergo synthesis into neutral fat in the organism. To this latter conclusion Radziejewski was led by his experiments on the feeding of animals with fats which do not normally exist in the body. Hofmann, however, is of opinion that Radziejewski's conclusions are much wider than his premises, as his experiments merely prove that foreign fats are not stored up. The same is shown by Subbotin's experiments with spermaceti.

Hofmann's method consisted in starving dogs till all the body-fat was used up, and then feeding them with large quantities of fat, mixed with as small a proportion as possible of lean meat. After a few days the animals were killed, and the whole quantity of fat in the body determined. The fat found was regarded first as that derived from albuminoids. If the quantity found is not greater than might possibly be derived from albuminoids, it is considered that all the fat of the food has been burnt and none deposited. If, on the other hand, a larger proportion of fat is found than can be accounted for in this way, it can only have come from the food. This would not, however, decide the question whether the fat was stored up in the cells, for it might exist in the blood. If, however, not more than usual is found in the blood, and an amount corresponding with the quantity absorbed is found, this quantity may be considered as fat really deposited in the tissues of the body.

The first point to determine was when the whole of the fat of the body had been used up by the process of starvation. Considerable differences in time are observed, according as the animal has or has not a large store of albuminoids, as well as fat, in its system. In general it is found that the fat of the body is almost entirely absorbed when the excretion of urea suddenly becomes greatly increased after a long period of starvation. This indicates that the wants of the organism require the combustion of a large amount of nitrogenous constituents to make up for the fat which has now disappeared.

A dog so starved was found capable of assimilating considerable quantities of fat when mixed with a small proportion of flesh. At the end of a few days, however, dyspeptic symptoms appeared, and almost pure fat was passed as excrement. This was attributed to the fatty condition of the liver which was induced. The animal in five days increased in weight more than 21 p.c. of its weight on the last day of starvation. This increase was shown not to be due to water alone, or to the small

amount of lean meat of the food. Analysis of the blood likewise proved that this did not contain more than the usual proportion of fat.

The whole amount of fat in the body was determined by thoroughly mincing the whole animal, and reducing all its tissues to a uniform mass. Fractional analysis of this mass gave uniform results, and allowed of easy estimation of the whole fat in the body.

The results show that in five days a dog had absorbed 1854.0 grams of fat. If 130.7 grams be taken as the amount derived from albuminoids, a total of 1984.7 grams represents what was used by the organism. The quantity found in the body by analysis was 1352.7 grams, giving 632.0 grams as the quantity which had undergone combustion. These figures show that a very large amount of fat may be absorbed from the food and deposited in the tissues. The deposit takes place principally in the liver and mesentery.

Hofmann questions whether it will be possible by the above method to determine whether fatty acids may undergo synthesis into fat, as it is impossible to give large quantities of soaps to animals without inducing serious derangement of the alimentary canal.

That fats are deposited in the organism, and not all burnt off, is also shown by the experiments of Pettenkofer and Voit, which prove that the amount of carbon given off by an animal receiving a large proportion of fat in its food is far below what would be required to cover the amount of fat consumed.

Extraction and Purification of Fats.—The following process is described by H. Pohl (*Dingl. polyt. J. sci.* 254):—

The fresh raw fat, freed as far as possible from fleshy matters, is cut into thin slices and washed free from blood, &c. with pure cold water. The washed fat is then placed in a cylindrical stoneware vessel about 4 feet high and 18 inches wide, standing in a water-bath which can be heated by steam. A cock of wood or stoneware at the bottom of this vessel enables it to be emptied without removal from the water-bath. After the cylinder has been three-fourths filled, a kind of sieve of stoneware is laid on the surface of the fat; 10 per cent. of pure highly diluted hydrochloric acid is added (3 lbs. acid of sp. gr. 1.12 to 100 lbs. water), and a well-fitting cover of stoneware is laid over the top. On warming, as the fat melts in the cells, the acid dissolves the membranous portions, and the sieve gradually sinks to the lower part of the cylinder, carrying with it the skinny matters and unmelted fat, while the pure melted portion collects in the upper part of the vessel. When all the fat is melted, the dilute acid solution is run off at the bottom, and the fat is washed two or three times with boiling water, to the last portion of which a little magnesium carbonate is added to ensure perfect naturalisation.

The washed fat is dissolved in an equal volume of Canadian oil, which separates a nitrogenous matter. The solvent is then recovered by distillation. The resulting fat is scentless and tasteless, almost colourless, and absolutely neutral. It contains no trace of water or of nitrogenous matter, and therefore remains free from all tendency to become rancid when kept.

The rancid odour which fats often acquire by keeping, arises from the presence of volatile fatty acids and other volatile products, which do not exist in the fresh fat, but are produced by decomposition. These substances may be removed by heating the fat to a certain temperature. According to Dubrunfaut (*Compt. rend.* lxxi. 37) fish-oils are entirely deprived of their odorous principle by simply heating them to 330°, and fatty acids distil over with steam when heated above 100°, whereas neutral fats are fixed under these conditions, but behave like the fatty acids when submitted to a current of steam at 300°–330°. When fat is melted in a frying-pan at 140°–150° and then cautiously sprinkled with water, the steam thus evolved carries off with it all the offensive matters, and leaves the fat sweet.

Saponification.—A method of saponification was described some years ago by Mège-Mouriès (*Compt. rend.* lviii. 864), depending on the property of fats in the state of emulsion (*état globulaire*) to take up soda-ley containing sodium chloride without dissolving in it. Melted tallow is brought into this state by heating it to 45° with a 5 to 10 per cent. of aqueous soap-solution; and if soda-ley containing common salt be then added, and the action promoted by assiduous mixing, the tallow is completely saponified at the same temperature in a few hours (2,000 kilo. in three hours). At a somewhat higher temperature, a little above 60° C. (140° F.), the globules of soap thus formed unite into a semi-fluid transparent layer, which floats on the salt-liquor containing glycerin; and by decomposing this layer with the exact quantity of dilute sulphuric acid required, and pressing the mixture of fatty acids thereby separated, stearic acid melting at 58°–59° is obtained, together with nearly colourless oleic acid. The process is said by its inventor to be recommended by the rapidity of the operation.

the beauty of the products, and the avoidance of loss (the product of fatty acids amounting to 96-97 p.c. of the calculated quantity). According to De Milly, on the other hand (*Dingl. polyt. J.* clxxvi. 145), this method of saponification is less advantageous than that commonly practised, being more costly and not yielding any glycerin. Legrand also (*ibid.* 151) finds it disadvantageous, at least for the manufacture of soaps, chiefly on account of imperfect combination of the fatty acids, and the consequent too great solubility and want of durability of the soap.

F. Knapp (*Dingl. polyt. J.* clxxx. 309) has obtained the following results in accordance with those of Mège-Mouriès. When melted tallow is triturated in a mortar with starch-paste and water, a uniform mobile emulsion is formed, from which on standing the tallow separates on the surface as a creamy layer. On freeing it from adhering starch-paste by agitation with water, the milky mixture appears under the microscope as an aggregate of very small, globular, transparent bodies, with somewhat ragged surface and having usually a diameter not exceeding that of the starch-granules of leguminous fruits. Tallow in the form of this emulsion is quite permanent. When diffused in soda-ley, either concentrated or dilute (3 p.c.), it forms in a few hours at 45°-60°, in a somewhat longer time at ordinary temperatures, a coherent floating layer of soap, small quantities of unsaponified fat remaining however enclosed in it. Microscopic examination shows that a rapid interchange of constituents is going on between each individual globule of tallow and the surrounding ley, and that the attack of the ley, even when it is rather concentrated and therefore forms a soapy envelope round each granule of tallow, nevertheless penetrates by diffusion into its interior. The easy and rapid saponification of fats in the utricular state depends therefore on their microscopic division; it takes place in the same manner in ethereal solutions, and instantly in liquids containing fat, alkaline-ley, and soap uniformly dissolved, or when the base employed forms, not a gelatinous, but a pulverulent or flocculent soap. In the ordinary soap-boiler's process, the fat is likewise emulsified at the beginning, and almost completely saponified by prolonged contact in the cold with the alkaline-ley; and if the saponification afterwards proceeds but slowly when heat is applied, this arises from the circumstance that the soapy envelopes melt the individual fatty globules, and thus destroy the minute division of the fat. The further action is then brought about chiefly by the solubility of the fats in the hot soap already formed. It appears therefore advantageous in all cases that the fat emulsified by the alkaline ley should first be left to itself for some time at a moderate heat.

Further experiments by Knapp (*Dingl. polyt. J.* xcii. 198) have led to the following results: The soap produced from emulsified fats by digestion in the cold, separates on the surface of the liquid in the form of a cake, which, according to the strength of the ley employed, is sometimes lurd and brittle, sometimes soft and more or less hydrated. After repeated rinsing the cakes do not dissolve completely in boiling distilled water, but a few drops of the alkaline-ley suffice to render the turbid boiling liquid perfectly clear. Cakes prepared from tallow dissolve completely in warm strong alcohol, after the subjacent liquid has been saturated with carbonic acid, with exception of a residue of sodium carbonate. The filtered and evaporated soap-solution gives, on decomposition with sulphuric acid, a quantity of sodium sulphate equivalent to 11 p.c. of anhydrous sodium oxide, that is to say, an amount not differing much from that of ordinary soap, showing that the saponification is complete. In carrying out the process on the large scale, it would be necessary, after removing the excess of ley, to dissolve the soap-cake at the boiling heat, without previously rinsing it, so as to obtain a clear solution at once. For the preparation of the emulsion, mucilaginous substances, such as gum, would be too costly; soap is better adapted for the purpose, but the change is most advantageously effected by means of the caustic ley which serves for the saponification. It must be diluted with very pure water, which may be added to it in any quantity without producing turbidity, whereas water containing common salt, acids, &c., immediately causes the separation of white flocks which rise to the surface like a thick cream. Excess of ley must especially be avoided, as it drives the fat immediately to the surface. In saponifying solid fats, the containing vessel and the water must of course be raised to the melting points of the fats.

Fat of Seeds and Fodder.—The quantity and elementary composition of the fat of various seeds, and of hay, straw, &c., has been determined by J. König (*Landwirtschaftliche Versuchs-Stationen*, xiii. 241). The fat was extracted by ether, and in the case of drying oils which oxidise quickly, both the seed and the ethereal extract were dried in a stream of hydrogen. The ethereal extracts, except in the case of the oil-seeds, were freed from chlorophyll by means of animal charcoal. This treatment involves a slight loss, as the charcoal obstinately retains a small quantity of fat:—

TABLE A. *Quantity of Fat in Seeds, &c.* (König.)

	Fat per cent. in fresh substance	Fat per cent. in dry substance		Fat per cent. in fresh substance	Fat per cent. in dry substance
Linseed	31·94	35·21	Rye	1·35	1·44
Rape seed	41·90	45·49	Wheat	1·14	1·23
Hemp seed	32·37	35·25	Oats	4·04	4·53
Poppy seed	40·07	43·39	Barley	1·51	1·59
Beech-nut	23·08	28·18	Maize	4·47	4·85
Palm-nut kernel . .	48·07	52·85	Lupino	5·20	6·10
Earth-nut	51·51	55·25	Peas	·81	·93
White sesame . . .	49·31	52·50	Beans	·83	·96
Black sesame . . .	46·02	49·28	Grass hay	1·39	1·52
Cocoa-nut	64·48	67·76	Clover hay	1·43	1·61
Madia seed	37·32	40·44	Rye straw	·76	·83
Cotton seed	19·49	21·72	Oat straw	·81	·88

The fat obtained from the purified ethereal extract is, in the case of hay, a mixture of fat and wax. These may be separated with tolerable accuracy by dissolving the crude fat in hot absolute alcohol, the wax then separating on cooling; it is washed with cold alcohol, and weighed. Among the seeds examined, rye alone contained an appreciable amount of wax. Dry fodder gave the following percentages of fat and wax:—

TABLE B. (König.)

	Fat	Wax		Fat	Wax
Meadow hay (mean of five samples)	1·07	·45	Rye straw . . .	·52	·31
Clover hay	1·23	·38	Oat straw . . .	·55	·33
			Rye grain . . .	1·35	·09

The elementary composition of the various fats was determined from fats purified by treating their ethereal solution with animal charcoal. The lupine fat was further treated with hydrochloric acid, and again exhausted with ether, to separate the alkaloid which it contains. In table C (page 507), the fluid or solid nature of the fat is indicated by the letters *f* and *s*.

The percentage composition of the various fats agrees in most cases with that of a mixture of the three glycerides:—

Triolein	77·38 carbon.	11·76 hydrogen.	10·86 oxygen.
Tristearin	76·85 „	12·36 „	10·79 „
Tripalmitin	75·93 „	12·16 „	11·91 „

Rape oil gives an unusually high proportion of carbon; this arises from its containing the glyceride of brassic acid. Earth-nut fat apparently contains fatty acids low in the series, as the fats known to be present, namely, palmitin, arachin, and hypogæin, have all more carbon than was found on analysis. Palm-nut kernel fat is probably rich in some of the lower fatty acids, as indeed is suggested by its odour. Cocoa-nut fat is known to contain the glycerides of capric, caprylic, and caproic acids; the presence of these accounts for the low amount of carbon found. The specimens of oat, maize, and lupine oil had become somewhat oxidised by exposure to air. The oil of maize is apparently a drying oil.

The fats of the seeds of oats, rye, tares, and linseed, have been further examined by König, Kiesow & Aronheim (*Landw. Versuchs-Stationen*, xvii. 1). The fats were saponified with lead oxide to remove glycerin, &c.; the watery extract was evaporated; the lead plaster treated with ether to remove lead oleate; and the residual lead salts were decomposed with acid and extracted with ether to obtain the solid acids. By this treatment 100 parts of the several fats were found to yield:—

	Oats	Rye	Tares	Linseed
Oleic acid	60·5	91·6	96·31	102·8
Solid acids	36·7	8·1	2·11	·2
Soluble in water, glycerin, &c. . . .	2·8	1·3	1·6	

TABLE C. *Elementary Composition of Vegetable Fats.* (König.)

Consistence of fat	Source of fat	C.	H.	O.	Consistence of fat	Source of fat	C.	H.	O.

No glycerin could be detected in the first three fats, and the quantity of solid acids in linseed oil was but small. The elementary composition and melting point of the solid acid indicated in each case a mixture of palmitic and stearic acids. The acids in the fat of oats, rye, and tares, must be present almost entirely in the free state, a small portion being probably combined with cholesterin; and linseed oil must contain a considerable proportion of free acid, as 5.2 p.c. glycerin is equivalent to only 42.7 p.c. of linoleic acid, if present as trilinoleate.

The fat of meadow hay extracted by ether may be separated by cold alcohol into a fluid soluble portion, and a solid waxy matter which is insoluble. Both these fats saponify in great part when treated with alcoholic potash; and the resulting soaps decomposed in the usual way, yield cerotic, palmitic, and oleic acids.

The unsaponified portion of the waxy matter heated with benzoic acid to 200° in a sealed tube for several hours, is resolved into a hydrocarbon and the benzoic ethers of several fatty alcohols, viz. ceryl alcohol ($C^{27}H^{56}O$), an alcohol of the same species, probably $C^{25}H^{52}O$, cholesterolin ($C^{26}H^{54}O$), and a fluid alcohol $C^{22}H^{46}O$, which forms with benzoic acid an ether liquid at ordinary temperatures and easily soluble in absolute alcohol; the fluid alcohol is readily oxidised by chromic acid mixture to acetic acid and an acid which melts at 20° and contains 73.57 p.c. carbon and 12.41 hydrogen. The hydrocarbon gave by analysis 84.96 p.c. carbon and 15.28 p.c. hydrogen, agreeing most nearly with the formula, $C^{20}H^{42}$, but not improbably consisting of cerotic $C^{27}H^{54}$.

The fat of oat straw contains the same acids as that of hay. The portion soluble in alcohol contains the same fluid and solid alcohols as hay-fat but not the hydrocarbon (König u. Kiesow, *Landw. Versuchs-St.* xvi. 47; *Deut. Chem. Ges. Ber.* vi. 500, König, Kiesow u. Aronheim, *loc. cit.*)

On the Digestibility of the Fat of Meadow Hay, see E. Schulze (*Landw. Versuchs-St.* xv. 81; xvi. 329; *Chem. Soc. J.* [2], x. 1037; xii. 85).

On the Influence of the Addition of Fat to the Food on its Digestibility, see Hofmeister (*Landw. Versuchs-St.* xvi. 347; *Chem. Soc. J.* [2], xii. 83).

FATTY ACIDS. *Occurrence in Wood Vinegar.*—According to Barré (*Compt. rend.* lxxviii. 1222), the crude acid obtained by the dry distillation of wood, contains, besides acetic acid, small quantities of formic and larger quantities of propionic,

butyric, valeric and caproic acids, these latter separating as an oily layer on adding sulphuric acid to the difficultly crystallisable mother-liquor of the sodium acetate.

In *Hungarian Fusel-oil*.—A sample of wine fusel-oil from Pesth having a dark hock colour and a strong nauseous odour, when freed by distillation from water, ethyl alcohol and amyl alcohol, left an acid residuo (a little more than half the original liquid) which was found to contain capric acid together with a little caprylic and perhaps ceananthylic acid; no pelargonic acid (Grimm. *Ann. Ch. Pharm.* clvii. 264).

For the mode of separation see CAPRIC ACID (p. 249). The same acids were found by Fischer in crude ceananthic ether (iv. 174). Capric acid has also been found by Rowney in the fusel-oil of the Scotch distilleries (ii. 753).

Preparation from the Soapy Waters obtained in the washing of Wool.—These wash-waters are acidulated with sulphuric acid—on the average 50 lbs. sulphuric acid of 66° Bm. to 7,000 litres of liquid. The separation of the fatty acids is facilitated by warming. The fatty mud thus obtained, containing on the average 400 lbs. of solid matter to 7,000 litres of water, is pressed after draining off the water, first while cold then when hot. The quantity of fat thus expressed amounts to only 100 lbs. to 7,000 litres of water, while 200 lbs. of the mud remains as press-cake. The fat is clarified by boiling with dilute sulphuric acid and subsequent washing with water, and bleached by treatment with potassium chlorate or with potassium chromate and sulphuric acid. The mixed product of solid and liquid fat may be used as such for soap-making; or it may be separated, by slow cooling after fusion, into the solid and liquid portion, and the two used separately for lubrication, soap-making, &c. The press-cake still contains 34.74 p.c. fat and 22.37 p.c. of other organic substances; it is said to be applicable chiefly for gas-making (Märker u. Schulze, *Dingt. polyt. J.* excv. 173).

Preparation of solid fatty acids without distillation.—Solid fatty acids may be prepared in a short time without distillation, by treating neutral fats with 2 p.c. of sulphuric acid. The black mass thereby formed is soluble in oleic acid and may be separated, together with this latter, by pressure. If the fatty substances be mixed with water, the addition of the acids produces at first a slight coloration which afterwards disappears; and if the addition of acid be continued till the colour becomes permanent, a solid perfectly white mass separates, from which the acid may be separated by decantation. Further addition of acid and heating converts this solid mass into charcoal, no longer soluble in the fatty bodies, which melt and float on the water (Bouis, *Deut. Chem. Ges. Ber.* ii. 79).

FELSPAR. *Orthoclase and Albite*.—The following analyses of these minerals from the granites of Scotland are given by S. Haughton (*Phil. Mag.* xl. 59). a.-d. *Orthoclase*; a. From Stirling Hill, Peterhead: sharp opaque flesh-coloured crystals with a coating of albite. b. From Rubislaw, Aberdeen: flesh-coloured opaque crystals associated with white mica, from a granite not containing albite, which in contradistinction to the eruptive granite of Stirling Hill, is designated as 'metamorphic.' c. Peterculter, Aberdeen: large white transparent crystals from 'metamorphic' granite. d. Callernish on the west coast of Lewis: large grey crystals with a tinge of flesh-colour from metamorphic granite. e. *Albite*: clearly translucent, spotted on the surface with ferric oxide; occurs as a coating on the orthoclase a.

Albite and Orthoclase from Harzburg. (A. Streng, *Jahrbuch f. Mineralogie*, 1871. 715.)—These two minerals occur in the graphic granite of the Radautal, near Harzburg. The albite is found—1. Crystallised in druses, mostly implanted on orthoclase in parallel rows. 2. Imbedded in the orthoclase in distinct layers, partly parallel to αP , partly to $\alpha P\infty$. 3. Intergrown with orthoclase in lamellæ, recognisable only by the microscope, the lamellæ being partly parallel to $\alpha P\infty$, partly to $(\alpha P\infty)$. 4. As an independent constituent of the graphic granite, but in this case also intergrown with small quantities of orthoclase. Thin slices of both minerals, when examined by the microscope, are seen to be interspersed with very minute, blue or greyish-blue, granular, and extremely thin brown-red lamellæ of some foreign mineral or minerals. The lamellæ probably consist of iron-glance or mica.

The albite crystals are mostly twins, having their axis of combination perpendicular to the brachypinacoid $\alpha P\infty$, very rarely parallel to the principal axis. Simple crystals are, however, also found, not exhibiting any re-entering or projecting

edges. The crystals are mostly combinations of the faces $\infty P'$, ∞P , ∞P_3 , ∞P_3 , ∞P , ∞P , ∞P (occurring as a truncation of the acute edge of P' : ∞P), P , ∞P , ∞P , and P .

The faces ∞P and ∞P are mostly predominant, the prismatic faces subordinate, sometimes, however, equally developed with the other faces. The eight prismatic faces are never present altogether. The crystals are white to colourless, have a strong lustre, and are translucent to transparent. Sp. gr. = 2.600 at 12°.

The analysis of this albite showed that it is a mixture 20 mol. pure albite (sodic feldspar), and 1 mol. anorthite (calcic feldspar), or 94.85 p.c. albite and 5.15 anorthite.

	Calc.	Found	Or:		Calc.	Found
SiO ₂	67.40	67.75		Si	31.69	31.86
AlPO ₃	20.43	18.42		Al	10.92	9.85
Fe ₂ O ₃	—	2.08		Fe	—	1.52
CaO	1.03	0.92		Ca	0.74	0.66
MgO	—	0.14		Mg	—	0.08
K ₂ O	—	0.38		K	—	0.32
Na ₂ O	11.14	11.81		Na	8.26	8.76
	100.00	100.00				

The orthoclase occurs in drusy cavities of the graphic granite, in crystals from 1 to 2 inches long, and of simple form, exhibiting mostly only the prismatic face ∞P and the three pinacoids. P is rarely visible. The mineral is greyish white, opaque, and dull. Analysis gave—

	SiO ₂	AlPO ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	
Or,	65.21	20.40	1.04	0.55	0.06	9.27	4.77	= 101.40
	Si	Al	Fe	Ca	Mg	K	Na	O
	30.66	10.91	0.81	0.39	0.04	7.78	3.51	47.37 = 101.40.

These numbers give—

$$R^2R^3 : R^1 : Si = 1 : 1.15 : 5.84,$$

showing that the orthoclase in question is very impure, since for pure orthoclase the ratio is 1 : 1 : 6. If the impurities be regarded as iron-glance, and the iron be accordingly left out, the ratio becomes 1 : 1.07 : 5.84, which does not differ much from that of pure orthoclase. The ratio of the alkalis and alkaline earths shows that the mineral is a mixture of about 6 molecules of pure orthoclase with 5 molecules of a sodio-calcic feldspar containing but a small proportion of calcium.

The mineral from the augitic granite of the Radanthal described by Fuchs (*Leont. Jahrb.* 1862, 789) as oligoclase, and containing 65.83 p.c. SiO₂, 20.46 AlPO₃ with a trace of Fe₂O₃, 0.71 CaO with trace of MgO, 6.94 K₂O, and 5.89 Na₂O, appears rather to be an albite rich in potash, since the proportion of lime is much too small for oligoclase.

Orthoclase from Elba, in which G. vom Rath found 3.40 p.c. Na₂O to 11.93 K₂O, was also found by Streng, on microscopic examination, to be intersected by lamellæ and small crystals of albite.

The following orthoclases and mixed orthoclasic felspars have been described and analysed by G. vom Rath (*Jahrb. f. Mineralogie*, 1870, 890; *Pogg. Ann.* cxliv. 375, 594).

(1). *White or Yellowish Orthoclase from S. Piero in Elba*.—Characteristic forms: ∞P . ∞P . ∞P_3 . and $\frac{1}{2}P$. The crystals are mostly simple, but twins likewise occur. Interposed laminae of albite give the crystals the appearance of perthite, and produce peculiar phenomena of weathering, resulting in a corroded appearance. Selected material was used for analysis since the orthoclase is usually intergrown with quartz in the manner of graphic granite. Sp. gr. = 2.540; after ignition (loss 0.39 p.c.), 2.515; after repeated ignition at a higher temperature, 2.506.

SiO ₂	AlPO ₃	K ₂ O	Na ₂ O
64.64	19.40	11.95	3.40 = 99.39

This felspar was found by Streng (*loc. cit.*), on microscopic examination, to be intersected with lamellæ and small crystals of albite.

(2). *Orthoclase from Bolton in Massachusetts*.—This mineral is accompanied by large crystals of green augite and brown titanite. The surface of the crystal is rough, drusy, and of a yellowish colour, the interior pure white, semi-transparent. The

cleavage faces OP and $(\infty P\infty)$ are slightly curved, but without any trace of twinning or albite lamellæ; colour and lustre similar to those of adularia. Sp. gr. 2.586. Loss by ignition 0.05 p.c.

A very similar feldspar, accompanied by fine crystals of augite, scapolite, and titanite, is found in the neighbourhood of Diana, Lewis City, New Jersey.

(3). *From Pargas in Finland*, also accompanied by augite. The crystals are sometimes 2 centimeters long, but mostly much smaller. They are white, and covered with a dull white crust of milky aspect. The edges are rounded. Sp. gr. 2.576. Loss by ignition 0.13 p.c.

	SiO_2	Al_2O_3	CaO	MgO	K_2O	Na_2O
(1). . .	64.64	19.40	—	—	11.95	3.40 = 99.39
(2). . .	65.23	19.26	0.42	—	11.80	2.98 = 99.69
(3). . .	64.96	19.40	0.49	0.25	12.80	2.32 = 100.22

All three analyses agree nearly with the composition of an orthoclase containing 3 at. K to 1 at. Na (or a mixture of 3 mol. potash feldspar to 1 mol. albite), which requires 65.58 SiO_2 , 18.73 Al_2O_3 , 12.87 K_2O , and 2.82 Na_2O .

The two following orthoclasic feldspars exhibit abnormal composition, and should perhaps be regarded as mixtures of orthoclase, albite, and anorthite.

(4). *Feldspar from the Syenite of Laurvig.*—This mineral is the principal constituent of the remarkable rock which extends along the coast of Norway from the Langesund fjord to the Christiania fjord. The crystals are bluish to brownish grey, and exhibit a composite structure. A thin section parallel to OP appears, even by ordinary light, as an intimate combination of curved lamellæ, exactly like the intergrowth of orthoclase and albite exhibited in perthite. In polarised light this striation of the surface is much more evident, the lamellæ which are inserted nearly parallel to the orthopinacoid exhibiting a variety of brilliant colours. Sp. gr. 2.619. Loss by ignition 0.31. Analysis gave numbers agreeing approximately with a mixture of 1 mol. orthoclase, 3 mol. albite, and 2 mol. anorthite:—

	SiO_2	Al_2O_3	CaO	MgO	K_2O	Na_2O
Analysis . . .	62.81	23.21	2.60	0.07	4.23	7.54 = 100.46
Calculation . .	62.48	22.94	4.16	—	3.50	6.92 = 100

(5). *Feldspar from the Syenite of Monte Monzoni* (Toul, near Rizzoni), Fassa. — This feldspar forms the predominating constituent of the beautiful coarse-grained syenite which in some places may be regarded as of more or less pure feldspathic constitution. The light-grey feldspar occurs in grains $\frac{1}{2}$ to 2 centimeters in diameter, together with small quantities of black hornblende and a very few small granules of titanite. Microscopic examination in polarised light showed that this feldspar also contained a quantity of small grains of plagioclase imbedded in its substance. No striation was, however, visible, the granules of plagioclase being merely intergrown with the orthoclase in parallel directions, but otherwise irregularly. Sp. gr. 2.665. Loss by ignition 0.89 p.c. (the mineral splits when ignited).

Analysis gave the following numbers, agreeing closely with the composition of a mixture of 5 mol. orthoclase, 4 mol. albite, and 2 mol. anorthite:—

	SiO_2	Al_2O_3	CaO	K_2O	Na_2O
Analysis . . .	63.36	21.18	1.66	8.89	4.91 = 100
Calculation . .	63.96	20.78	2.06	8.65	4.55 = 100

The somewhat considerable quantity of lime is accompanied, as in the Laurvig feldspar, by an increase in the proportion of alumina and a decrease in that of the silica, which is in accordance with the supposition that the plagioclase mixed with these feldspars is a mixture of albite and anorthite. Other orthoclasic feldspars, loxoclase for example, containing lime with a large proportion of soda, are probably constituted in a similar manner.

Triclinic (sodio-calcic) Feldspars.—These feldspars, viz., albite, oligoclase, andesine, labradorite, and anorthite, form an isomorphous group, the end-terms of which are albite and anorthite, the former being a pure soda-feldspar, the latter a pure lime-feldspar, whilst the others are isomorphous mixtures of these two, approximating in physical properties and chemical composition to the one or the other according as the soda or the lime predominates. This view, first suggested by Sartorius v. Waltershausen (*Ueber die vulkanischen Gesteine in Sicilien u. Island*, 1853), and further developed by Tschermak (*Wien. Akad. Ber.* 7 [1 abth.], 566; *Jahresb.*, 1865, 888), has lately been corroborated by the observations of Streng (*Jahrb. f. Mineralogie*, 1871, 598 and 715) and of G. vom Rath (*Pogg. Ann.* cxliv. 210).

Streng observes that the composition of albite and anorthite may be represented as follows:—

the atomic group CaAl in anorthite being equivalent to the group NaAl in albite, and the second group CaAl in the former to Si^2 in the latter.

The formulæ of the two minerals may also be written as follows:—

The general formula of a sodio-calcic feldspar may then be written in the form $\text{Na}^{2n}\text{Si}^{2n}\text{Ca}^{2-2n}\text{Al}^{1-n}\text{AlSi}^{\text{iv}}\text{O}^{16}$, in which n is a fraction intermediate between 0 and 1, whose denominator shows the number of molecules of albite which are present in the number of molecules of any other triclinic feldspar denoted by the numerator.

These formulæ must not be looked upon as constitutional formulæ, but merely as indicating that equivalent groups Ca^2Al , Na^2Si^2 , play an analogous part in the two compounds. Analysis shows indeed—and this is the chief chemical argument in favour of the theory—that an increase in the proportion of lime in a sodio-calcic feldspar is attended with an increase of the alumina and a decrease of the silica, while, on the other hand, an increased proportion of soda is attended with a diminution of the alumina and an increase of the silica; also that a definite proportion of lime to soda corresponds in all cases with a definite amount of silica.

The crystallographic differences between the three most important members of the series of sodio-calcic feldspars, viz., albite, oligoclase, and anorthite, are shown in the following table, in which

c denotes the principal axis	} in the right upper octant.
A the inclination of the axial planes ab, ac	
B " " " ab, bc	
C " " " ac, bc	
α the angle between the axes b, c	
β " " " a, c	
γ " " " a, b	

$a : b : c$	A	B	C	α	β	γ
<i>Albite.</i>						
0.6284 : 1 : 0.5556	93°36'	116°18'	89°18'	94°22'	116°24'	87°26'
<i>Oligoclase from Vesuvius.</i>						
0.6322 : 1 : 0.5525	93°28'	116°13'	91°36½'	93°4½'	116°23'	90°4'
<i>Anorthite.</i>						
0.6341 : 1 : 0.5501	94°10'	116°3'	92°34'	93°13'	115°55½'	91°12'

The values of A and B , as also those of α and β , are nearly the same in the three minerals, the chief differences lying in the values of C and γ . These differences, however are not greater than those exhibited by many other isomorphous substances which are capable of crystallising together. It must be observed also that the magnitudes of the angles, and therefore also the ratios of the axes, are not constant, even for one and the same crystal, but vary with the temperature, and that bodies are comparable with one another, as regards their physical properties, not at the same temperatures, but at temperatures equally distant from their melting points, which differ greatly for the different feldspars. When a triclinic crystal is heated, not only the angles of the faces, but likewise their parametric relations, are altered, as also the angles of the axial planes and of the axes. If the angle of the axes a, b in oligoclase, which is nearly 90°, is altered in either direction by heating, it will be altered in the opposite manner on cooling, the angle in question becoming in the one case more acute, and causing the

form of the crystal to approximate to that of albite, while in the other case it will become more obtuse, and nearer to that of anorthite.

Lastly, the mode of formation of its twin crystals shows that oligoclase is intermediate between albite and anorthite. In anorthite the axis of combination is parallel to the macrodiagonal; in albite it is perpendicular to the brachydiagonal, while in oligoclase it is sometimes in the first direction, sometimes in the second.

This view of the constitution of triclinic feldspar is further supported by the crystallographic description and chemical analysis of nine of these minerals from different localities lately published by G. vom Rath (*Pogg. Ann.* cxliv. 219).

a. *Andesin* from *Vesuvius*: identical in crystalline form with the formerly-described oligoclase from the same locality.

b. *Oligoclase* from *Niedermendig*.

c. *Oligoclase* from a tourmalin rock in the Veldin, from a coarse-grained mixture of black tourmalin and quartz. The oligoclase appears in crystalline grains an inch in diameter, having a bluish-white colour and a fine, distinct striation on the face P.

d. *Andesin* from the hornblende-melaphyre of Monte Mulatto, near Predazzo: very distinctly striated on *oP*.

e. *Andesin* from the diorite porphyry of Fréjus (Dep. du Var).

f. *Labradorite* from the diorite of the Veldin: a coarse-grained mixture of distinctly striated plagioclase and blackish-green hornblende. The labradorite is bluish-white, and translucent when fresh; snow-white when somewhat decomposed.

g. *Labradorite* from the porphyrite of the Tannbergthal (near Schöneck in the Saxon Voigtland). Nearly transparent and colourless crystals, sometimes 3 centim. long, accompanied by red orthoclase, roundish red quartz-grains, and iron pyrites.

h. *Labradorite* from the dolerite of Hafnefjord in Iceland. This mineral, together with augite, constitutes a doleritic lava, the so-called Klöflava of Iceland, was called *Hafnefjordite* by Forchhammer, who regarded it as a distinct species: but his analysis, which gave 61.2 p.c. silica to 8.8 p.c. lime, appears to have been made on an impure specimen.

i. *Plagioclase* (oligoclase) from the basalt of the Hartenberg in the Siebengebirge. This feldspar which contains a much larger proportion of potash than any of the preceding, may be regarded either as a mixture of albite (8 mol.), anorthite (3 mol.), and orthoclase (3 mol.), or of 3 mol. of an albite rich in potash and 1 mol. anorthite.

The following table contains the results of the analyses of the nine sodio-calcic feldspars above specified. The small figures denote the percentages of silica, &c., as calculated from the formulae:—

Composition of Sodio-calcic Feldspars.

	Specific gravity	Silica	Alumina	Lime	Potash	Soda	Magnesia	Ferrio oxide	Total	Ratio of molecules of Albite : Anorthite	Formula
a	2.647	58.53 58.48	26.55 26.49	6.43 8.02	0.89	7.74 7.01	—	—	100.14	4 5	$\text{Na}^8\text{Ca}^1\text{Al}^{11}\text{Si}^{10}\text{O}^{101}$

i	2.632	63.56 63.93	21.81 21.90	2.32 2.98	3.65	6.84 7.45	0.95	0.66	99.81	3 1	$\text{K}^1\text{Na}^4\text{Ca}^2\text{Al}^{11}\text{Si}^{10}\text{O}^{100}$

The composite nature of these feldspars is indicated by the striation of some of their faces, which would naturally result from the juxtaposition of a number of thin lamellae of two different minerals.

Two sodio-calcic feldspars from the Ural, analysed by vom Rath (*Pogg. Ann.* cxlvii. 274), exhibit a similar constitution :—

a. Oligoclase from Scheitansk near Mursinsk, where it occurs in clefts in the granite which formerly yielded the well-known red tourmalines. The crystal examined measured 3 or 4 centimeters in its several dimensions; it is terminated at both ends by the cleavage-faces oP . It is transparent and colourless, which is seldom the case with sodio-calcic feldspars, and is more like adularia and some varieties of sanidine, in not exhibiting the twin-striation parallel to the brachydiagonal which is usually seen in triclinic feldspars. Sp. gr. 2.642 (at 18°). Loss by ignition 0.38 :—

SiO^2	Al^2O^3	CaO	MgO	K^2O	Na^2O
63.83	22.58	3.42	0.06	1.02	8.86 = 99.77

Oxygen ratio: $(CaO + K^2O, Na^2O) : Al^2O^3 : SiO^2 = 0.985 : 3 : 9.687$. In composition this mineral is more nearly related to the oligoclase from the tourmaline-rock of the Veltin than to any other of the nine triclinic feldspars, and, like the latter, may be regarded as a mixture of 5 parts by weight of albite and 1 part of anorthite.

b. Andesin from the Uvelka mountain near Orenburg : a fragment 7 centimeters long and broad, $2\frac{1}{2}$ centimeters thick, marked on the very perfect cleavage-face oP , with an extremely fine striation, which, however, does not cover the whole face. The mineral is fresh, translucent, white, reddish in some parts from admixture of a small quantity of iron-glance. The feldspar is intergrown with grey quartz and black mica, the latter being sometimes interlaminated in a peculiar manner parallel to oP . Sp. gr. 2.651. Loss by ignition 0.33 :—

SiO^2	Al^2O^3	Fe^2O^3	CaO	K^2O	Na^2O
60.34	24.39	0.18	5.56	0.73	8.44 = 99.64.

Deducting the ferric oxide, which probably belongs to the iron-glance, the oxygen-ratio is $1.025 : 1 : 8.478$.

This andesin is most nearly related to that from the melaphyre of Monte Mulatto near Predazzo (p. 512), and, like the latter, cannot be exactly represented in composition by a mixture of albite and anorthite. If we start from the proportion of lime and alkalis shown by the analysis, the proportion of silica comes out rather too high for such a mixture; and if, on the other hand, we start from the observed quantity of silica, the calculated quantity of the lime is too great in proportion to that of the soda.

Rammelsberg has lately pointed out that the analysis of every sodio-calcic feldspar yields two atomic ratios, namely, that of $Al^3 : Si$ and that of $Na : Ca$. He designates as normal analyses those in which these two ratios lead to the same result. It is only however, in about 10 p.c. of the analyses discussed that this condition is exactly fulfilled; in 40 p.c. the two ratios lead to nearly the same proportion of albite and anorthite, while in the remaining 50 p.c. the calculation founded on the ratio $Ca : Na$ leads to a result essentially different from that which is founded on the ratio $Al^3 : Si$.

The analysis of the Scheitansk feldspar gives $Al^3 : Si = 1.484$, corresponding with a mixture of 5 mol. albite and 2 vol. anorthite, which requires $Ca : Na = 1.5$. Now the analysis, after conversion of the potash into its equivalent quantity of soda, gives $Ca : Na = 1.502$, showing that this mineral has the normal constitution of a sodio-calcic feldspar.

In the Orenburg mineral, $Al^3 : Si = 1.425$, corresponding with 5 mol. albite + 4 mol. anorthite, which requires $Ca : Na = 1.25$, whereas the analysis, after conversion of the potash into the equivalent quantity of soda, gives $Ca : Na = 1.290$. If, on the other hand, we start from this, the ratio $Al^3 : Si$ becomes $= 1 : 4.367$. The Orenburg mineral belongs, therefore, to those sodio-calcic feldspars in which calculation from the two ratios leads approximately to the same result.

Petersen (*J. pr. Chem.* [2], vi. 197) objects to the mixture theory of the sodio-calcic feldspars, chiefly for the following reasons:—1. The striation peculiar to plagioclase feldspars is not always observed where it might be expected to occur; orthoclase from the syenite of Laurvig in Norway, containing a large amount of soda, does not show it; neither does the plagioclase from the basalt of the Hartenberg in the Siebengebirge, though very rich in potash, exhibit any trace of admixture of orthoclase. 2. Admitting the possible isomorphism of albite and anorthite, it is nevertheless difficult to imagine the replacement of Si^2 by $CaAl^2$, or of Ca^2Al^2 by Na^2Si^2 , and it appears scarcely necessary to admit special laws of isomorphism in the case of the feldspars, when no such supposition is made in other cases of similar character. A well-defined transparent crystal of calcspar, for example, containing a considerable

proportion of magnesium, is still regarded as calcspar, and not as a mixture of calcspar and bitter spar. Garnet also, though sometimes richer in ferrous or manganous oxide, sometimes in lime or magnesia, nevertheless forms well-defined, transparent, homogeneous crystals, which can scarcely be regarded as mixtures. The same is the case with the hyalophane of Binnenthal, which has the composition $\text{RO} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$ ($\text{R} = \frac{1}{2}\text{Ba} + \frac{1}{2}\text{K}^2\text{Na}^2$), and shows that a large proportion of potash renders felspars monoclinic. There are also numerous cases of artificially prepared crystals containing several isomorphous elements, which cannot easily be regarded as mixed crystals. Wetzien's experiments have shown how much copper can be introduced into rhombic zinc sulphate, $\text{ZnSO}_4 + 7\text{H}_2\text{O}$, or into monoclinic ferrous sulphate, $\text{FeSO}_4 + 7\text{H}_2\text{O}$, without altering the crystalline form or the amount of water. This could scarcely be the case if the crystals containing copper were mixtures. 3. Anorthite is easily and completely decomposed by strong hydrochloric acid, whereas oligoclase is scarcely attacked: hence, according to the mixture theory, hydrochloric acid might be expected to dissolve out the lime-constituent of sodio-calcic felspars more easily than the soda-constituent, but such is not the case. 4. Oligoclase from the diorite of Hof and from the diabases is free from lime; that from the gneiss of Aschaffenburg contains only a trace of lime. In all these oligoclases the oxygen-ratio of the alkalis, the alumina and the silica is as 1 : 3 : 10, whereas in albite and orthoclase it is as 1 : 3 : 12. 5. Although crystals of albite are found intergrown with those of orthoclase and *vice versa*, nevertheless transparent orthoclases rich in soda are perfectly homogeneous, and probably therefore contain soda as an essential constituent. Since, then, these orthoclases rich in soda, and transparent albites rich in potash, must be regarded, not as mixtures, but as individual bodies, the same is most probably the case with oligoclase, labradorite, and andesine, which last Petersen regards as only an oligoclase rich in lime.

Decomposition of Felspar by Saline Solutions.—Birker and Ulbricht (*Annalen der Landwirtschaft*, 1871, 170) have examined the influence of saline solutions and other agents on the weathering and decomposition of felspar. For this purpose 1 kilogram of powdered felspar and $2\frac{1}{2}$ litres of distilled water were placed in a flask, together with the substances mentioned below, the amount of dissolved ingredients being determined after the materials had remained together for about 2½ years.

In the cases in which air or carbonic anhydride was used, the gas was passed to the bottom of the flask at intervals of from 2 to 4 weeks; in the other cases the flasks were made air-tight, and shaken at the same intervals.

The felspar used contained 8.51 p.c. K_2O , 3.37 Na_2O , 1.3 BaO , 16.03 Al_2O_3 , and 65.52 SiO_2 .

In the following table the quantities of ingredients found in solution are given in grams:—

Experiments	K_2O	Na_2O	CaO	MgO	SO_3	SiO_2

From these numbers it is seen that the action of distilled water with and without air was practically the same. Calcium carbonate, calcium nitrate, with and without carbonic acid, gypsum with and without carbonic acid, potassium carbonate and bicarbonate, and ferrous hydrate, had little more action than water alone. Carbonic acid, and calcium carbonate with carbonic acid, showed an increased action on the alkalis and silica. In the experiments with lime a much larger quantity of alkalis was dissolved, the lime at the same time entering into combination with the silica. Sulphate of ammonia had an energetic action, more especially on the potash; only in the experiments with this salt and in that with lime, was potash dissolved in larger quantity than soda. In the case of the ammonia sulphate, the base had entered into some combination with the silica, which was not decomposed either by washing until all sulphuric acid was removed, or by heating to 100° C. Eichhorn (*Jahresb. f. Agrikulturchemie*, 1859-60, 16) has already shown that silicates which are decomposed by hydrochloric acid, such as chabasite, absorb ammonia from its salts. Magnesia acted more energetically than any other agent, seven times more alkalis and three times more silica being dissolved with its aid than with water alone. Its somewhat slower action in combination with carbonic acid was probably due to the crystallising of bicarbonate on the sides of the vessel.

Sodium nitrate dissolved about double the quantity of potash that water did, but its action was less than that of sodium chloride. These comparative results are in unison with those of Dietrich on basalt (*J. pr. Chem.*, lxxiv. 12, and *Jahresb. f. Agrikulturchemie*, 1862-63, 14).

FERMENTATION. Liebig (*Ann. Ch. Pharm.* eliii. 137) has continued his experiments with reference to Pasteur's germ-theory of Fermentation (*1st. Suppl.* 612). Pasteur regards the formation of acetic acid from alcohol in the ordinary process of vinegar-making, as essentially dependent on the presence of a peculiar fungus, the *Mycoderma aceti*. According to Liebig, on the other hand, it is a simple process of oxidation. Many organic substances possess, as observed by Schönbein, the power of absorbing oxygen from the air, just like finely divided platinum, the oxygen thus taken up being transferable to other bodies and capable of oxidising them. This indeed was shown thirty years ago by De Saussure, who oxidised hydrogen by contact with organic matters in a state of putrefaction or decay. In the same manner vapour of alcohol is oxidised in contact with decaying wood, the latter being used, as is well known, in the quick method of vinegar-making. A wood-shaving which had been used in a vinegar-work for twenty-five years, did not exhibit, on microscopic examination, the slightest trace of a fungus. Mother of vinegar may in like manner bring about the oxidation of alcohol, but the process is not a physiological one, and the acetic acid is a product, not of a fungus, but of oxidation.

The processes of decomposition of organic matters may be divided into three groups, the first including alcoholic, lactic and butyric fermentation; the second and third, the formation of acetic and of nitric acid, and the fermentation of urino. Fermentations of the first class, when once set up, do not require the further aid of oxygen, whereas in those of the second and third class, oxygen plays a definite part. Urinary fermentation is determined by the two processes going on simultaneously, and the same is true with regard to the putrefaction of animal bodies and to the fermentation of dextrin in beer-wort.

Pasteur on the other hand (*Compt. rend.* lxxiii. 1419) defends his views on alcoholic and acetic fermentation, and maintains the exactness of the experiments on which they are based. He states that he has been able to produce fermenting media by bringing together only three kinds of substance, namely a fermentable body, properly selected mineral salts, and fermentative germs. If, for example, to a very pure solution of crystallised calcium lactate there be added the phosphates of ammonium, magnesium, and calcium, together with small quantities of ammonium sulphate, and finally vibrios or fully developed vibrios, the lactate will disappear in a few days, and an immense number of new vibrios will be developed. As long as any calcium lactate remains, the vibrios multiply and move about in the liquid; but when the whole of the lactate is decomposed, the vibrios fall dead to the bottom. Moreover not the smallest quantity of wine ever turns sour in contact with the air, without the previous presence of *Mycoderma aceti*.

Pasteur moreover finds (*Compt. rend.* lxxv. 784) that if a saccharine liquid suitable for fermentation be put in a vessel in which it can be sown with a particular organism, without fear of any other getting into it spontaneously from the air, and then a trace of pure *Mycoderma vini* be sown in it, the liquid will in a few days be completely covered with a pellicle of the fungus, which can be shown to grow at the expense of the air, absorbing its oxygen, and giving out nearly the same volume of carbon dioxide, and to produce no alcohol in the liquid. If now the pellicle be submerged in the liquid,

bubbles of carbon dioxide soon begin to rise from it, and alcohol is formed; at the same time its cells swell up and cease to multiply, and the internal structure of their plasma becomes very greatly modified. Thus the same cells acquire or lose the power of acting as a ferment, according as they are deprived of air, or exposed to it. action. This experiment also succeeds with the true fungi, such as *Penicillium glaucum*.

Yeast and other ferments therefore differ from the other lower organisms only in possessing the faculty of living and multiplying regularly and continuously without contact with the atmosphere. These observations appear to remove the mystery of fermentation. Instead of requiring free oxygen to burn the materials which serve for their nutrition, they obtain the heat necessary to their existence by living upon oxygenated bodies like sugar, which can furnish heat by their decomposition.

Viewing fermentation in this light, all living bodies may become ferments under certain conditions. Thus, when an animal is suddenly killed, life does not at once cease in the organs of the body, or in the physiological elements of these organs, and when this goes on in them without the influence of free oxygen, it does so at the expense of the surrounding materials from which the necessary heat is obtained, and they behave like ferments to these materials.

Bérard has shown that when fruits are exposed to the air, they absorb oxygen and replace it by carbon dioxide, but that when placed in an inert gas, like carbon dioxide itself, they also evolve carbon dioxide. The gas evolved under the latter circumstances he considers to be a product of a sort of fermentation. Pasteur confirms this view, for he finds that alcohol is formed even when the fruit is placed in an inert gas. When this experiment is made with suitable precautions, no beer-yeast or other ferment is produced.

Grapes thus exposed to carbon dioxide acquire at the same time exactly the odour and flavour of expressed grape-juice, quite distinct from that of the fresh grape.

Dumas (*Compt. rend.* lxxv. 277) regards fermentation as the chemical decomposition of sugar by the vital force of yeast-cells, and considers that Pasteur's researches have placed the matter beyond dispute. He has himself made a number of experiments, the results of which are opposed to the views of Berzelius and of Liebig, and show that fermentation is not merely set going by the ferment, but is continuously dependent upon it, and susceptible of measurement and modification like any other chemical phenomenon.

In one series of experiments he endeavoured to transmit the movements of a fermenting solution of sugar to a solution of pure sugar separated from it either by various liquids or by a septum of collodion, or else resting upon it in direct contact, and failed in every case to do so, or even to cause the inversion of the sugar.

Berzelius having attributed the fermentation of sugar to the contact-action of the yeast, Dumas tried the effect upon sugar of another chemical phenomenon also attributed to contact, namely, the liberation of oxygen from hydrogen dioxide and manganese dioxide. This was effected in a solution of sugar, and produced no change whatever in it. Various other chemical actions excited in a solution of sugar were also found to be without any effect upon it; so that its alcoholic decomposition cannot apparently be produced by another chemical action.

Schönbein has shown that ozone and hydrogen dioxide are formed during slow combustions, and among these Liebig classes fermentations; but Dumas does not find that either ozone or hydrogen dioxide is produced during fermentation. Oxygen passed through a fermenting liquid does not appear to affect it in any way.

By dividing a mixture of yeast and water equally among solutions of sugar, the yeast being always in excess, it was found that, under similar circumstances as regards pressure and temperature, the duration of the fermentation was proportional to the quantity of sugar. Cane-sugar requires twice as long for its fermentation as glucose; so that as much time is required to invert the sugar as to ferment it. It is estimated that about 400 milliards of yeast-cells are required to ferment a solution of one gram of pure cane-sugar in one hour. Fermentation proceeds more slowly in darkness, and in a vacuum.

Neutral gases do not affect the power of yeast. *Sulphur*, in a fermenting liquid, is converted into hydrogen sulphide having an odour of onions, and appears to be the only substance, besides sulphuretted compounds, that enters into reaction with ferments. Yeast is by this reaction shown to be a reducing agent. Sulphur does not appear to hinder fermentation, as it has been stated to do. Very dilute *acids* do not affect fermentation: larger doses destroy it. Very dilute *alkalis* retard fermentation: larger doses arrest it. *Alkaline carbonates* hinder it only in very large doses.

Sal ammoniac causes yeast to precipitate almost as rapidly as potato-starch deposits from water. *Potassium silicate* and *borax* conglutinate it, so that it becomes clotted like silver chloride.

When fresh yeast is placed in a saturated solution of *neutral potassium tartrate*, no change is perceived, and on removing the yeast to a solution of sugar, fermentation almost instantly commences, and rapidly follows its course. But the liquid, after the fermentation, presents all the characters of a solution of ordinary albumin. When the tartrate, the yeast, and the sugar and water are mixed together at once, no such effect is produced; so that it must be caused in the other case, 1st, by the absorption of the saline solution by the yeast, and 2ndly, by the displacement of this by the sugar solution. The action of the neutral tartrate and of such salts as potassium silicate, borax, soap, &c., can therefore effect a physiological analysis of yeast, similar to that of blood by the action of certain neutral salts.

The *acid tartrate of potassium* and some other salts seem rather to favour fermentation; others retard it; others, again, such as *common salt*, permit inversion of the sugar to occur, but prevent its fermentation, while others altogether prevent both inversion and fermentation, these being potassium cyanide, potassium monosulphide, and strange to say, potassium acetate.

Sodium sulphite and *thiosulphate*, and *potassium sulphocyanate* furnish, by a fermentation which sometimes soon ceases, and sometimes continues to its natural termination, an alcoholic liquid which, when distilled with solution of potash, yields an alcohol containing aldehyde and a matter exhaling a very agreeable fruity odour. The alcohol becomes milky when mixed with water. The potash-solution deposits much aldehyde-resin on cooling, and yields on evaporation salts having special characters.

Potassium thiosulphate disengages hydrogen sulphide during the whole of the fermentation, and the product which accompanies the alcohol exhales an odour of garlic.

Lastly, with regard to the action of salts as bearing upon the theory of fermentation, it may be mentioned that when, as in the presence of the acid potassium tartrate, fermentation proceeds actively, the yeast-cells are clear, well defined, and full of a plastic matter containing brilliant and very active corpuscles, and send out numerous offshoots; whereas, when the fermentation languishes, as in the presence of salts of iron or manganese, the cells appear contracted, tuberculated, granular, and shrivelled, and, without recent offshoots.

A solution of *borax* coagulates yeast, and the supernatant liquid cannot, like yeast-water, invert cane-sugar. Borax prevents the action of yeast-water upon sugar, of *emphase* upon amygdalin, also that of diastase upon starch, and the action of *myrosin*. (Dumas.)

According to Béchamp (*Compt. rend.* lxxv. 1036), two yeasts, apparently identical and pure, do not always yield the same results. Under the same conditions, yeast from the same lot always produces an equal quantity of acetic acid; but, other things being equal, one sample of yeast may produce four times as much acid, or may require a time four or five times as long to complete the fermentation, as another. Contact with the air, even with a large surface, far from augmenting the quantity of acetic acid, diminishes it, but generally shortens the period required for the fermentation.

In experiments made in apparatus where the air was displaced by a current of carbonic anhydride, from two to four times as much acetic acid was produced as in similar experiments made under exposure to the air. It is possible to produce in a saccharine solution a weight of acetic acid greater than the dry weight of the yeast used; the acid cannot therefore come from the yeast. The hotter the yeast is nourished in the solution, the less is the amount of acid produced. An increase of temperature shortens the duration of the fermentation, and augments the amount of acid. Pressure increases the quantity of acid.

Influence of Pressure on Fermentation.—Experiments on this subject have been made by H. T. Brown (*Chem. Soc. J.* [2], x. 570; xi. 973). He finds that during the alcoholic fermentation of grape-juice or malt-wort, besides carbonic anhydride, there are evolved—nitrogen, hydrogen, and hydrocarbons of the paraffin group, and sometimes nitric oxide; that, moreover, the proportion of the gases unabsorbed by potassium hydrate is largely increased when the operation is carried on under diminished pressure. At the ordinary pressure, by far the larger proportion of these gases is nitrogen (70 to 90 p.c.), but under diminished pressure (400 to 450 mm.), the hydrogen preponderates (60 to 90 p.c.) Nitrogen, however, does not occur when the solutions are free from albuminoids, even if ammonium salts are present in considerable quantity. The increase of the proportion of hydrogen, resulting from diminution of the pressure, is accompanied by formation of a comparatively large amount of acetic acid and aldehyde, so that it would seem that water is decomposed during the alcoholic fermentation, and that this result is facilitated by the diminution of the pressure. The presence of nitric oxide in the evolved gases was found to be due to the reduction of nitrates originally present in the solutions.

Diminished pressure retards the progress of the alcoholic fermentation in a remarkable way, although there does not seem to be any simple relation between them. It is certain, however, that under diminished pressure less sugar is decomposed than during an equal time at the ordinary pressure, and that the proportion of the carbonic anhydride to the alcohol produced is greater. This difference is not due to any injury of the yeast cells caused by the removal of the pressure, but appears rather to be an exemplification of Morby's law, 'that pressure weakens or strengthens chemical affinity, according as it acts against or in favour of the change of volume;' there is indeed a decided contraction in volume during the alcoholic fermentation. The acetic acid produced is derived directly from the sugar.

Influence of Temperature.—According to J. Pierre (*Compt. rend.* lxxiii. 317), the more rapid fermentation of sugar which takes place at comparatively high temperatures is attended with a more abundant formation of the higher alcohols, butylic and amyllic, and consequently with a diminished production of ethylic alcohol. When the temperature is kept down to the lowest point at which fermentation can go on, scarcely any butylic or amyllic alcohol is obtained, but propylic alcohol is formed, which, in testing by the alcoholimetric process, is reckoned as common alcohol.

Alcoholic Fermentation by means of Mucor Mucedo. (A. Fitz, *Dent. Chem. Ges. Ber.* vi. 48–58).—De Bary in 1857, and afterwards Rees, discovered that the mould-fungus, *Mucor Mucedo*, immersed in saccharine solutions, is capable of setting up the alcoholic fermentation, the spores of the fungus multiplying by gemmation after the manner of beer-yeast. The mucor cells, however, are easily distinguished from yeast cells by their enormous size and by the red coloration produced by zinc chloride in their cellulose envelope. In the presence of air, mucor also develops a luxuriant mycelium. Fitz also finds that the spores of this fungus develop differently according to the presence or absence of oxygen. In the absence of oxygen, they multiply by gemmation, and alcoholic fermentation is set up, but in the presence of air, a luxuriant reticulated mass is produced, no fermentation occurring at first, but only oxidation of the sugar through the agency of the mycelium. This continues till the oxygen is consumed, when the mycelium breaks up into isolated cells, and fermentation commences.

Mucor fermentation proceeds best at a temperature between 25° and 28°. The gas evolved is pure carbonic anhydride.

Mucor yeast is very sensitive to the presence of alcohol, and the fermentation soon comes to an end. Mucor can only be employed for the fermentation of solutions containing less than 7 per cent. of sugar, and is therefore useless for the fermentation of wine.

Succinic acid is formed in the mucor fermentation, but no glycerin has been detected in the product of the reaction.

Dextrin, inulin, and milk-sugar do not ferment under the influence of mucor.

Alcoholic Fermentation of Milk-sugar.—Blondlot finds that milk, under favourable circumstances, produces a special alcoholic ferment, which differs from ordinary yeast in requiring agitation to enable it to become active, in operating in an intermittent manner, requiring rest and agitation alternately, and in not manifesting any action below 20°. A temperature of 30° to 35° is the best for the purpose. No carbonic acid gas is evolved until the milk is shaken, and the quantity diminishes gradually as the fermentation approaches completion. When the fermentation has ceased, an addition of milk-sugar or of ordinary glucose causes it again to become active. The alcohol produced has an agreeable taste, but is apparently contaminated with a little butylic alcohol.

New Theory of Alcoholic Fermentation.—A. Petit (*Compt. rend.* lxxiii. 267) supposes that in a solution of sugar containing globules of yeast, water is decomposed, the oxygen uniting, at least for a moment, with the substance of the globules, while the hydrogen in the nascent state attaches itself to a molecule of sugar, and causes its decomposition, the products being alcohol, carbonic anhydride, and one molecule of hydrogen, which decomposes a further molecule of sugar, and so the reaction proceeds:—

A single molecule of hydrogen should therefore theoretically decompose an indefinite quantity of sugar, were it not that secondary reactions occur, the principal of which consists in the formation of glycerin:—

The reason for considering the hydrogen the *primo agent*—although the oxygen might equally well be so regarded, and nothing proves that under certain conditions of ex-

periment it is not so—is that, on allowing two similar liquids to ferment, but with the addition of 1 p.c. of sodium sulphite to the one, the same disengagement of carbonic anhydride took place in both cases, although the oxygen had served to convert the sulphite into sulphate. In this experiment no acids were formed.

If the fermentation takes place in the absence of sulphites, the oxygen forms succinic and acetic acids.

Fermentation of Fruit.—Fruit protected from the air evolves considerable quantities of carbon dioxide, alcohol and acetic acid being at the same time formed in the interior, whilst a proportionate diminution takes place in the quantity of sugar contained in the fruit.

(Observations on the fermentation of apples yielded the results given in the following table:—

	Duration of expt.	Weight of apples	Loss of weight	Loss of sugar	Gas evolved	Alcohol	Acetic acid
	hours	grams	grams	grams	grams	grams	grams
1 . . .	184	348.0	14.3	26.0	13.10	10.01	0.11
2 . . .	157	353.6	7.6	6.0	5.30	4.00	0.10
3 . . .	234	531.5	22.5	36.4	21.05	20.56	0.29
4 . . .	150	407.3	31.3	45.6	24.50	21.80	0.35
5 . . .	124	338.9	3.9	5.4	3.00	2.89	0.17
6 . . .	184	341.0	4.0	—	2.40	4.27	0.17

In the later stages of the evolution of carbon dioxide, the alcoholic ferment was invariably found to be fully developed, and budding at all parts of the interior of apples, the peel of which remained intact. In the juice of apples the globules became transformed into long chains in the course of a few hours. During the first stage of evolution of gas, however, no ferment in the growing state was found either in the apples or in the juice expressed from them. The juice contained only isolated globules of various sizes: but even at this stage, alcohol was formed, as shown by experiment 5.

The ferment in the budding state was not observed in apples exposed to the air. The question, whether in this case alcohol is formed in the fruit, is not yet decided.

The gas evolved from the interior of an apple under reduced pressure was found to contain 15 p.c. of oxygen and 5 of carbon dioxide, the rest being nitrogen. The gas evolved from mellow or rotten apples contains no oxygen (Lechartier a. Bellamy, *J. Pharm.* [4], xiii. 251; *Compt. rend.* lxxv. 1203).

The following observations on the fermentation of bilberries, wine, and honey have been made by Boussingault (*Ann. Ch. Phys.* [4], xxvi. 362).

Bilberries (fruit of *Vaccinium Myrtillus*).—The berries were allowed to ferment spontaneously in a flask connected with a jar standing over mercury.

Bilberries	Weight employed	Containing		Acid expressed as H ² SO ⁴
		Sugar	Alcohol	
Before fermentation .	grams 9486.5	grams 598.6	grams 0.0	grams 64.32
After . . .	0166.3	0.0	239.63	64.88
Difference . . .	— 320.2	— 598.6	+ 239.63	+ 0.56

The sugar, which, judging by its rotatory power, seemed to be wholly inverted sugar, should have given 305.9 of alcohol; only 239.63, or 78 per cent. of this was obtained.

These 239.63 grams of alcohol produced represent 229.3 grams of carbonic anhydride. The loss of weight after fermentation was 320.2, and there was, as shown in the table, but very inconsiderable increase in the proportion of acid.

White Wine of Lampertloch.—Must of sp. gr. 10795 at 17° was taken and strained from the stalks, skins, and stones.

FERMENTATION.

Fermentation of White Wine.

	Weight of must	Sugar by copper test	Alcohol	Acid expressed as H ² SO ⁴
Before fermentation	grams 9715.5	grams 1688.46	grams 0.0	grams 30.74
After ,,	8955.0	traces	781.41	47.82
Difference	-760.5	-1688.46	+781.41	+8.08

The alcohol obtained was about 91 p.c. of the amount which the sugar should theoretically have yielded.

The alcohol produced represents 747.8 of carbonic anhydride, the loss actually experienced being 760.5.

By a series of observations of the rotatory power of the must during the progress of the fermentation, it was found, as already shown by Dubrunfaut, that the dextro-glucose is destroyed by fermentation before the levulose.

Honey.—Fermented with washed beer yeast.

	Volume	Weight	Sugar by copper test	Alcohol	Acid expressed as H ² SO ⁴
Before fermentation	litres 3.845	grams 4012.87	grams 378.73	grams —	grams 0.62
After ,,	3.837	3823.00	traces	177.65	3.07
Difference	-0.008	-189.87	-378.73	+177.65	+2.45

The sugar should have produced 193.57 grams of alcohol. Calculating from the alcohol produced, 170 grams of carbonic anhydride should have been evolved. The actual loss incurred was nearly 190 grams.

Nature and Origin of Ferments.—A. Mayer (*Ann. Chem. Pharm.* clvii. 227) has made a series of experiments on alcoholic fermentation and the mode of nutrition of the yeast-plant, from which the following conclusions are drawn. The salt most intimately related to the proper physiological function of yeast—the conversion of sugar into alcohol and carbon dioxide—is acid potassium phosphate, since the exclusion of that salt exerts immediately, and directly, an injurious effect upon the fermentative process. It cannot be replaced by the sodium or ammonium phosphates, or by any other salt of potassium.

Other salts are, however, necessary to the complete nutrition of the yeast-plant. If a mixture of water, sugar, and an appropriate nitrogenous body, in proper proportions, be taken, and no mineral constituent except potassium phosphate be added, fermentation sets in actively, after the addition of a very small quantity of yeast, but after a time the yeast-cells are found to be incompletely formed, and they are no longer capable of keeping up vigorous alcoholic fermentation.

The salts which prevent this degeneration of the yeast-plant, and so must be regarded as food for it, are those of magnesium, although these stand in no direct relation to the decomposition of the sugar. The minutest quantity of sulphur suffices for the nutrition of the yeast-plant, and this substance appears to be present even in the purest sugar-candy. All the other constituents of the ashes of the plant bear no relation to its nutrition, and calcium may be entirely removed without injury.

These results show that the requirements of the yeast-plant are much simpler than those of the higher plants and animals. Iron, for instance, and probably calcium may be completely absent from growing yeast. It is also manifest that the several functions of plants demand specific forms of nutriment for their due performance.

With regard to the nutrition of yeast by nitrogenous substances, the following results were obtained: they are somewhat different from those commonly received. The albuminous, and many other highly organised bodies, are ill adapted to the nutrition of the yeast-plant. Ammonium salts, and nitrogenous organic substances similar in constitution to ammonia, are quite competent to the nutrition of the yeast-plant. But this plant differs from the higher vegetable organisms in being incapable of de-

giving the chief portion of its nitrogen from the nitrates. Pepsin was found to be the best food for yeast, and the diastase of beer was also found to be a good nitrogenous substance for this purpose, and for supporting vigorous alcoholic fermentation; but with respect to diastase, it was found that this result in no way depended upon the facility with which that body ferments, for previous heating of the liquid to the boiling point exercised no influence on the subsequent fermentation by means of yeast.

During alcoholic fermentation yeast not only decomposes sugar into alcohol and carbon dioxide, but the organism secretes unknown nitrogenous substances which are no longer capable of affording nourishment to the plant.

With regard to the connection between the nutrition of the yeast-plant and alcoholic fermentation, Mayer's experiments show that yeast does not require the access of free oxygen for its growth, and differs in this respect from other vegetable organisms; it does not *breathe* in the same sense as the higher plants, animals, and even other fungi do. The dictum that every organism, in order to furnish manifestations of life, must appropriate oxygen, cannot, therefore, be unreservedly admitted, and the following is proposed as a substitute for it:—that for the completion of the manifestations of vitality in every organism, chemical forces must come into play, such chemical forces being transmuted into heat and mechanical motion; further, that the chemical forces derived from the affinity for oxygen of organic substances in plants must be considered only as a special case of the above general law, although the most common one. If this modification of the generally received theory be admitted, the vital changes undergone by yeast in a saccharine solution may be classed with those changes of matter which take place in the higher organisms, and at the same time the series of phenomena taking place during the growth of the yeast-plant become explicable. The splitting up of a carbo-hydrate into alcohol and carbon dioxide is accompanied by a loss of chemical force—the alcohol formed having a much smaller thermic equivalent than the sugar from which the alcohol was formed. The case is one of internal combustion (*innere Verbrennung*). Moreover, the formation of cellulose in the cell-wall of the newly formed yeast-plant is a case of splitting up of sugar into more highly and less oxidised products, and during the process there is a consumption of chemical force. The connection between the splitting up of the sugar and the budding of the yeast-plant is thus indicated with much probability.

From the experiments of Béchamp (*Compt. rend.* lxxviii. 877) it appears that, under some circumstances, the mother of vinegar, a conglomeration of microzymes, can be transformed into bacteria, and under other circumstances into a cellular ferment which can produce the normal alcoholic fermentation from cane-sugar. Subsequent researches (*Ann. Ch. Phys.* [4], xliii. 443) have shown that the converse of this is also true, and that the cellular ferment may be transformed into microzymes and bacteria.

A mixture of starch and yeast kept at a temperature of 24° – 35° soon liquefies, and the yeast undergoes remarkable changes. The cells swell, become transparent, and gradually disappear. Myriads of microzymes of great agility spring into existence, then vibrios appear, and as these increase the microzymes diminish. The vibrios in their turn are succeeded by myriads of bacteria, and finally the bacteria gradually disappear, leaving nothing present but microzymes, simple or coupled together. During these changes a small quantity of gas is disengaged; no butyric acid is formed, and but little acetic and lactic acids.

A similar experiment made in presence of calcium carbonate produces somewhat similar physiological results, but, in addition, the vibrios are preceded or accompanied by a crowd of little bodies resembling the *amylobacters* of Trécul (*Compt. rend.* lxxiii. 1153), which, however, soon disappear, leaving only bacteria present. In this experiment pure carbon dioxide is disengaged at first, and afterwards a mixture of carbon dioxide and hydrogen. The soluble starch and dextrin disappear, producing a corresponding quantity of alcohol, acetic, and butyric acids. The ferments which proceed from these operations can serve indifferently as lactic or butyric ferment.

As, then, the mother of vinegar when changed into bacteria becomes lactic or butyric ferment, and when transformed into cellular matter becomes alcoholic ferment, and as pure yeast becomes lactic or butyric ferment when reduced to microzymes, vibrios, or bacteria, it is evident that the property of being a ferment of any particular nature does not depend essentially upon the matter of the ferment, but upon its organisation or structure.

Liebig contested the statement that an alcoholic ferment can be produced in a saccharine mixture without the previous addition of an albuminoid substance. Béchamp, however (*Compt. rend.* lxxiv. 125), arrives at a contrary conclusion. A mixture of 250 grams of cane-sugar, 1 gram of magnesium phosphate, 0.5 gram of calcium phosphate, and 1,500 c.c. of water, when exposed to the air, soon becomes very acid; gas is given off as abundantly as in a fermentation with ordinary yeast; and in 91 days, when the evolution of gas has ceased, the mixture yields 356 c.c. alcohol of 86° .

Acetic acid is also present, but neither butyric nor lactic acid. The ferment consists of very small oval cells and mobile granulations. Experiments with cane-sugar and other salts, as potassium nitrate, sodium phosphate, alum, &c., gave very similar results.

Béchamp also finds that beer-yeast, when suspended in water, exhausts itself and secretes phosphoric acid, and that amongst other products formed, one, named by him *zymase*, is capable of inverting cane-sugar. The phosphoric acid and *zymase* exist in the interior of the yeast-cells, from which they are separated by exosmosis, and amongst the other products are leucine and tyrosine. An experiment upon 350 grains of moist yeast, representing 84 grams of the dry substance, furnished 5 grains of leucine and 5 decigrams of tyrosine (*Compt. rend.* lxxi. 689; lxxiv. 184).

When the yeast which works off from new beer in cask during the process of cleansing is allowed to settle, the fluid portion removed, and water added to the remainder, nearly all the cells of yeast rise to the surface in three days, and under the microscope they are seen to move with the agility of the most active monads. These bodies resemble in size and shape the yeast-cells from which they have been derived, and their surface is covered with fine dark granules which appear to have resulted from an alteration of the superficial membrane (Trécul, *Compt. rend.* lxxiv. 23).

According to Hoppe-Seyler (*N. Rep. Pharm.* xx. 764) the ferment which converts cane-sugar into grape-sugar forms, when separated from beer-yeast, a white powder, which is soluble in water, and may be preserved unaltered in the dry state under alcohol. Living beer-yeast does not give it up to water, but if the yeast be killed by addition of a little ether, the ferment may easily be extracted by water and separated from the solution. The aqueous solution quickly effects the transformation of the sugar.

Ash of Yeast.—The ash of yeast has been analysed by Béchamp (*Compt. rend.* lxxiii. 337) with the following results:—

SO ²	P ² O ³	K ² O	Na ² O	CaO	MgO	Fe ² O ³	Al ² O ³	SiO ²
5.665	55.628	28.691	0.804	1.608	6.878	0.840	undetermined	= 100.114

Another experiment gave 5.771 p.c. SO², 56.94 P²O³, and 6.94 MgO.

The incineration was effected by means of bismuth nitrate in the manner described under 'Ash of Organic Bodies' (p. 108).

On the origin and development of Bacteria and Vibriones, and their relation to Fermentation and Putrefaction, see BASTIAN (*Proc. Roy. Soc.* xxi. 129, 224, 325, 349).

Antiferments or Antiseptic Substances. *Mercuric oxide* completely prevents alcoholic fermentation, and likewise the conversion of cane-sugar into grape-sugar; cupric salts act in a similar manner. *Ferric salts* colour yeast dirty yellow; after two or three days, however, the colour disappears, and regular fermentation slowly sets in. The *chlorides of potassium* and *sodium* appear slightly to accelerate alcoholic fermentation. *Caustic alkalis*, added in sufficient quantity to produce strong alkaline reaction, do not interfere with it, but they render it imperceptible for some time by absorbing the carbonic acid. *Chloroform* prevents fermentation to a considerable extent, a few drops added to 100 c.c. of a fermenting mixture containing 5 p.c. sugar sufficing to arrest it. *Quinine* acts in the same way. *Nicotine* accelerates fermentation slightly; so does *strychnine* at first, but afterwards retards it. *Creatine* appears to retard fermentation, but is itself at the same time converted into creatinine, which accelerates it. *Hydrocyanic acid* retards fermentation, or arrests it completely; its action, however, does not extend to the yeast-water or only so far as to exert a preservative action upon it. The yeast when freed from the hydrocyanic acid regains its activity. This action of hydrocyanic acid upon yeast is similar to that which it was observed by Schönbein to exert on the colouring matter of the blood (Liebig, *Ann. Ch. Pharm.* cliii. 137).

Calvert (*Proc. Roy. Soc.* xx. 197) made a series of experiments on a solution of albumin to which was added one-thousandth part of an antiseptic substance. He found that such substances may be divided into four classes:—

1. Those substances which entirely prevent the development of protoplasmic life and of fungi: these are phenol and cresol.
2. Those which prevent the development of vibrios without stopping the production of fungi: zinc chloride, mercuric chloride, and zinc sulphophenate.
3. Those, on the contrary, which permit the production of vibrios and prevent that of fungi: lime, quinine sulphate, pepper, and prussic acid.
4. Those which do not prevent the production either of protoplasmic life or of fungi: sulphurous, sulphuric, nitric, arsenious and acetic acids; caustic potash, soda and ammonia; solution of chlorine; sodium, calcium, and aluminium chlorides; calcium hypochlorite; potassium chlorate; calcium sulphate; ferrous sulphate; calcium bi-

sulphate: sodium thiosulphate; sodium phosphate; calcium phosphate; potassium permanganate, potassium and sodium sulphophosphates; picric acid; turpentine; wood-charcoal.

Acids, while not preventing the development of vibrios, facilitate the production of fungi: this applies especially to sulphuric and acetic acids. Alkalies, on the contrary, are not favourable to the production of fungi, but favour the development of vibrios. Zinc chloride and mercuric chloride completely prevent the development of animalcules, but do not stop the formation of fungi. Chlorine and calcium hypochlorite stop the production of vibrios only when employed in great excess; and when calcium hypochlorite is so used, it acts with violence upon the proteic matters, producing a disengagement of nitrogen. Quinine sulphate completely stops the formation of fungi, and this fact leads to the supposition that, as quinine sulphate is remarkably efficacious in cases of intermittent fever, this malady may be caused by the introduction into the human economy of fungoid bodies. This seems all the more probable when it is considered that this fever is most prevalent in swampy countries where there is much decomposition of vegetable matter. Wood-charcoal possesses no antiseptic properties: it absorbs the putrid gases produced and causes their oxidation.

According to Ralutau a. Papillon (*Compt. rend.* lxxv. 755) 1 p.c. of sodium silicate prevents the alcoholic fermentation of grape-juice. Urine containing 2 p.c. of the salt undergoes no decomposition, even in 15 days, and the evolution of ammonia is scarcely sensible with 1 p.c. Milk mixed with one-fourth of its volume of water containing one twenty-fifth part of the silicate, remains free from acidity at the end of five days, and if the cream be then removed, the remaining liquid will be found to be alkaline, and without a single flake of casein. An emulsion of three sweet and three bitter almonds made with water containing one twenty-fifth part of the salt is quite inodorous, and remains so at the expiration of ten days. It appears then that silicate of sodium, like borax, prevents fermentation and putrefaction, only its action is more energetic. 2 grams of borax dissolved in 40 grams of water, and injected into the veins of a dog, produced no appreciable effect upon the health of the animal; while an injection of 1 gram only of sodium silicate under the same conditions caused death. In the latter case the effects produced were purging and vomiting, and the urine contained albumin; the appetite gradually diminished, and the animal died in nine days.

Petit (*Compt. rend.* lxxv. 881) finds that when a solution of cane-sugar contains 1 p.c. of sodium silicate, fermentation commences slowly after the addition of the yeast, but when established it proceeds rapidly and very regularly. 1 p.c. of borax has no effect on fermentation. The same proportion of ferrous sulphate causes the fermentation to proceed slowly but regularly. With copper sulphate the fermentation commences, but soon stops. With 1 p.c. of arsenic trioxide the fermentation proceeds slowly, but very regularly.

Acetic acid is more antifermentative than the same quantity of a mineral acid. 1 p.c. of oxalic acid markedly slackens the rate of fermentation.

The most antifermentative bodies tried were mercuric oxide and chloride.

Sulphites do not hinder fermentation, and are themselves converted into sulphates as the fermentation proceeds.

Function of Chalk in Butyric Fermentation.—Béchamp finds that the addition of a drop or two of phenol or creasote to 100 c.c. of sugar-solution checks butyric but not alcoholic fermentation, and hence concludes that the butyric ferment is more easily killed than the more highly developed cell of beer-yeast. According to O. Loew, on the other hand (*Chem. News*, xxiii. 100), beer-yeast may also be destroyed by a sufficient addition of phenol; and its greater vitality is due simply to the relatively larger quantity of it compared with that of the butyric ferment, which is introduced into a sugar-solution from the air. Béchamp moreover finds in chalk a butyric ferment, which is not destroyed by phenol (*1st Suppl.* 614). According to Loew's experiments, this ferment does not exist in the chalk in its natural state, but is introduced from the air during pulverisation, and the inaction of phenol with regard to it is due to the absorption of the phenol by the chalk, so that to arrest the fermentation a considerable quantity of phenol is required. That marble excites fermentation in a liquid containing phenol less easily than chalk, arises not from the absence of microzymes, but from the inferior capacity of the marble to absorb phenol; for when phenol is not present, marble after exposure to the air excites the butyric fermentation just as well as chalk. The retardation of butyric fermentation by small quantities of phenol may also be prevented by addition of animal charcoal.

FLUORENE $C_{13}H_{10}$. A fluorescent hydrocarbon discovered in the portion of coal-tar boiling at 300° – 340° , by Berthelot (*Ann. Ch. Phys.* [4], xii. 222), who, however, did

not assign any definite formula to it. It is best obtained by crystallising the portion which distils between 300° and 305° from a mixture of alcohol and benzene, whereby a quantity of acenaphthene is separated from it.

Dibromofluorene $C^{12}H^8Br^2$ crystallises in beautiful monoclinic tables. When it is brought to a red heat in presence of lime, it yields a hydrocarbon melting below 1000° , and having the odour and appearance of diphenyl. Fluorene is, therefore, probably a diphenyl methylene $C(C^6H^5)^2$. *Fluorene picrate* crystallises in fine red needles, melting at 80° – 82° , and having the composition $C^{12}H^{10}.C^6H^3(NO^2)^2O$ (Barbier, *Compt. rend.* lxxii, 442).

FLUORESCIN $C^{20}H^{12}O^3$. This substance, the phthalcin of resorcin, is obtained by heating resorcin and phthalic anhydride together at 195° . It crystallises from alcohol in brown crusts, and is precipitated by acids from its alkaline solution as a brick-red powder. By treatment with zinc-dust in an alkaline solution it is reduced to colourless fluorescein, which is the phthalin of resorcin. When strongly heated with sulphuric acid, fluorescein yields a red body which dissolves in alkalis with a blue colour. This red-solution dyes blue like indigo, but the colour is neither so fine nor so fast (A. Baeyer, *Deut. Chem. Ges. Ber.* iv, 658).

FODDER-PLANTS. Under this head we treat of those forage plants which are not noticed under their respective names. Fodder crops are always cut while green, and before the formation of seed, and are either consumed by cattle in the fresh state, or made into hay. The composition of all these crops is, from their immature condition, subject to a far wider range of variation than the composition of grain crops, which are not harvested till the functions of the plant are completed.

The composition of a fodder crop may be said to depend—1. On its age, and the relative development of its parts; 2. On the composition of the soil in which it grows; 3. On the special characters belonging to its species. With crops harvested in a perfectly mature condition, the element of species has a preponderating effect on the composition, and the nature and richness of the soil have a smaller influence. With fodder crops, on the other hand, it is the state of development of the plant which most determines its composition, and the nature and richness of the soil have a large effect, while the special characters due to the particular nature of the plant are often so effectually hidden by the large influence of the two first-named conditions, that it becomes a task of great difficulty to ascertain what is the intrinsic difference between two fodder plants.

The proportion of water in a plant is greatest when young, and decreases during its growth.

The percentage of nitrogen in the dry plant decreases considerably during growth; this is true not only of the whole plant, but of all its parts, save the blossom, which increases in nitrogen as ripening commences. The diminution of nitrogen in the whole plant is, however, largely due to the alteration of the proportion of its parts as growth proceeds. In an immature plant the leaf is the part richest in nitrogen; a plant in its youngest condition consists principally of leaves, and at this period the plant contains its highest percentage of nitrogen; as the stem, which is poor in nitrogen, is developed, the percentage of nitrogen in the plant falls. The fall in the whole plant is thus more rapid in the earlier stages of its growth than in any of its parts.

The percentage of ash in the dry substance of the plant decreases considerably with age; while, however, the ash falls in the whole plant, it rises in the leaves as the plant matures. The percentage of fat also diminishes with age. Fat occurs in greatest quantity in the leaf, and its proportion in the whole plant diminishes with the growth of the stem.

The percentage of carbohydrates in the dry substance, on the other hand, increases considerably during growth; there is especially a large formation of cellulose as the plant matures, a fact which has great influence in determining the nutritive value of a fodder crop.

These facts are well illustrated by the following table, which shows the composition of plants taken at different dates from the same field. The analyses of Grass from a water-meadow were by Way (*Jour. Roy. Agri. Soc.* xiv, 171); the analyses of Vetches by Ritthausen (*Jahresb. Agr. Chemie*, 1859–60, 79); the analyses of Lucerne by Kühn (*Landw. Versuchs-Stationen*, xvi, 86); and the analyses of Red Clover by E. Wolf (*Ann. d. Landwirthschaft*, 1871, 130). The table states the composition of the dry plant, and, where the information is obtainable, the percentage of water in the fresh plant is also given.

The composition of the ash of a plant also undergoes alteration during growth. The analyses of the ash of the water-meadow grass just referred to have been already given in this Dictionary (see 'Grass,' vol. ii. 943); the increase of silica in the older grass, and the diminution of potash, are very striking. The changes which take place in the ash of graminaceous crops during growth will be noticed in detail under 'Oats' and 'Wheat' in the present volume; we will here give some of the results of Ulbricht's elaborate investigation on Red clover (*Landw. Versuchs-Stationen*, iii. 241, and iv. 1). Ulbricht examined clover grown on arable land, and clover grown in a garden soil; both the first and second crops were in each case the subject of investigation. Samples of each of the four crops were taken in several stages of growth: 1. At the first appearance of stem formation; 2. At first appearance of flower buds; 3. At full blossom; 4. When the seed was ripe. At each of these stages the various parts of the plant were separately analysed. The results yielded by the first crop on the garden soil, and the first crop on the field soil, are given in the table on page 526.

It will be noticed that in several points the results obtained in the poor and rich soil are very different, but the following general facts are evident:—

Clover increases in dry substance during growth; the leaves are the driest part till the blossom is matured. The proportion of ash in the dry substance diminishes as growth proceeds. In the young plant the leaf-stalk and stem contain most ash; the ash in the stem, however, rapidly decreases, while the ash in the leaf increases, so that at full bloom, and afterwards, the leaf surpasses all other parts in its contents of mineral matter. In the young plant potash is found chiefly in the leaf-stalk and stem, and in much smaller quantity in the leaf. The stem contains but little lime in proportion to its potash, but the leaf contains much lime in proportion to its potash (the same is true of graminaceous plants), and the amount of lime in the leaf steadily increases as the plant matures. The increase of lime and magnesia during the maturation of leguminous plants has been also noticed by Ritthausen. Phosphoric acid has its first maximum in the leaf, but after the formation of blossom it concentrates in this part of the plant. Silica, as with graminaceous plants, is found in greatest quantity in the leaf. Chlorine is at first chiefly located in the stem and leaf-stalk, and afterwards in the blossom. Nitrogen and sulphur find their maximum in the leaf till the blossom has become ripe, which then surpasses the leaf in nitrogen, and perhaps in sulphur.

Hellriegel (*Landw. Versuchs-Stationen*, iv. 31) has shown that the amount of the various ash-constituents present in the sap varies with the age of the plant. Experimenting on the clover crops used by Ulbricht, he found that the amount of potash existing dissolved in the sap was greater in the leaf than in the stem, and diminished in all parts by age. In the leaves of a very young plant 75 p.c. of the potash present was found in solution, but at full blossom only 37 p.c. was found dissolved in the leaves, and 15 p.c. in the stem. Lime, on the other hand, did not diminish in solubility as the plant matured, about 70 p.c. of the contents of the leaves being uniformly soluble, and about 50 p.c. in the stem. Magnesia, save in the case of the very young plant, exhibited the highest solubility of all the bases. Of phosphoric acid only about 20 p.c. was found in solution in the leaves, but rather more in the stem; its solubility was not altered in any marked degree by age. In the very young leaves 27 p.c. of the silica was found in solution; at full bloom this had fallen to 16 p.c. It is notable that at blooming time the blossom contained more soluble potash, phosphoric acid, and silica, than any other part of the plant. It appears that at those times, and in those organs in which the process of formation proceeds most vigorously, there the active ingredients of plant-food are most abundantly present in a soluble form.

Chlorine	—	—	—	—	—	—	—	—

Carbonic acid, ash, and chlorophyll are not included in the ash. The oxygen equivalent of the chlorine is deducted.

Voelcker (*Jour. Roy. Agri. Soc.* 1867, 30) determined the composition of clover at different stages of growth, and also the total amount of the dry substance that was soluble in water. On June 2, the soluble matter was 41·04 per cent.; this steadily fell, and on July 28 it amounted to only 29·27 p.c. The changes in the composition of fodder crops by age are clearly of such a nature as to diminish their nutritive value; crops cut for hay, should, therefore, not be allowed to pass the commencement of full blossom; the maximum amount of nutritive matter is probably then obtained, but rapid deterioration follows if the crops are allowed to become older.

As already stated, the composition of fodder crops is largely influenced by the nature of the soil, and of the manure employed. On a rich soil, producing luxuriant growth, fodder crops will be found to contain more water, more ash, more nitrogen, and more fat, than the same crops growing less rapidly, on a poorer soil. The tendency of high manuring is, in fact, to produce a great bulk of immature produce. We cannot better illustrate the effect of manure in altering the composition of green crops than by quoting some of the results obtained at Rugby by sewage irrigation on meadow land, and published by the Royal Commissioners, Messrs. Lawes and Way, in their report. The following table shows the composition of the sewaged and unsewaged grass in 1863. The grass was cut for green food throughout the year, each cutting being separately analysed; from these analyses the average composition of the whole produce from each plot has been calculated. The produce is, for the purpose of comparison, reckoned as hay containing 15 per cent. of water; the average amount of water in the fresh grass is also given.

The amount of nitrogen in the sewaged grass was in individual cases as high as 25·27 p.c. of albuminoids in the hay. In the case of green crops grown with sewage, we have the effect of manure in its most striking form; manures applied to a dry meadow have a less marked effect on the composition, and the effect is further diminished if the crop is allowed to grow to its full extent before being cut; the excess of soil-food under these conditions has time to discharge its proper functions, and determine a greater assimilation of carbon from the atmosphere, and the result of manuring appears in the quantity rather than in the quality of the crop. Messrs. Lawes and Gilbert have kindly supplied the writer with an abstract of the composition of the meadow hay obtained in experiments conducted for 18 years at Rothamsted; during this period the same manures have been applied each year to the same plot. The results are shown in the table on page 532.

With the increasing bulk of the crop we see that there is a small increase in the amount of water in the hay. The ash of the hay is greater wherever ash-constituents have been supplied in the manure; it is greatest where ash-constituents have been applied alone, and therefore relatively in greatest excess, and least where the crop has been increased by the use of ammonia, without any ash-constituents having been applied for 18 years. With regard to the nitrogen in the crop the case is somewhat complicated. The nitrogen is highest, as we should expect, where ammonium salts have been applied alone, and where nitrogen is, therefore, in great excess of all the

other food-constituents, but it is not lowest on the plots receiving no nitrogen. This is partly due to the fact that on the plot receiving only cinereals (a mixture of superphosphate with salts of potassium, sodium, and magnesium), and to a less extent on the unmanured plot, there is a considerable amount of leguminous herbage, which is not found on the other plots. Leguminous plants are far more nitrogenous than the grasses, and hay containing some clover will, other things being equal, contain more nitrogen than grass hay. The hay on the plot receiving cinereals and 400 lbs. of ammonium salts appears to stand lowest as to nitrogen because it is a purely grass-hay, but still more because the crop, under the influence of a liberal manure supplying no excess of nitrogen, is here better matured, tending more to stem and flower than on the unmanured plot. When the ammonium salts are doubled, as in the next plot, and the nitrogen supply becomes excessive, the percentage of nitrogen in the hay rises at once. There can be little doubt that if the grass crops at Rothamsted were cut in a less mature condition, the differences in their composition would be found to be far more considerable. The same amount of food which is only adequate for a large full-grown plant is excessive for a young, and therefore small, plant.

The composition of the ash of a fodder crop is greatly influenced by the nature of the soil. The ash of a perfected seed is very constant in its composition, whatever be the manure applied, but the ash of a green plant is greatly affected by the nature of the soluble matters in the soil; a luxuriantly growing plant contains in fact an excess of many of the ash-constituents which it requires. The alteration in the composition of the ash resulting from differences in the soil, or in the manure, will be best illustrated by giving the ash analyses of some of the experimental hay crops at Rothamsted already described. The analyses represent the average composition of the ash in three successive years, 1856-8 (*Jour. Roy. Agri. Soc.* 1859, 398), they are here recalculated to 100 parts, omitting charcoal and sand.

It is seen that wherever potash was applied the amount in the ash is about one-half more than in the ash of the crops receiving no potash. Also wherever ammonium salts (mixed sulphate and chloride) were employed, the ash becomes exceedingly rich in chlorine. Phosphoric acid is increased in every case where it was applied, but only to a small extent. This increase, both of base and acids, resulting from the manure, is accompanied by a corresponding falling off in lime and silica. The high carbonic acid and low silica in the ash of hay manured with cinereals only is due to the large amount of leguminous herbage present.

A further instance of the influence of soil on the composition of the ash will be found on comparing the ash analyses of clover grown in a garden and field soil already given; the clover from the field is far richer in lime and magnesia, and much poorer in potash than clover of the same age from the garden soil. Kreuzhage (*Jahresb. Agr. Chem.*, 1866, 270) gives ash-analyses of clover manured with various salts. There is an increase of potash, soda, phosphoric acid, and chlorine, where these were applied, but no increase of lime or magnesia followed their application. The extent to which potash and lime can be substituted for each other in green clover is very great, the

percentage of potash in the ash ranging from 15-40, and the lime varying as greatly in an inverse direction. The same is true of other leguminous fodder crops. The plant seems to take potash by preference when it can get it, and to assimilate lime as a substitute. It is thus well established that the composition of the ash of green crops is, within certain limits, largely dependent on the nature of the soil and of the manure applied.

The influence of climate and season on the composition of fodder crops is mainly one affecting their maturity. In a cold wet season blossoming is retarded, and takes place but partially; the crop then has a composition proper to a less mature condition than when the season is dry and warm, and blossoming takes place earlier and more abundantly. The great influence of season in this respect has been already illustrated, as far as the proportion of ash is concerned, by the table showing the composition of the hay grown at Rothamsted during eighteen years; it will be seen that the percentage of ash in the hay is influenced to a greater extent by season than by manure; the same is true of the variations in nitrogen, which the table does not supply.

We come now to the last element in the composition of fodder crops, namely, the characters proper to the different species. What has been already said concerning the vast influence of age, soil, and season on the proportion of the constituents of a green plant, makes it very clear that to distinguish accurately between different older crops they must all be grown under precisely similar conditions, and harvested at the same stage of development. Different investigators have taken pains that some of the necessary conditions should be uniform in the plants they selected for analysis, but no investigator seems to have succeeded in insuring the presence of all the conditions required for an exact comparison. The results of different investigators are also seldom comparable, working as they necessarily have done in different soils and seasons. It is impossible, therefore, to prepare a table which shall compare exactly the composition of fodder crops; all that can be done is to call attention to some general principles which determine differences between different species, and to give some averages of analyses of the more ordinary crops, harvested at the time of blossoming.

Leguminous crops contain in all their parts a considerably larger amount of nitrogen than graminaceous crops; they also yield a larger amount of ash. It is quite possible, however, that an immature, richly manured graminaceous crop may contain more both of nitrogen and ash than a mature leguminous crop. The two great classes of leguminose and graminaceæ include nearly all the fodder crops; to distinguish between the characters of the different species in these two classes we cannot do better than notice the habit of the plant. A plant the character of which is to produce a large proportion of leaf to stem will contain more nitrogen than a plant of the same habit of which is to produce smaller or fewer leaves. Thus, as Aрендt and I have observed, such grasses as *Briza media* and *Lolium perenne* will always stand amongst the less nitrogenous grasses, while grasses of such habit as *Holcus lanatus* and *Bromus mollis* will rank amongst the more nitrogenous. In the same manner *Festuca repens* must stand amongst the most highly nitrogenous clovers, and *Trifolium* 2nd Sup.

folium incarnatum will rank with those containing least nitrogen. The woody fibre will follow an inverse order to the nitrogen, and will be more abundant in stemmy than in leafy herbage. As the leaf is the driest part of the plant, a plant with abundant foliage will evidently contain less water than another of the same class which runs to stem. Similar reasoning might probably be applied to other ingredients if our knowledge were more extended: thus Arendt and Knop observe that leafy grasses or sedges contain considerably more silica than others which have a greater proportion of stem; in making this comparison, however, it must be recollected that the more luxuriant the plant, the less silica will it contain. A leafy grass, according to the same observers, will also contain 2-3 times as much lime as magnesia, while grasses with leaves close to the stem contain these bases in nearly equal proportions.

The following investigations have been made on the composition of individual species. Way (*Jour. Roy. Agri. Soc.* 1853, 171) has published full analyses of 19 grasses, 11 leguminous fodder crops, and 10 weeds and meadow-plants all collected when in blossom. The most nitrogenous grass was *Bromus mollis*, containing 17.29 p.c. of albuminoids in the dry state; the least nitrogenous was *Briza media*, containing 6.08 p.c. The most nitrogenous leguminous plant was *Vicia sativa*, containing 23.61 p.c.; and the least nitrogenous, *Melicago sativa*, containing 12.76 p.c. of albuminoids in the dry state. Amongst the weeds, *Poterium Sanguisorba* and *Plantago lanceolata* were the most nitrogenous, containing respectively 16.75 and 14.29 p.c. of albuminoids. Way's ash-analyses of these plants have been already given in this dictionary; see 'Fodder' and 'Grass' (ii. 630, 943).

Ritthausen and Scheren (*Jahresb. Agr. Chemie*, 1859, 76) have published complete analyses of 21 grasses and 8 leguminous plants gathered at the time of blooming. The most nitrogenous grass was *Alopecurus geniculatus*, containing 13.0 p.c. of albuminoids; and the least nitrogenous, *Phleum pratense*, containing 6.3 p.c. of albuminoids in the dry state. The most nitrogenous leguminous plant was *Vicia cracca*; the least nitrogenous, *Trifolium pratense*; they contained respectively 24.0 and 14.28 p.c. of albuminoids in the dry.

Arendt and Knop (*Landw. Versuchs-Stationen*, 1860, 32) have given analyses of 22 grasses, and of 10 sedges and rushes, nearly all at the time of blooming; they determined the nitrogen, and some of the ingredients of the ash. Among the grasses *Holcus lanatus* was the most nitrogenous, containing 17.6 p.c. of albuminoids, and *Festuca elatior* and *Agrostis Spica Venti* the least nitrogenous, both containing 7.4 p.c. of albuminoids in the dry. Of the sedges, *Carex acuta* contained 16.4 p.c., and *Carex vulpina* 12.2 p.c. of albuminoids, these being respectively highest and lowest. *Juncus conglomeratus* yielded 13.5 p.c. of albuminoids. The ash in the whole series ranged from 13.7 to 5.7 p.c., the highest ash being given by *Carex remota*, and the lowest by *Juncus conglomeratus*. The ash of the true grasses ranged from 9.58 to 6.0 p.c., *Hordeum marinum* yielding the highest, and *Glyceria aquatica* the lowest ash.

The following table exhibits the average composition of various fodder crops when in full blossom; the analyses are calculated as hay containing 15 p.c. of water. The figures given for Meadow-hay are the mean of more than 50 analyses, and represent hay of good quality. The figures for Red Clover are the mean of 11 analyses, and fairly represent the composition of good clover hay. The remaining figures are in each case the mean of only a few analyses, and are less trustworthy. The ash given is with carbonic acid deducted:—

	Water in Fresh	Water in Hay	Albumi- noids	Fat	Non-nitro- genous Extractive Matter	Woody Fibre	
Grasses, mean of 18 species (Way)	68.8	13	9.4	2.6	38.8	28.5	5.7
Grasses, mean of 21 species (Ritthausen and Scheren)	70.8	15	7.8	2.1	35.1	34.0	6.0
Meadow hay		15	9.2	2.8	41.0	25.8	6.2
Red clover	78.0	15	11.2	3.1	37.2	24.8	5.7
White clover	80.0	15	15.7	3.6	36.7	22.1	6.9
Trefoil	80.0	15	15.7	3.3	34.4	25.8	5.8
Vetches	82.0	15	14.5	2.6	35.2	26.9	6.8
Lucerne	74.0	15	14.5	2.5	34.8	26.7	6.1
Sainfoin	79.0	15	13.9	2.6	34.7	28.7	6.1
Crimson clover	82.0	15	12.9	3.0	30.8	32.2	5.1
Kidney vetch	83.0	15	9.5	2.4	39.5	28.6	5.1

The higher amount of fibre in the grasses than in the meadow hay may partly be due to different methods of analysis, which, in case of the determination of fibre, have varied greatly; but probably the difference arises chiefly from the fact that meadow hay contains a good deal of young undergrowth, which would not be included in the flowering grasses selected for analysis. After-math (autumnal) hay is richer in nitrogen than the first crop, the season being less favourable to the maturity of the plant. It is seen from the table that meadow grasses contain less water than the clovers, when both are compared at the time of blossom.

The composition of the ash of fodder crops is subject, as already seen, to so wide a range of variation that it would only be misleading to quote analyses in cases in which no general average is obtainable; we give therefore only ash-analyses of meadow hay and of red clover hay. The analyses are in each case the mean of a large number:—

	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	Cl	SiO ²	CO ²
Meadow hay	26.95	5.70	13.45	4.82	.45	6.06	5.17	7.73	27.53	3.07
Red clover hay	26.31	1.22	25.93	9.30	.57	7.55	2.28	2.82	2.05	22.77

The characteristic difference between the ashes of leguminous and graminaceous fodder crops is the nearly entire absence of silica in the former, and the presence of a large quantity of carbonic acid. It is the practice of German chemists to deduct this carbonic acid and recalculate the ash to 100 parts. This plan has occasional advantages, but it entirely destroys the characteristic feature of the ash, and the relation of the ash-analysis to the amount of ash yielded by the plant, thus introducing much confusion if full details are not given. The ashes of the other leguminous fodder-crops are very similar to that of red clover, and subject to the same violent fluctuations in the lime and potash.

From the above data it is easy to calculate the quantities of nitrogen and of ash constituents which ordinary crops of hay remove from the soil. Taking the average crop of meadow hay at 1½ ton, and of clover hay at 2 tons per acre, the quantities removed by these crops will be in pounds per acre:—

	Nitrogen	K ² O	CaO	MgO	P ² O ⁵	SiO ²	Total Ash
Meadow hay, 1½ ton	49.3	56.3	28.1	10.1	12.7	57.5	209
Clover hay, 2 tons	101.6	87.4	86.1	30.9	25.1	6.8	332

The composition of hay does not differ from that of the plant from which it is made if the drying is carefully and quickly conducted; the finer parts of the plant are, however, apt to be broken off in hay-making, so that the percentage of albuminoids will often be a little lower, and of fibre a little higher in the hay than in the green crop. When hay suffers from rain in the field, there may be a considerable loss both of soluble ash and albuminoids (see Boyer, *Jahresb. Agr. Chemie*, 1867, 257). The amount of water in hay is subject to much variation. In the Rothamsted Park hay the extremes are 11.5—23 p.c.; this will be about the range in good hay. Clover hay generally contains rather more water than meadow hay.

The changes which hay undergoes in the rick have been little studied. The active fermentation which takes place in damp hay and results in the well-known heating of the rick and change of colour in the hay is accompanied, according to Voelcker (*Jour. Roy. Agri. Soc.* 1867, 30), by a great loss of sugar and other soluble carbo-hydrates, and also of soluble albuminoids, while aldehyde and acetic acid are among the products. According to Hösäus (*Jahresb. Agr. Chemie*, 1867, 258) ammonia is also formed. The loss of organic matter in dark brown hay is shown by its high percentage of ash. It has been supposed that the fibre of the hay becomes more digestible by fermentation in the rick, but there are no experiments which show that its solubility is thereby increased. The small amount of heating that takes place in well-made hay is probably without material effect on its composition.

The nature of the fat of hay has been made the subject of a special investigation by König and Kicsow (*Landw. Versuchs-Stationen*, xlii. 241; xvi. 40 and 47. *Deut. Chem. Ges. Ber.* vi. 500). The fat from meadow hay, when purified from chlorophyll by treating the ethereal solution with animal charcoal, amounts to about 1.52 p.c. of the dry substance, that from clover hay amounts to 1.61 p.c. (see table B, p. 506). This

fat is separated, by solution in boiling absolute alcohol, into a waxy substance which is deposited on cooling, and into a fluid fat which remains in solution. König first regarded the fluid fat as a true glyceride, but E. Schulze (*Landw. Versuchs-Stationen*, xv. 81) has shown that the fat of hay yields no glycerin. König and Kiesow have now ascertained that the waxy matter contains ceryl alcohol, cholesterol, and a hydrocarbon melting at 65° – 66° , and having the percentage composition 84.96 carbon and 15.28 hydrogen; this agrees with the formula $C^{20}H^{42}$, but the new body is possibly cerotene, $C^{21}H^{44}$. Cerotic acid, and various unidentified members of the acrylic series, were also found in the fat from the hay.

Method of Analysis.—The analysis of fodder is effected on the partially dried substance. Water and ash are determined in the usual way, the ignition for ash being conducted at as low a temperature as possible. Fatty matters are separated by extracting the dry substance with ether till no more soluble matter is removed. The ethereal solution may be purified from chlorophyll by treatment with animal charcoal, but some loss is suffered in this operation, as the charcoal, even when well washed, retains a little of the fat. The ether is finally evaporated and the residue dried and weighed. The nitrogen is generally determined by combustion with soda-lime, and the amount of total albuminoids calculated from the nitrogen found. For this purpose the nitrogen is by different chemists multiplied by numbers ranging from 6.25–6.33, according to the view taken of the general composition of albuminoids. The lower number is most generally employed on the continent. It is very probable that in an immature plant, containing materials not yet fully elaborated, the whole of the nitrogen is not present as albuminoids, but exists partially in a lower form. The subject has been little studied, but it is well known that vetches and other plants contain asparagine (Cossa, *Gazzetta chimica italiana*, i. 683), and leucine (Morup-Besanz, *Deut. Chem. Ges. Ber.*, vii. 146), and that green crops grown by sewage contain nitrates (Müller, *Landw. Versuchs-Stationen*, xvi. 241). In the absence, therefore, of exact determinations, it must not be supposed that the nutritive value of highly manured crops necessarily rises with the rise in nitrogen.* The determination of vegetable fibre presents peculiar difficulties. The fibre present is at least of two kinds, cellulose $C_6H_{10}O_5$, and lignose, a substance which encrusts the cells and contains about 10 p.c. more carbon than cellulose. These bodies are differently acted on by reagents; thus, purified cotton (cellulose) is almost completely dissolved by sulphuric acid, sp. gr. 1.53, when allowed to remain in contact for many hours, while cork and other tissues rich in lignose are scarcely acted on. On the other hand, digestion in the cold with nitric acid, sp. gr. 1.10, and potassium chlorate (F. Schulze's method), dissolves lignose pretty readily, but has little effect on cellulose (Church's *Laboratory Guide*, 3rd edition, 196). For some account of the very various methods that have been employed in determining fibre, see Pillitz (*Zeitschr. anal. Chem.* xi. 46). The plan most usually employed is that of Henneberg and Stolman. 3 grams of the dry substance in coarse powder are mixed with 150 c.c. of water and brought to boiling; 50 c.c. of sulphuric acid containing 5 p.c. of oil of vitriol are then added, and the whole is boiled for half an hour, water being added to maintain the volume at 200 c.c. The whole is allowed to cool, the clear liquid syphoned off, and the residue transferred to a weighed filter and well washed with hot water. The fibre is then returned to the beaker, and the original operation repeated, substituting for the sulphuric acid 50 c.c. of a 5 p.c. solution of sodium hydrate. After boiling for half an hour a considerable volume of cold water is added, and after standing the clear liquor is syphoned off, the fibre collected on the weighed filter, washed first with hot water, then with a few drops of hydrochloric acid, then well washed with water, and finally with a 1 p.c. solution of ammonia till the washings are colourless; the filter is then dried at 100° and weighed. As the fibre is not quite pure, it is necessary in exact analyses to determine both ash and nitrogen in the fibre after weighing; the nitrogen is then calculated as albuminoids, and both albuminoids and ash are deducted from the crude fibre. In the case of substances containing fatty matters these should be removed with ether before commencing the determination of fibre. The reagents employed in this method dissolve the softer parts of both cellulose and lignose to a small extent. A trustworthy method of distinguishing between lignose and cellulose in the analysis of feeding materials is much to be desired, as the results of the German feeding experiments show that cellulose is digested by ruminants, while lignose is not. R. W.

FORMIC ACID. $CH^O^2 = H.COOH$. **Synthesis.**—This acid is produced by the union of hydrogen and carbon dioxide under the influence of the silent electric discharge: $H^2 + CO^2 = CH^2O^2$. When a stream of the mixed gases was passed

* The feeding experiments conducted at Rugby by the Royal Commissioners with sewage and unsweated grass, showed that an increase of nitrogen in the crop did not determine a greater feeding value if the conditions necessary for maturing the crop were absent. Thus late autumn sewage grass, though far more nitrogenous, was not equal in feeding value to the spring crops.

through a Siemens' induction-tube, a contraction of volume took place, the resultant gas was found to contain carbon monoxide, with a small quantity of marsh gas, and small drops of an oily liquid were deposited in the tube, which gave the characteristic reactions of formic acid (Brodie, *Proc. Roy. Soc.* xxi. 245).

On the Heat produced in the Formation and Decomposition of Formic Acid, see HEAT.

Conversion of Formic Acid into Methyl Alcohol.—Calcium formate, subjected to dry distillation, yields formic aldehyde, and this compound, treated with sodium-amalgam, yields a small quantity of methyl alcohol (Lieben a. Kossin, *Ann. Ch. Pharm.* cxviii. 107).

Synthesis by means of Nascent Formic Acid.—When ethylene gas is passed through a boiling aqueous solution of potassium cyanide and potassium hydrate (which yields formic acid), and the liquid afterwards distilled with sulphuric acid, an acid distillate is obtained, yielding a lead salt, only a small portion of which is soluble in water; and on distilling the soluble portion with sulphuric acid, boiling the distillate with mercuric oxide to remove formic acid, treating the product with sulphuretted hydrogen, and the filtrate with silver carbonate, a small quantity of a silver salt is obtained, having the characteristic acicular form of silver propionate. A similar result is obtained by passing ethylene gas through a mixture of oxalic acid and glycerin at 110°–120°. It appears, then, that formic acid, in the nascent state, is capable of uniting with non-saturated hydrocarbons, yielding acids containing more carbon than the hydrocarbon employed (Carstanjen a. Schertel, *J. pr. Chem.* [2] iv. 51).

FORMIC ALDEHYDE or FORMALDEHYDE, $\text{CH}_2\text{O} = \text{H} \cdot \text{CHO}$. This compound is formed in small quantity, together with formic acid and marsh gas, by the action of the silent electric discharge on a mixture of hydrogen and carbon dioxide: the formation is represented by the equation:

It appears, also, to be produced in a similar manner from a mixture of hydrogen and carbon monoxide, the marsh-gas obtained in both reactions probably resulting from its decomposition: $2\text{CH}_2\text{O} = \text{CO}_2 + \text{CH}_4$ (Brodie, *Proc. Roy. Soc.* xxii. 172).

Formaldehyde is also produced: a. By decomposition of methylal, $\text{H} \cdot \text{CHO}(\text{CH}_3)_2$, which is related to it in the same manner as acetal to acetic aldehyde. When a mixture of methylal and sulphuric acid is warmed, an odour of formaldehyde becomes perceptible, and a sublimate is formed consisting of the solid modification of formaldehyde. The action of cold sulphuric acid on methylal also gives rise to the liberation of formaldehyde, which, at the moment of its formation, combines with the sulphuric acid, forming a compound analogous to sulphate of chloral.

b. By the action of acids on methylene acetate, obtained by digesting methylene iodide with silver acetate and glacial acetic acid at 110°, and rectifying the distilled product over silver acetate. The portion boiling between 130° and 170° may be used either as such, or after being heated to 100° for six or eight hours with an equal weight of water. The latter liquid, which contains either free formaldehyde or the compound $\text{CH}_2 = (\text{OH})(\text{OC}^2\text{H}^3\text{O})$ is called by Baeyer 'aqueous methylene acetate' (A. Baeyer, *Dent. Chem. Ges. Ber.* v. 1094; vi. 220).

Action of Formaldehyde on Aromatic Hydrocarbons.—Benzene treated with a mixture of methylal, acetic acid, and sulphuric acid, is converted into diphenyl-methane $\text{CH}_2(\text{C}_6\text{H}_5)_2$:

A mixture of 40 grams methylal, 120 benzene, and 400 glacial acetic acid is treated with a mixture of equal parts of glacial acetic acid and sulphuric acid till the greater part of the benzene has separated; the mixture after 24 hours is gradually mixed with 2,000 grams of sulphuric acid, keeping it cool; and the whole is left at rest for some hours, after which it is diluted with water and shaken up with ether. The ethereal solution when distilled yields diphenyl-methane.

Diphenyl-methane treated in a similar manner with methylal and acids is converted into a hydrocarbon, $\text{C}^{14}\text{H}^{14}$, which crystallises from alcohol in leaflets melting at about 90°, and having a constitution represented by the formula:

or else into the hydrocarbon $\text{C}^{12}\text{H}^{12}$, whose constitution is represented by the formula $\text{C}^6\text{H}^6 - \text{CH}_2 - \text{C}^6\text{H}^6$.

Formaldehyde and diphenyl yield a hydrocarbon which separates from chloroform in crystals.

When concentrated sulphuric acid is added to a mixture of methylene acetate, benzene and glacial acetic acid, an oil is formed which boils between 260° and a temperature above 360° , and consists of hydrocarbons.

Mesitylene, treated in a similar manner, gives a very characteristic reaction; by adding a cooled mixture of 10 parts acetic acid and an equal volume of sulphuric acid to a solution of 1 part mesitylene, 1 part methylene acetate, and 10 parts acetic acid, and leaving the mixture, after agitation from time to time, at rest for 24 hours, large colourless crystals are formed consisting of dimethyl-methane, $\text{CH}_2(\text{C}_6\text{H}_4)_2$, which, by recrystallisation from ether, is obtained in monoclinic prisms having almost the form of cubes; they melt at 130° and resolidify at 62° . This body is so readily produced that its formation may be used as a test either of mesitylene or of formaldehyde. The reaction never fails, even if, instead of the pure aldehyde, a solution of methyl alcohol and chromic acid in glacial acetic acid is used (Bayer, *loc. cit.*)

Action on Phenols.—Aqueous methylene acetate and hydrochloric acid yield, with phenol, a colourless resin, with pyrogallol, a substance resembling tannin; and with resorcin, an insoluble body which burns like tinder. Gallic and salicylic acid form similar substances: the compound obtained with gallic acid forms colourless needles having the composition $\text{C}^{12}\text{H}^{12}\text{O}^{10}$ (Bayer).

FRANGULIN, $\text{C}^{20}\text{H}^{20}\text{O}^{10}$, and **FRANGULIC ACID**, $\text{C}^{11}\text{H}^{10}\text{O}^4$ (1st Suppl. 623). A. Faust (*Ann. Ch. Pharm.* clxv. 229), prepares frangulin by digesting the bark of *Rhamnus frangula* for three days with alcohol of 90 p.c. at 25° – 30° ; partially distilling off the alcohol; adding lead acetate to the residue as long as a precipitate is formed; precipitating the filtered liquid with lead acetate; diffusing this precipitate through alcohol; and decomposing it with sulphuretted hydrogen. The resulting liquid filtered at the boiling heat yields, on cooling, crystals of frangulin.

Casselmann describes frangulin as crystallising under the microscope in square tables; Faust could not discern these tables either in his own preparation or in a specimen prepared by Casselmann; moreover, the two samples melted at 226° and 225° respectively, instead of 243° , as stated by Casselmann. Frangulin, after recrystallisation from hot alcohol, forms a lemon-yellow crystalline mass, and dissolves in alkalis with a deep cherry-red colour; when boiled with hydrochloric acid, it splits up into glucose and frangulic acid:

Frangulic acid, isomeric with alizarin, is most conveniently prepared by boiling the bark with rain-water for an hour, adding caustic soda, equal to one-twentieth or one-thirtieth of the weight of bark taken, and boiling again for several hours. The resulting liquid extract is supersaturated with hydrochloric acid, and boiled for some hours, whereupon the frangulic acid separates, and can be collected on a cloth filter; the dried and pulverised precipitate is boiled with alcohol, and the hot alcoholic solution precipitated by neutral lead acetate (which scarcely precipitates frangulic acid); the filtrate is precipitated with basic lead acetate; the precipitate disseminated through alcohol and decomposed by sulphuretted hydrogen; and the resulting liquid is heated to boiling and filtered hot, the acid then separating from the filtrate on cooling. This treatment with lead salts, &c., is repeated several times; and the purified acid, after being dried and boiled with benzene to separate sulphur, is finally recrystallised several times from hot alcohol. Different samples of bark differ much in the quantity of frangulic acid obtainable from them; in one case, 50 lbs. yielded only a few grams.

Frangulic acid melts at 252° – 254° , and sublimes partially at lower temperatures: it is but little soluble in hot water, and insoluble in cold water and alum-solution; alkalis dissolve it, with a red colour, removed on boiling with zinc-dust; on treating it with red-hot zinc-dust, anthracene is produced in small quantities; it crystallises with $1\frac{1}{2}$ mol. water, the last $\frac{1}{2}\text{H}_2\text{O}$ being removed only at 180° .

Dibromo-frangulic acid, $\text{C}^{11}\text{H}^8\text{Br}_2\text{O}^4$, is obtained by adding bromine to an alcoholic solution of the acid; it is a light-red crystalline mass, difficultly soluble in cold alcohol.

Diacetyl-frangulic acid, $\text{C}^{11}\text{H}^8(\text{C}^2\text{H}_3\text{O})_2\text{O}^4$, is obtained by heating the acid with an excess of acetyl chloride in sealed tubes to 130° – 150° ; it dissolves in about 300 parts of boiling alcohol, separating almost wholly on cooling, as a crystalline mass of four-sided prisms, visible under the microscope; it melts at 184° , and when decomposed by caustic potash-solution yields frangulic acid in its purest form.

FREIESLEBENITE (ii. 710). The crystalline system of this mineral has been variously stated to be monoclinic, rhombic, and triclinic. To decide this question, v. Zepharovich availed himself of the opportunity of examining a very fine crystal from Příbram, 2 mm. long, $\frac{1}{2}$ m. broad, and terminated at one end with 22 exceedingly lustrous

faces, together with many other less perfect ones from the same locality. All his determinations accorded in indicating the rhombic system as the true one. The specific gravity of these crystals differing not inconsiderably from that of freieslebenite, v. Zepharovich examined the typical specimens of the latter from Freiberg and Hiendelaencina, and found them to agree, in respect to form and density, with the data given in Brooke and Miller's *Mineralogy*. The Příbram mineral, therefore, is not freieslebenite, as Reuss, from his analytical results, which undoubtedly correspond with the composition of freieslebenite, was led to believe.

v. Zepharovich arrived at the following conclusions:—

1. The mineral hitherto termed freieslebenite consists of two distinct species, the one monoclinic, the other rhombic.
2. The two species have the same composition, but differ in form and density.
3. The substance $\text{Ag}^1\text{Pb}^2\text{Sb}^3\text{S}^{11}$ is, therefore, dimorphous.
4. The rhombic species, which has been termed diaphorite, and has a density = 5.90, is found at Příbram; no freieslebenite accompanies it. At Bräunsdorff, near Freiberg, it is also met with sparsely, and in association with freieslebenite.
5. The monoclinic species, freieslebenite, whose density is 6.35, appears most prominently at Freiberg and Hiendelaencina.
6. The forms of diaphorite and freieslebenite are allied by similar facial inclinations, and they in turn show a relation to the similarly constituted species, stephanite and antimonite (v. Zepharovich, *Jahrb. f. Mineralogie*, 1871, 277).

FUCUSOL. This substance, isomeric with furfural, obtained by boiling seaweeds with dilute sulphuric acid, has been re-examined by Stenhouse (*Proc. Roy. Soc.* xx, 80), who discovered it (ii, 718). The results of the new investigation agree perfectly with those of the former one as regards the differences in the physical properties of furfural and fucosol, the difference between the products obtained by the action of ammonia on the two substances, and between the bases derived from these products. *Fucosaniline hydrochloride* crystallises, like furfuraniline hydrochloride, in needles of a splendid purple colour.

Furfural, boiled with water and silver oxide, yields silver pyromucate, $\text{C}^2\text{H}^2\text{AgO}^3$, which crystallises in scales. Fucosol, similarly treated, yields an isomeric silver salt which is moderately soluble in boiling water, and crystallises, on cooling, in long flat needles.

β -Pyromucic acid, separated from this salt by hydrochloric acid, crystallises from its aqueous solution in small rhomboidal plates melting at 130° , whereas ordinary pyromucic acid forms flat needles melting at 133° (Stenhouse), at 134.3° (Schwanert).

G.

GADOLINITE. The bi-refracting crystals of gadolinite from Hitteröo, containing 10 to 12 p.c. of glucina, are monoclinic, having the axial ratio 1 : 0.848 : 0.630; angle of inclined axes = $90^\circ 32'$; $\infty\text{P} = 116^\circ$ (Descloizeaux, *Ann. Chim. Phys.* [4], xviii, 305); compare 1st *Suppl.* 627.

GAHNITE, Al^2ZnO^2 , or $\text{ZnO}.\text{Al}^2\text{O}^3$. The specimens of this mineral found in the Franklin Furnace at Mine Hill, New Jersey, differ from the gahnite of other localities in the frequent occurrence of the cubic plane. These planes are often the largest, giving the crystals the form of cubes with truncated dodecahedral edges, and only small octohedral planes. There are also minute planes of the trapezohedron 202, truncating the edges of the dodecahedron; others of the trigonal-trisoctahedron 30; and sometimes two planes between the cubic and octohedral which appear to belong to the forms 404 and 808. These surfaces, rounded and feebly lustrous, blend in a curved surface, and do not admit of accurate measurement. The inclinations on a cubic plane are: for 404, $160^\circ 30'$; for 808, $170^\circ 30'$. The crystals vary in diameter from $\frac{1}{8}$ to $1\frac{1}{2}$ inch, are blackish green, their fragments being olive-green, and have a hardness = 7.5, and a specific gravity = 4.80–4.91. Two analyses gave as a mean result:—

Alumina	49.78	Oxygen-ratios.	
Ferric oxide	8.58	23.20)	25.77
Zinc oxide	39.62	2.57)	
Manganous oxide	1.13	7.82)	
Magnesia	0.13	0.25)	8.12
Silica	0.57	0.05)	
	99.81		

This gives the ratio of oxygen of R and H as 1 : 3.17. By assuming 1.56 p.c. of the ferric oxide to be present as the lower oxide, the ratio becomes exactly 1 to 3. This variety of gahnite is richer in zinc than any heretofore examined. It occurs in association with black mica, apatite, calcite, and a brownish variety of chrysolite which contains zinc (G. J. Brush, *Sill. Am. J.* [3], i. 28).

GAIZE, called also *Pierre morte*, is a siliceous rock underlying the cretaceous strata in the Department of the Ardennes, and forming in the southern part a layer 100 meters thick. It has a gray-blue to light brown colour; sp. gr. = 1.48. When gently ignited it loses 0.022 of its volume, and has then a specific gravity of 1.44. It may be cut with a knife. Crucibles made of it bear, without alteration, a temperature at which iron melts. It contains a large amount of soluble silica, and when boiled, after calcination, with caustic soda, yields a sodium silicate which, in the dry state, contains 68-69 p.c. of silica. The first eleven of the following analyses are by H. Sainte-Claire Deville & Desnoyers (*Compt. rend.* lxx. 581); the twelfth by A. Scheurer-Kestner (*ibid.* lxxii. 767).

GALACTIN. A nitrogenous substance obtained, according to Morin (*J. Pharm.* [4], xiv. 11), from milk by first precipitating the casein with acetic acid; coagulating the albumin by boiling; removing fat by ether; concentration; filtration from earthy phosphates; allowing the sugar to crystallise out; and finally precipitating the galactin by alcohol. As thus prepared it contains a little gelatin. 36 parts of dried milk yielded about 1 part of galactin.

Galactin is soluble in water, insoluble in ether and in alcohol, and is not transformed into gelatin by boiling its aqueous solution. It is precipitated by tannin, but the precipitate differs from the corresponding precipitate with gelatin in redissolving at a temperature of 60°. This property renders the detection of galactin in morbid fluids easy.

Galactin emulsifies fats. It is found in blood, gastric juice, animal membranes, milk, eggs, and many morbid animal fluids, and probably plays an important part in animal nutrition. It likewise exists in notable quantity in the juices of edible plants, and in the fluid of the embryonal cotyledons.

GALBANUM OIL. The blue oil obtained by distillation of galbanum appears, from Kachler's experiments, to be most probably identical with blue chamomile oil (p. 278).

GALLEIN and **GALLIN** (A. Baeyer, *Deut. Chem. Ges. Ber.* iv. 457, 565).—*Gallein*, $C^{14}H^{14}O^4$, is a colouring matter produced by heating pyrogallie acid with phthalic acid, or, better, with phthalic anhydride, for some hours, to 170°-200°, until the mass becomes thick; on dissolving it in hot alcohol, filtering, and adding water to

the filtrate, a precipitate of nearly pure gallein is obtained, which is easily purified by crystallisation from hot dilute alcohol. The crystals appear brown by reflected and blue by transmitted light; when the solution dries up, the gallein remains as a mass with a greenish-yellow metallic lustre. It is almost insoluble in cold water; in hot water it is sparingly soluble with a red colour; in alcohol it dissolves freely, forming a dark-red solution. Ether also takes up a little, but the solution is colourless. Gallein bears a strong resemblance to hæmatein, the colouring principle of logwood; like the latter, it dissolves in caustic potash with a splendid blue colour, the solution soon assuming a dirty tinge, and in ammonia with a violet colour. The colours which it produces on cloth mordanted with iron and alumina, are finer and more stable than logwood colours, and resemble more those of barwood.

Gallein is decomposed by heat like hæmatein, carbonisation taking place and no sublimate being formed. It is also converted by reducing agents into a colourless compound, gallin, just as hæmatein is converted into hæmatoxylin.

Gallein may also be formed by heating pyrogallie acid with trimetic, pyromellitic and prehnitic acids, as well as with phthalic acid. This shows that the phthalic acid takes no part in the reaction, which is simply a dehydration: $3C^6H^4O^3 - 2H^2O = C^{18}H^{10}O^8$. Other dehydrating agents, such as sulphuric acid and zinc chloride, yield on fusion with pyrogallie acid, brown or black bodies, but no gallein.

Gallin, $C^{18}H^{10}O^8$.—When gallein is boiled with a large quantity of water to which zinc and dilute sulphuric acid are added, the dark colour of the liquid changes to a light reddish-yellow, and on cooling, oily drops separate, which after some time become crystalline. These crystals consist of gallin rendered impure by gallein; the gallin is best purified by crystallisation from a warm aqueous solution of pyrogallie acid. It is obtained in beautiful glistening rhombohedrons and prisms, which are nearly colourless; dried *in vacuo*, they yield, on analysis, numbers agreeing with the formula above given. Gallin, in the solid state, or in aqueous solution, very readily assumes a red colour; it is less stable than hæmatoxylin, which in other respects it greatly resembles, being reoxidised to gallein in contact with ammonia, just as hæmatoxylin is converted into hæmatein. It dyes mordanted fabrics like gallein.

GALLIC ACID, $C^6H^4O^3$. This acid and pyrogallie acid are very easily oxidised by electrolysis. At first no oxygen is evolved at the positive pole, the gas being entirely absorbed; afterwards carbon dioxide is evolved, and eventually a mixture of this gas with oxygen and carbon monoxide (Bourgoin, *J. Pharm.* [4], xiii. 376).

Derivatives of Gallie acid.—In the preparation of ellagic acid by heating gallie acid to 120° with arsenic acid, if the product, insoluble in water and consisting chiefly of ellagic acid, be treated with sodium-amalgam, then acidified, filtered and agitated with ether, several substances are obtained which are distinguished from one another by the difference of their solubility in water.

Amongst them is a substance, $C^{14}H^{10}O^7$, consisting of pale greenish-yellow, glistening needles, which are sparingly soluble in cold water, and when treated with calcium hypochlorite, become first dirty violet, then brown, and finally almost colourless; with ferric chloride they become greenish-blue, then green, and on the addition of soda, greenish-brown; with ammonia they turn brown; with silver nitrate, brownish-black from reduced silver; and with nitric acid, yellowish. Strong sulphuric acid dissolves them partially, with yellow colour. Manganese dioxide and strong sulphuric acid give a fine purple-red.

The substance $C^{14}H^{10}O^7$ is a weak acid, and the salts which it forms with the alkaline earths oxidise quickly in the air; a crystalline barium salt, however, appears to be formed by treating it with barium carbonate in a stream of hydrogen.

Occasionally, another crystalline substance, probably $C^{12}H^8O^6$, is obtained, which is also a weak acid, and but slightly soluble in water; it becomes red by treatment with ferric chloride. Amongst the products which are more soluble in water, and reddened litmus strongly, is found a substance which crystallises in plates, and gives a bluish-green reaction with ferric chloride (Rombold, *Ann. Ch. Pharm.* clvi. 116).

Dibromogallie acid, treated with silver oxide, yields carbonic and pyrogallie acids; heated with aniline, it yields gallie acid, together with pitchy products. Gallie acid is also produced on heating the dibrominated acid with argentocyanide of potassium (Priwoznik).

Acetyl and Benzoyl Derivatives.—By the action of acetyl chloride on gallie acid, Nachbaur has obtained a compound which he regards as tetracetyl-gallie acid (ii. 761). Schiff, however (*Ann. Ch. Pharm.* clxiii. 209), finds that, by the action of either acetic anhydride or acetyl chloride, a crystallisable product results, which yields 42.6 p.c. of acetyl on decomposition by magnesia, and is therefore triacetyl-gallie acid, $C_{18}H_{10}O_8 \cdot 3(C_2H_3O)_2$, which requires 43.5 p.c. acetyl, whereas the tetracetyl-acid would

require 51 p.c. Nachlaur also found that benzoyl chloride gave a dibenzoyl-acid; but Schiff finds that it is a tribenzoyl-compound. Neither the triacetyl- nor the tri-benzoyl-gallic acid gives any coloration with ferric chloride: hence no phenolic hydroxyl is present in these compounds.

In accordance with these results, Schiff assigns to gallic acid the formula

Bromacetyl-gallic acid, $\text{C}^6\text{H}^2 \begin{Bmatrix} (\text{OH})^2 \\ \text{OC}^2\text{H}^2\text{BrO} \\ \text{COOH} \end{Bmatrix}$, is formed by the action of gallic acid on bromacetyl bromide. It is an uncrystallisable compound, soluble in hot alcohol, and precipitable by water (Priwoznik, *Deut. Chem. Ges. Ber.* iii. 642).

Tetracetyl-dibromogallic acid, $\text{C}^6\text{Br}^2 \begin{Bmatrix} (\text{OC}^2\text{H}^3\text{O})^2 \\ \text{COOC}^2\text{H}^3\text{O} \end{Bmatrix}$, is formed, with evolution of hydrochloric acid, on dissolving dibromogallic acid in acetyl chloride. It is very slightly soluble in cold water, easily in boiling water, also in alcohol and in ether; crystallises in colourless needles which melt under water at 91° , and decompose at a temperature a little above their melting-point. The aqueous solution gives, with ferric chloride, a violet colour quickly turning green (Priwoznik).

GALLIC ETHERS (Ernst a. Zwenger, *Ann. Ch. Pharm.* clix. 27). These ethers can be readily prepared by passing a current of dry hydrochloric acid through a boiling solution of gallic acid in anhydrous alcohol. When an excess of hydrochloric acid and of alcohol is employed, the acid is almost entirely converted into the ether. On evaporating the dark-coloured liquid to dryness at 100° , slowly heating the residue to its melting-point, and then crystallising the product two or three times from water, the ether is obtained in the pure state.

Ethyl Gallate, $\text{C}^6\text{H}^2 \begin{Bmatrix} (\text{OH})^3 \\ \text{COOC}^2\text{H}^5 \end{Bmatrix} + 2\frac{1}{2}\text{H}^2\text{O}$, crystallises from its aqueous solution in transparent rhombic prisms of a pale yellow colour, which melt in their water of crystallisation at 90° . It is scentless, and its solutions have a bitter taste and acid reaction. It is only slightly soluble in cold water, but dissolves easily in hot water, and crystallises out almost completely on cooling. It dissolves readily in alcohol and ether, and may be crystallised from chloroform—in which, however, it is but slightly soluble—in anhydrous colourless needles which melt at 150° . When cautiously heated, it sublimates in lustrous needles. Potassium and sodium hydrate decompose the ether in the cold, with liberation of alcohol; and if the air be permitted to have access to the solution, the alkaline gallate formed quickly oxidises, and assumes a dark colour. The ether gives precipitates with the salts of most of the heavy metals, but they have not been obtained of constant composition. The lead salt is a yellowish-white precipitate, the zinc salt a white, and the copper salt a reddish-brown precipitate. Ferrous salts colour the solution of the ether a pale violet, which changes to blue on exposure to the air, whilst ferric salts give the blue colour at once. Silver and gold salts are quickly reduced in the cold. The only compound of the ether which has been obtained of constant composition, was prepared by adding a slight excess of a cold saturated solution of acid sodium carbonate to a warm saturated solution of the ether. In a few minutes a compound having the formula $\text{C}^6\text{H}^2\text{Na}(\text{C}^2\text{H}^3\text{O})^3 + \text{C}^6\text{H}^2(\text{C}^2\text{H}^3\text{O})^3$ separated in small, hard, yellow crystals. These were almost insoluble in cold water, but could with care be crystallised from hot water. The crystals are decomposed by hydrochloric acid, which removes the sodium and leaves pure gallic ether. When they are heated between two watch-glasses, the gallic ether sublimates, whilst the sodium ethyl gallate remains behind in a partially decomposed state. On heating a solution of the sodium-compound for some time, or better, a solution of the ether in an excess of sodium carbonate, a lemon-yellow crystalline precipitate is obtained, which is insoluble in cold water, but dissolves easily in solutions of the alkaline hydrates; the addition of hydrochloric acid to its alcoholic solution produces a pale yellow crystalline precipitate, which has the properties and composition of ellagic acid, $\text{C}^{10}\text{H}^6\text{O}^8 + 2\text{H}^2\text{O}$. The lemon-yellow powder is acid sodium ellagate, $\text{C}^{10}\text{H}^2\text{NaO}^8 + \text{H}^2\text{O}$, and is formed by oxidation of the sodium-compound of ethyl gallate:

Acid potassium carbonate has no action on the ether in the cold, but on applying heat, potassium ellagate is formed. When a solution of ethyl gallate in ammonia is exposed to the air, it first acquires a rose-red tinge which, after a time, becomes deep

red, and the solution finally deposits a greenish-yellow crystalline precipitate of ammonium colligate, which is scarcely soluble in ammonia.

According to Schiff (*Ann. Ch. Pharm.* cxliii. 209), an aqueous solution of ethyl gallate gives with excess of lead acetate, a precipitate having the composition $Pb_2 \{C^2H^3(C^2H^3)O^3\}$. This salt treated with ethyl iodide yielded much lead iodide but no definite organic product.

Ethyl gallate, boiled for some hours with acetyl chloride, forms ethyl triacetyl-gallate, $C^2H^3(O.C^2H^3O)^3.COOC^2H^3$. The oily product began to crystallise after eight months standing; it was insoluble in water, soluble in alcohol, gave no violet colour with ferrous salt, or precipitate with lead acetate (Schiff).

Amyl Gallate, $C^6H^{12} \{ \frac{(OH)^3}{CO.O(C^2H^3)} \}$, crystallises in fine, silky, colourless needles which melt at 139° and sublime when cautiously heated. It is scentless and has a bitter taste. It is slightly soluble in cold water, but more readily in hot water, the solution solidifying on cooling to a crystalline pulp. Its solutions have an acid reaction, and when the ether is heated under the surface of water, it melts to an oil. It is readily soluble in cold alcohol and ether, also in hot chloroform. No compound analogous to that obtained from ethyl gallate was observed on treating the ether with acid sodium carbonate, but its other reactions with alkalis and metallic salts are similar to those of the corresponding ethyl-compound (Ernst a. Zwenger).

GALLOTANNIC ACID. See TANNIC ACID.

GALLS. The following comparative analyses of English and Aleppo galls are given by J. Barrow (*Chem. News*, xix. 116).

	Aleppo	English
Tannin	61.65	26.71
Gallie acid	1.60	traces
Woody fibre	15.68	47.88
Water	12.32	20.61
Colouring matter, &c.	8.75	4.80
	100.00	100.00

GARNET. A transparent garnet occurs at Jordansmühl, in Silesia, partly implanted on decomposed prehnite; sp. gr. = 3.609. The crystals are dodecahedral, with their faces somewhat curved. The analysis was made with material somewhat contaminated with an imbedded chloritoid mineral, to which must be assigned a part of the oxides of manganese and nickel, the remainder constituting a nearly pure calcio-aluminic garnet:

SiO^2	Al^2O^3	CaO	FeO	MnO..	NiO	MgO	H^2O
37.88	21.13	31.28	4.19	0.45	0.18	2.88	1.08 = 99.07

(Websky, *Zeitschr. d. deutsch. geolog. Ges.* xxi. 753).

A green garnet from S. Piero in Elba has been analysed by G. vom Rath (*ibid.* xxii. 637, 660). It occurs, together with a massive reddish-brown garnet, and occasionally admixed epidote, in groups which are intimately united in their origin with a saussurite-gabbro. Sp. gr. = 3.286.

SiO^2	Al^2O^3	Fe^2O^3	CaO	MgO	N†
30.29	16.16	10.05	29.23	5.85	0.64 = 101.22

The octohedral garnets of the locality occur in a cleft of a nearly related rock, a mixture of garnet and epidote. Another locality, a short distance off, yields crystals of the combination $\infty O . 2O_2$, without any indication of O. The garnet of the granite vein of S. Piero shows either ∞O or $2O_2$ predominant, sometimes with $3O_2^3$ and ∞O_2 subordinate. The colours are various, including shades of yellow, red, and green.

A light red garnet, sp. gr. 3.57, imbedded in a granular limestone from San Juan in Mexico, was found by Damour (*Compt. rend.* lxxiii. 1041) to contain:

SiO^2	Al^2O^3	Fe^2O^3	CaO	MgO	MnO	Loss by ignition
39.46	21.69	1.36	35.75	0.67	0.96	0.40 = 100.29

Small garnets, usually crystallised in dodecahedrons and easily detached from the rock, occur in a damourite slate in the neighbourhood of Salm-Château in Belgium. They belong to the variety known as spessartin, and contain 37 p.c. manganous oxide. This is somewhat remarkable in a crystallographic point of view, inasmuch as

* Partly as FeO.

† Loss by ignition.

the so-called spessartin has hitherto been known only in the form of the trapezohedron 202, or of the combination 202. ∞ O (de Koninck, *Jahrbuch f. Mineralogie*, 1873, 319).

Formation of Garnet from Chlorite.—Pseudomorphs of chlorite after garnet have often been observed. One lately obtained from the Saualp in Carinthia, exhibits the half of a garnet-dodecahedron broken through the middle, and surrounded by a crust of chlorite about 4 mm. thick. The garnet has a columbo-red colour and fatty lustre; the chlorite is dark green with fine scaly structure. The thin laminae of chlorite appear to be deposited on the faces of the crystal very irregularly, and the surface of separation of the garnet and chlorite is irregularly zig-zagged. Under the microscope it is plainly seen that the chlorite has been formed from the garnet.

Analysis of the two minerals gave:

SiO ²	AlPO ³	Fe ² O ³	FeO	CaO	MgO	H ⁺ O	
38.59	17.57	16.43	21.12	2.27	4.27	—	= 100.25
25.19	21.66	9.09	14.92	—	18.73	11.53	= 100.12

To convert the garnet into chlorite, a third of the silica (13 p.c.), a third of the ferric oxide, a third of the ferrous oxide, and the whole of the lime have been removed, and at the same time 14 p.c. of magnesia and 11 p.c. water have been added (Niedzwiedki, *ibid.* 951).

Conversion of Garnet into Mica.—A case of pseudomorphosis of garnet into mica has been found in the mica crystals occurring in a vein of pegmatite at Roestoeel, near Arendal. As in another part of the same vein a great number of unchanged garnets are found, and the innermost part of some of the mica crystals consists of unchanged garnet, there can be no doubt that the mica crystals, which have the crystalline form of the garnet, owe their origin to a true pseudomorphosis. Comparing the experimentally determined composition of the unchanged garnets and of a mica crystal, it is found that the less soluble compounds, ferrous oxide, and the oxides of manganese, calcium, and magnesium, have been replaced by the more soluble oxides of potassium and sodium (A. Helland, *Pogg. Ann.* cxlvi. 480).

On the converse transformation of Mica into Garnet which accompanies the formation of Granulite from Gneiss, see GRANULITE.

GAS ANALYSIS. Frequent use is made in gas analysis of balls made of the dioxides of manganese or lead, or of lead phosphate, which, however, are extremely liable to break, especially after they have been soaked with phosphoric acid. To obviate this inconvenience, Ludwig (*Ann. Ch. Pharm.* clxii. 53) recommends mixing plaster of Paris with those absorption-agents which are not fusible, making the mixture into a paste with water, and pressing it round the platinum wire into the mould, the inside of which has been oiled. A hard ball, firmly attached to the platinum wire, is thus formed in a few minutes; but in order to prevent absorption of carbonic acid by the physical action of the pores, this ball has to be treated with phosphoric acid.

For the absorption of hydrogen sulphide, the balls are prepared by mixing two parts of lead phosphate with three parts of plaster of Paris. For the absorption of sulphur dioxide, balls consisting of plaster of Paris and dioxide of lead or manganese give good results.

For the determination of carbon monoxide, balls of plaster of Paris steeped in a mixture of one volume of saturated chromic acid solution and two volumes of water are left twelve hours in the mixture of gases to be examined. The carbonic acid formed has to be determined by absorption with potash.

The mould used for the preparation of the balls must in this case have its inside covered with a layer of paraffin, as oil would be acted upon by the chromic acid.

Gas Analysis for Technical Purposes.—C. Winckler (*J. pr. Chem.* [2], vi. 301) employs for technical gas analysis, an apparatus which is a modified form of Hoffmann's apparatus for the decomposition of ammonia, &c. It consists of a two-limbed tube, one limb of which is wider than the other, and furnished near the upper and lower ends with glass stopcocks, the space between these being graduated into fifths of cubic centimeters.

The second limb of the tube is connected with the first by means of caoutchouc tubing; it is also furnished with a stopcock (as in Hoffmann's apparatus). The apparatus may be turned upon its stand either vertically or horizontally, as required. The gas to be analysed is made to pass through the apparatus for some time, the stopcocks are then closed, and the volume of gas in the graduated tube is noted. The liquid which is to act as absorber is poured into the second tube, and by opening the lower stopcock of the graduated tube, some of it is made to pass into this latter.

To promote absorption, the apparatus is placed horizontally for a few minutes. After a little time the vertical position is resumed, and more liquid allowed to enter.

and so on, until on opening the connecting stopcock no further in-rush of liquid takes place. The level of the liquids in both tubes being made to coincide, the volume of liquid in the graduated tube corresponds with the volume of gas absorbed. If several constituents of a gas are to be estimated, a number of these instruments will be required.

To reduce the gas to a stated temperature, generally that of the absorbing liquid, it is made to pass through a small flask containing mercury, which is surrounded by a quantity of the liquid at the ordinary temperature of the air. The gases are usually passed through wetted cotton-wool before entering the graduated tube.

Water vapour is absorbed by strong sulphuric acid, carbon dioxide by caustic potash, and so on. A mixture of oxygen, carbon dioxide, sulphur dioxide, and nitrogen is analysed by absorbing the first three gases with pyrogallic acid in caustic potash; in another trial the oxygen and carbon dioxide are absorbed by caustic potash alone; and in a third, the sulphur dioxide only is removed by a solution of iodine in potassium iodide.

Carbon monoxide is absorbed by a solution of cuprous chloride in hydrochloric acid; if the gas contains at the same time carbon dioxide and oxygen, these are removed by bubbling it through tubes containing a solution of pyrogallic acid in caustic potash previous to its entering the apparatus.

The numbers given are generally within 0.1–0.3 p.c. of the theoretical amounts.

Another, and somewhat complicated, apparatus for technical gas analysis, especially for the determination of oxygen in the gases from the lead chambers, is described by Max Liebig (*Dingl. polyt. J.* cccvii. 37).

A simplified form of Frankland and Ward's apparatus for gas-analysis is described by J. Parry (*Chem. News*, xxiv. 282).

GASES. Absorption by Charcoal.—Experiments on the influence of pressure on the absorption of ammonia, carbon dioxide, and cyanogen gases by cocoa-nut charcoal have been made by J. Hunter (*Chem. Soc. J.* [2], ix. 76). Several series of observations were made on each gas. The results of those series which included the greatest range of pressure are given in the following table, in which V denotes the volume of gas absorbed by one volume of cocoa-nut charcoal at 6° C. and under the pressure P in millimeters.

Ammonia		Carbon Dioxide		Cyanogen	
V.	P.	V.	P.	V.	P.
170.7	760.0	73.2	760.0	107.5	760.0
174.3	1104.3	84.0	927.9	107.7	1160.6
176.0	1178.0	85.5	1014.6	110.3	1201.2
178.2	1269.2	87.3	1100.2	112.0	1628.8
180.8	1369.5	91.6	1412.8	115.4	1873.4
183.5	1486.5	95.5	1625.6	121.0	2204.7
188.7	1795.1	100.4	1912.9	124.9	2678.2
196.7	2002.6	108.0	2324.1		
209.8	2608.5	113.0	2960.2		
		132.4	3793.2		

These numbers show : 1. That the amount of absorption increases with the pressure.
2. That the same change of pressure produces about the same amount of increase in the quantity of each gas absorbed.

On comparing the relative weights of the absorbed gases, it is found that cocoa-nut charcoal absorbs a greater weight of cyanogen than of either ammonia or carbon dioxide.

Influence of Temperature.—Hunter has also made experiments on the influence of temperature on the quantity of ammonia and cyanogen absorbed by charcoal (*Chem. Soc. J.* [2], x. 649). Former experiments (1st Suppl. 630) had indicated that a gas capable of being largely absorbed by charcoal exists within the pores of that substance in a partially liquid state, and in accordance with this it is found that the volume of ammonia gas absorbed by cocoa-nut charcoal decreases regularly and continuously from 0° to 50°, but that at this point, beyond which probably the ammonia can no longer exist in the partially liquid state, a sudden change occurs, and from 50° to 80° the quantities of gas given off are considerably less for equal increments of temperature than between 0° and 50°. For cyanogen, on the other hand, the decrease of absorptibility is regular and continuous from 0° to 80°.

The following table exhibits the volumes, V , of the two gases (reduced to 760 mm.) absorbed by cocoa-nut charcoal at the temperatures, T , Centigrade :—

Ammonia		Cyanogen	
V .	T .	V .	T .
175.7	0°	113.7	0°
169.6	5	110.9	5
163.8	10	109.6	10
157.6	15	108.2	15
148.6	20	107.0	20
140.1	25	105.3	25
131.9	30	103.7	30
123.0	35	101.1	35
114.1	40	99.2	40
104.2	45	97.8	45
96.0	50	96.2	50
90.2	55	94.4	55
88.1	60	92.1	60
86.4	65	90.0	65
82.6	70	88.2	70
		86.7	75

The absorption of cyanogen is almost entirely confined to the first ten minutes, after which it proceeds much more slowly.

Hydrogen and nitrogen are but very slightly absorbed by cocoa-nut charcoal, one volume of the charcoal absorbing, on the average, 4.4 vol. hydrogen and 15.2 vol. nitrogen reduced to 3° C. and 760 mm.

Diffusion of Gases. J. Loschmidt (*Wien. Acad. Ber.* lxi. [2], 367; lxii. [2], 468; *Jahresb.*, 1870, 58) has made experiments on the free diffusion of gases, by means of an apparatus consisting of two glass tubes of equal length and diameter, closed at one end, and placed vertically one above another, the communication between them being closed or opened at pleasure by means of a sliding metal plate worked by a screw. The tubes were filled, first with mercury, then with the gases to be experimented upon, the apparatus placed vertically, the slider opened, shut again after half-an-hour to an hour, and the gaseous mixture analysed. In this manner, experiments were made with air and carbon dioxide; hydrogen and carbon dioxide; hydrogen and oxygen; carbon dioxide and oxygen; carbon dioxide and carbon monoxide; carbon dioxide and marsh gas; carbon dioxide and nitrogen monoxide; sulphur dioxide and hydrogen; carbon monoxide and oxygen; carbon monoxide and hydrogen;—at temperatures between -21° and $+21^{\circ}$.

The diffusion-constant, K_1 , calculated from the results of the experiments on these several mixtures, that is to say, the velocity with which the two gases mix, is approximately in inverse proportion to the square roots of the molecular weights, inasmuch as the values of K_1 , calculated from the formula

$$K_1 = \frac{K_0}{\sqrt{m_1 m_2}}$$

come out very nearly equal. Perfect agreement is not to be expected, since the value of K_1 is affected by the united influence of the volume and the form of the gaseous molecules, as well as by the nature of their constituent elements.

The diffusion-constant K is likewise proportional to the square of the absolute temperature, and with increased rarefaction, it is inversely proportional to the pressure of the gas,—so that

$$K = K_0 \frac{T^2}{p};$$

and by combining the expression $K = \frac{K_1 T^2}{p \sqrt{m_1 m_2}}$ with that of Gay-Lussac and

Boyle's laws, according to the mechanical theory of gases, viz.: $pv = \frac{mm^2}{2}$, as well as

with that of the absolute temperature, viz.: $T = \beta \frac{m m^2}{2}$, we arrive at the remarkable formula,

$$K = l \frac{v_1 v_2}{N},$$

in which v_1, v_2 denote the mean velocities of the molecules of the two gases, N the number of molecules in the unit of volume, and l a constant factor.

Wretschko (*Wien. Acad. Ber.* lxxii. [2], 575) has extended the preceding investigation to mixed gases. One of the tubes was filled with a gas A, the other with a gas B, and to both was added a third gas, C, in equal volumes p.c. The various gaseous mixtures were made with hydrogen, oxygen and carbon dioxide. A comparison of the resulting velocities of diffusion with those obtained by Loschmidt leads to the following conclusions:—

1. If the gas C is identical with either of the gases A, B, the diffusion-velocity of these gases is not altered by the admixture of C.

2. If C is different from both A and B, then—(a). The diffusion-velocity of A into B is altered by the admixture of C, to a greater degree in proportion as more of the gas C is present in each tube; and this velocity increases for the gases A and B when the gas C is specifically lighter than either; diminishes when C is specifically heavier than either; increases for the one gas and diminishes for the other when C, with regard to its sp. gr., lies between A and B;—(b). Whereas before diffusion there was an equal quantity of the gas in both tubes, this is no longer the case during diffusion, the specifically lighter of the two gases A and B being then found in larger proportion in the upper tube.

The preceding theorems relating to the diffusion, both of simple and mixed gases, have also been deduced by Stefan from the fundamental principles of the mechanical theory of gases (*Wien. Acad. Ber.* lxxiii. [2], 63-124), abstr. *Jahresb. f. Chem.* 1871, 51).

Diffusion through Septa.—Dufour (*Pogg. Ann.* cxlviii. 490) has made experiments on the diffusion of gases through porous walls, and the accompanying changes of temperature.

1. *Diffusion of Two Gases under Constant Pressure.*—On that side of the porous wall at which the gas diffuses inwards, there is an elevation of temperature, accompanied by a lowering of temperature at the other side. This is supposed to be due to a partial condensation of the gas on the porous substance in the one instance, and to a partial rarefaction in the other.

2. *Diffusion with Change of Pressure.*—When one gas diffuses into a porous vessel which already contains another gas (as hydrogen into a vessel containing air), there is a slight elevation of temperature, accompanied by an increase of pressure. As the first gas diffuses out, the thermometer falls until a point is reached at which it again begins to rise. Dry air diffuses into air which is relatively wetter than itself; this phenomenon is accompanied by the same changes of temperature as already noticed in the case of two gases.

Thermo-diffusion.—If a limited portion of a gas contained in an infinitely long tube were in a state of greater density than the rest, and it were heated unequally at both ends, a continuous motion of the gas would set in, which in the denser portion would be directed from the colder to the warmer end. This theoretical result, deduced by Neumann, has been verified experimentally by Feddersen (*Pogg. Ann.* clxviii. 302), who obtained a greater density of the gas in one portion of a glass tube by introducing a plug of some gas-absorbing substance, as spongy platinum or palladium, plaster of Paris, charcoal, or magnesia alba.

In one case a plug of spongy platinum 31 mm. long was placed in a glass tube 12½ mm. wide, each end of which was connected with a narrower glass tube 3½ mm. wide; a drop of sulphuric acid placed in each of these tubes indicated the movement of the gas column as soon as both ends of the platinum plug were heated unequally. When, for instance, one end of the plug was heated to 200°, whilst the other one was kept as much as possible at 8°, the following results were obtained:—

Time				Cold side		Warm side	
				Observed	Calculated for 10' time	Observed	Calculated for 10' time
h.	m.	h.	m.				
12	0	until	12 16	225 mm.	225 mm.	no tube	—
12	10	"	12 15	94 "	188 "	95 mm.	190 mm.
11	15	"	12 25	no tube	—	241 "	241 "
12	25	"	12 30	105 mm.	210 "	95 "	190 "
12	30	"	12 35	110 "	220 "	no tube	—

As all the other substances gave similar results, it appears to be a general fact that porous substances used as diaphragms have the property of drawing gases through them from the cold towards the warm surface. Exactly the reverse of this phenomenon takes place in the diffusion of two different gases through a porous diaphragm, as a rise of temperature is observed on that side of the diaphragm where the gas with the greater power of diffusion enters.

Endosmose of Gases through Vegetable Membranes.—Barthélemy (*Compt. rend.* lxxvii. 427) has made experiments on the passage of gases through the leaf of a begonia, which by gradual withering during winter, had become reduced to mere cuticular tissue. When common air was dialysed through it, the gas passing through contained 31.41 p.c. of oxygen. The comparative permeability of the membrane to various gases was ascertained by exposing one surface of the membrane to the gas, and relieving the other side of pressure, the experiments being continued till equal volumes of gas had in every case passed, the different times required showing the relative permeability. It appears that the leaf membrane admits carbonic acid 13 to 15 times more readily than nitrogen, and 5 to 7 times more readily than oxygen. This high relative permeability of carbonic acid is somewhat diminished if the gas be quite dry. These results are similar to those obtained by Graham with a caoutchouc membrane.

Mechanical Theory of Gases (Naumann, *Ann. Ch. Pharm.* 1870, *Suppl.* vii. 340; *Deut. Chem. Ges. Ber.* ii. 690; Gmelin-Kraut's *Handbuch der Chemie*, i. Band, 1 ste Abtheilung, p. 14).

(1). *Relations between Volume, Pressure, and Temperature.*—According to the theory of Kröning and Clausius, explained in the article HEAT (iii. 131), the individual molecules of gases are supposed to be continually moving forward in straight lines, till they come in contact with other molecules or with the walls of the surrounding envelope, after which they rebound like elastic balls and recommence their rectilinear movement. The pressure of the gas may be regarded as the sum of all the impacts made by its molecules on the sides of the envelope, in consequence of their progressive motion. The pressure on a unit of surface will therefore depend: 1. On the mass of the individual gas-molecules; 2. On their velocity; 3. On the volume of the gas; 4. On the number of gas-molecules present.

Now let m and M denote the masses of two gas-molecules, c and C their velocities. The strength of the impacts of these molecules being directly proportional to their masses and to their velocities, will also be proportional to the products of these magnitudes, that is, $mc : MC$. But the number of impacts which take place in a given time is also proportional to the velocity: consequently, the pressures are proportional to the products of the masses of the molecules into the squares of their velocities:

$$p_{mc} : P_{MC} = mc^2 : MC^2 = \frac{mc^2}{2} : \frac{MC^2}{2}; \dots \quad (1)$$

that is to say: *The pressure is proportional to the working force (vis vivâ) of the molecular movements.*

By the working force of the molecular movement of a gas we must here understand the mean working force of a molecule. For the several molecules, in consequence of their frequent collisions taking place in all imaginable directions, exhibit the most various changes of velocity, and at any given instant the most various amounts of working force, $\frac{mc_1^2}{2}$, $\frac{m^2}{2}$, $\frac{mc_2^2}{2}$, &c., the total amount of their working forces remaining, however, always the same. The pressure is therefore the same as if all the n molecules were actuated by the same working force, viz.:

$$\frac{mc^2}{2} = \frac{1}{n} \left(\frac{mc_1^2}{2} + \frac{mc_2^2}{2} + \frac{mc_3^2}{2} + \&c. \right)$$

Now let n be the number of gas-molecules at equal distances, and at rest, contained in a space whose cubical content is v . The unit of cubic space will then contain a number of molecules $n_1 = \frac{n}{v}$; the number situated on a straight line equal to the unit of length will be $\sqrt[3]{\frac{n}{v}}$; and the number in a square unit of surface will be $\left(\sqrt[3]{\frac{n}{v}}\right)^2$. Now in the state of motion the pressure on a square unit of surface must be proportional to the number of molecules which impinge upon that surface at equal times, *i.e.* directly proportional to the number of molecules in contact with it on any given instant, inasmuch as these molecules in their progressive motion come in contact with it at the same time. It is, moreover, directly proportional to the number of molecules situated on a unit of length, because the unit of surface will be struck more frequently in proportion as the distance between the molecules, or between the layers of molecules, is less. If the pressure corresponding with the volume v and number of molecules n , be denoted by p_{n1} , and the pressure corresponding with the volume V and number of molecules N , by P_{N1} , then—

$$\begin{aligned} p_{n1} : P_{N1} &= \left(\sqrt[3]{\frac{n}{v}}\right)^2 \sqrt[3]{\frac{n}{v}} : \left(\sqrt[3]{\frac{N}{V}}\right)^2 \sqrt[3]{\frac{N}{V}} \\ &= \frac{n}{v} : \frac{N}{V} = nV : Nv = n_1 : N_1 \quad . \quad . \quad (2) \end{aligned}$$

i.e. The pressures vary directly as the numbers of molecules and inversely as the volumes; or the pressures vary as the numbers of molecules in a unit of volume. This is Boyle's or Mariotte's law.

Since the relation of pressure $p : P$ existing under given conditions is made up of the proportion $p_{n1} : P_{N1}$ depending on the number of molecules in the unit of volume, and of the proportion $p_{mc} : P_{MC}$ depending on the masses and velocities of the molecules, equations (1) and (2) give:

$$\begin{aligned} p : P &= \frac{p_{n1}}{P_{N1}} \cdot \frac{p_{mc}}{P_{MC}} = nV \frac{mc^2}{2} : Nv \frac{MC^2}{2} \\ &= n_1 \frac{mc^2}{2} : N_1 \frac{MC^2}{2} \quad . \quad . \quad . \quad . \quad (3) \end{aligned}$$

i.e. The pressure exerted by a gas varies directly as the number and working force of the molecules, and inversely as the volume of the gas; or, as the number of molecules in the unit of space and the mean working force of the individual molecules.

This last equation follows also directly from the fundamental equation—

$$p = \frac{nmc^2}{3v} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

of which an elementary demonstration was given by Krönig under certain conditions which simplified the general problem (iii. 132), and a complete demonstration by Clausius (*Pogg. Ann.* c. 353), with the aid of the higher mathematical analysis. A complete demonstration of this important equation, requiring only the aid of elementary geometry and trigonometry, has lately been given by Pfaunder (*Pogg. Ann.* [1871], xlvii. 428); see also, Gmelin-Kraut's *Handbuch*, i. Abth. p. 18).

The relation between the pressure of a gas and the working force of its molecular movements, as given in equation (3), may also be represented by an expression depending only on the temperature. According to Gay-Lussac's law, established by experiment, the pressure of a perfect gas, whose volume remains constant, varies for each degree centigrade by $\frac{1}{273}$ of the pressure which it exerts at 0°. If then, p_0, p_1, p_2 be the pressure, answering to the temperatures t_0, t_1, t_2 , we have:

$$\frac{p_1}{p_2} = \frac{p_0 + \frac{t_1}{273} p_0}{p_0 + \frac{t_2}{273} p_0} = \frac{273 + t_1}{273 + t_2} = \frac{T_1}{T_2} \quad . \quad (5)$$

T_1 and T_2 denoting the temperatures reckoned from the absolute zero. Combining this with Boyle's law, according to which the pressure varies directly as the density,
2nd Sup.

or as the number $\frac{n}{v}$ of molecules contained in a given volume, we have :

$$p_1 : p_2 = \frac{n_1}{v_1} T_1 : \frac{n_2}{v_2} T_2 \quad . \quad . \quad (6)$$

i.e. The pressures of equal volumes of any gas vary directly as the number of molecules in the unit of volume, and as the absolute temperatures.

If, for the same gas, c_1 and c_2 denote the velocities of the molecules corresponding with the absolute temperatures T_1 and T_2 , equation (3) may be transformed into—

$$p_1 : p_2 = \frac{n_1}{c_1} \cdot \frac{mc_1^2}{2} : \frac{n_2}{c_2} \cdot \frac{mc_2^2}{2} \quad . \quad (7)$$

Consequently, from (6) and (7) :

$$\frac{mc_1^2}{2} : \frac{mc_2^2}{2} = T_1 : T_2 \quad . \quad . \quad (8)$$

i.e. The working forces of the molecular movement of any given gas vary as the absolute temperatures.

(2). *Equality of the Mean Working Force of Molecular Movement of Different Gases at the same Temperature.*—This proposition cannot be, or at least has not yet been, deduced from the fundamental properties of gases without the aid of the higher mathematics. Maxwell (*Phil. Mag.* [4], xix. 22) has shown that in a gaseous mixture, the molecules of all the component gases have the same working force of progressive motion; and an outline of his demonstration is given in Gmelin-Kraut's *Handbuch der Chemie* (p. 23). The main point consists in showing that, even supposing the working forces of molecular motion to have been different in the several gases composing the mixture, this difference would diminish at every impact between the molecules, and would actually in a very short time be reduced to nothing; that is to say, the several gases would all acquire the same working force of molecular motion. Now experiment shows that mixed gases diffuse in the same proportion as the constituents of the mixture when separate. Hence the molecular velocity, and therefore also the working force of molecular motion of the individual gases, cannot have been altered by the act of mixing. It follows, therefore, from Maxwell's theorem above cited, that before mixture also these several gases must, at the same temperature, have possessed equal working forces of molecular movement. Denoting, then, the molecular masses of two gases by m and M , and their velocities at the same absolute temperature by c and C , we have the equation :

$$\frac{mc^2}{2} = \frac{MC^2}{2} \quad . \quad . \quad . \quad (9)$$

If, then, in equation (8), which applies only to the same gas under different conditions, we substitute for mc_1^2 its equivalent MC_1^2 belonging to another gas, we have the equation :

$$\frac{\frac{1}{2}MC_1^2}{\frac{1}{2}mc_2^2} = \frac{T_1}{T_2} \quad . \quad . \quad . \quad (10)$$

i.e. For different gases, also, the mean working forces of molecular movement are as the absolute temperatures.

Avogadro's Law.—If in equation (3), page 545, representing the relation between pressure, number of molecules, volume, and working force of molecular movement, viz. :

$$\frac{p}{P} = \frac{nV \cdot \frac{1}{2}mc^2}{Nv \cdot \frac{1}{2}MC^2} \quad . \quad . \quad . \quad (11)$$

we substitute for the ratio of the working forces that of the absolute temperatures, namely, $\frac{\frac{1}{2}mc^2}{\frac{1}{2}MC^2} = \frac{T_1}{T_2}$, where T_1 and T_2 denote the absolute temperatures of the gases whose molecular masses are m and M respectively, we obtain

$$\frac{p}{P} = \frac{nVT_1}{NvT_2} = \frac{n_1T_1}{N_1T_2} \quad . \quad . \quad . \quad (12)$$

i.e. The pressures of different gases are as the number of molecules and their absolute temperatures, and inversely as the volumes, or directly, as the number of molecules in the unit of volume and as the absolute temperatures.

If now, in this last equation, we have

$$p = P, \quad T_1 = T, \quad v = V,$$

then

$$1 = \frac{n}{N}, \text{ and therefore } n = N. \quad (13)$$

i.e. At equal pressure and temperature, equal volumes of different gases contain equal numbers of molecules.

This is Avogadro's law, which is now regarded as affording the surest foundation for the determination of the atomic and molecular weights of all bodies which exist in or can be obtained in the gaseous state (see MOLECULE).

Deviations from the Laws of Boyle and Gay-Lussac. Researches on the influence of temperature on the deviations of gases from Boyle's law have been made by Amagat (*Compt. rend.* lxxii. 1170). Let p and p_1 be the pressures corresponding with the volumes V and V_1 at the temperature t ; also P ($> p$) and P_1 the pressures corresponding with the same volumes after the gas has been heated to T . Then, if the deviation depended only on the volume, we should have:

$$\frac{pV}{p_1V_1} = \frac{PV}{P_1V_1} \text{ i.e. } \frac{p}{p_1} = \frac{P}{P_1}.$$

The following table shows the mean values determined by experiment for sulphur dioxide, ammonia, and carbon dioxide:—

Name of Gas	Number of Experiments	t	$\frac{p}{p_1}$	T	$\frac{P}{P_1}$	Diff.
Sulphur dioxide	3	14°	0.50838	98°	0.50277	0.00561
Ammonia	2	13	0.50731	98	0.50402	0.00329
Carbon dioxide	3	13	0.50981	98	0.50771	0.00210

These numbers show that the deviation depends upon the temperature as well as upon the volume. Amagat explains this by supposing that with the greater working forces of the molecules at the higher temperature, the loss produced by their collision is proportionately less than the increase of pressure on the walls, in consequence of the increase of working force, notwithstanding the increased frequency of the collisions resulting from the higher velocity of the molecules.

Amagat has also determined the ratio $\frac{pv}{p_1v_1}$ for several gases at different temperatures and under nearly equal initial terminal pressures, the volume being in each case reduced to nearly one-half.

Name of Gas	Temperature	Initial Pressure	$\frac{pv}{p_1v_1}$
		cm.	
Sulphur dioxide	15.3°	69.153	1.0188
	98.5	91.523	1.0078
	98.4	69.255	1.0057
" "	15.5	69.221	1.0182
	97.8	69.283	1.0051
	7.7	70.586	1.0125
Ammonia	98.0	70.500	1.0018
	6.1	70.210	1.0129
	98.5	92.382	1.0062
Carbon dioxide	98.4	70.354	1.0051
	8.5	71.537	1.0061
	98.1	71.053	1.0026
" "	9.0	72.055	1.0064
	98.4	72.100	1.0021
Air	7.2	72.560	1.0010
	98.4	72.512	1.0001
	97.5	71.458	0.9993

From these numbers it appears, that towards 100° sulphur dioxide and ammonia deviate but little from Boyle's law, though somewhat more than air at ordinary temperatures; that at 100° carbon dioxide deviates but very slightly from the law, a result in accordance with Regnault's determinations of the density of this gas; and that at 100° atmospheric air may be regarded as conforming exactly to Boyle's law.

In another series of experiments (*Compt. rend.* lxxiii. 183), Amagat has determined the values of $\frac{pv}{p_1v_1}$ for sulphur dioxide and carbon dioxide, between the temperatures of 0° and 250°, the gases being originally under the atmospheric pressure, and then reduced to one-half of their volume; also the coefficient of expansion between the same limits of temperature.

Temperatures	Value of $\frac{pv}{p_1v_1}$		Expansion—Coefficient (air = 0.00367)	
	for SO ²	for CO ²	for SO ²	for CO ²
0°	—	—	—	0.003724
8	—	1.0065	—	—
Between 0 and 10	—	—	0.004233	—
„ 10 and 20	—	—	0.004005	—
15	1.0185	—	—	—
50	1.0110	1.0036	0.003846	0.003704
100	1.0054	1.0023	0.003757	0.003695
150	1.0032	1.0014	0.003718	0.003690
200	1.0021	1.0008	0.003695	0.003687
250	1.0016	1.0006	0.003685	0.003682

Hence it appears that, as the temperature rises, the deviation from Boyle's law and the coefficient of expansion both exhibit a regular decrease, the expansion-coefficient attaining its limiting value at the same temperature as that at which the gas begins to conform to Boyle's law.

Recknagel (*Pogg. Ann.* Ergänzungsband v. 563) has endeavoured to introduce into the law of tension of gases a precise mathematical expression of the influence of 'the neighbourhood of the condensation point,' and thereby so to generalize this law that it may represent the entire behaviour of the gas, including the phenomena which it exhibits in its passage to the liquid state. For carbon dioxide, with regard to the compressibility, increase of volume, and tension with temperature, and the tension and density of its saturated vapour, sufficient data have been furnished by the experiments of Regnault (*Mémoires de l'Académie des Sciences*, xxi. et xxvi.; *Jahresb.* 1847-48, 136; 1863, 88). The following results have been deduced:—

In place of the equation expressing the laws of Boyle and Gay-Lussac, $Pv = A_0(1 + \alpha t)$, there is obtained, for carbon dioxide and nitrogen monoxide, the equation:—

$$Pv = A_0(1 + \alpha t) \left(1 - \frac{B_t}{v}\right);$$

more general, and more exactly representing the results of observation, in which v denotes the volume of the unit of weight of carbon dioxide; B a function of the temperature determined by the tension of the vapour saturated at t° ; and $\alpha = 0.003612$. If P is estimated in atmospheres, and the unit of volume is that which is occupied by 1 kilogram of carbon dioxide at 0°, and 1 atmosphere tension, then $A_0 = 1.00710$; $B^0 = 0.00705$; $B_{100} = 0.0038$; and generally:

$$B^t = 1.00710(1 + \alpha t) \frac{1}{4M},$$

where M denotes the tension of the vapour saturated at t° .

Relations of Vapours to Boyle's and Gay-Lussac's Laws.—H. Horwig (*Pogg. Ann.* cxxxvii. 19, 592) has made experiments on the relation between the pressure, volume, and absolute temperature ($\alpha + t$) in the vapours of alcohol, chloroform, carbon bisulphide, ether, and water. The apparatus used was so contrived as to admit of a simultaneous variation of the pressure, volume, and temperature of the vapour. A graduated glass tube, filled with mercury, into which the liquid to be volatilised was introduced in bulbs of thin glass, was connected at its lower end with a tube wider at the bottom

but gradually narrowing towards the top, which served as a receiver for the mercury driven out of the graduated tube by the pressure of the vapour, and communicated at its narrow end, by means of a T-tube, with an air-pump and a monometer. The graduated tube and the receiver were placed in a copper water-bath, in the sides of which were inserted plates of glass through which the two tubes could be viewed. The bulbs having been burst, the pressure and volume of the vapour were observed at a constant temperature from the point of saturation of the vapour to the point at which, at the same temperature, it began to follow Boyle's law, a condition indicated by the constancy of the products pv , which had previously been continually increasing.

Denoting by p_1 and v_1 the pressure and volume at a certain temperature of the vapour in its pure saturated state,—that is to say, when it has just taken up the last drop of liquid,—and by P, V , the pressure and volume for a state of the vapour in which, at the same temperature, it conforms to Boyle's law, it is found that for the vapours of alcohol, chloroform, carbon bisulphide, ether, and water, in the saturated state, the relation between pressure, volume, and temperature, is expressed by the equation—

$$\frac{PV}{T_1 v_1} = 0.0595 \sqrt{a + t}$$

instead of $\frac{PV}{a + t} = \text{const.}$, which is the relation for perfect gases. For the products

pv lying between $p_1 v_1$ and PV , no definite law of variation has yet been discovered.

The vapours of alcohol and chloroform, when not in contact with the liquids, begin to follow Boyle's law at the temperature 9.5° , the great difference of their maximum tensions appearing to have no influence on the position of this point.

The equality of the coefficient 0.0595 for five vapours so different in most respects to those above mentioned, renders it probable that this coefficient has likewise the same value for all other vapours. If this be the case, the amount of deviation of the pure saturated vapour from Boyle's law, at any given temperature, must be the same for all vapours.

Mean Velocity of Molecular Movement for Imperfect Gases.—Suppose a kilogram of a gas at 0° to be under an initial pressure so small that the volume v_0 is extremely great, and consequently the attraction between the molecules may be regarded as nothing; and suppose that the pressure is increased to p'_0 , whereby the volume is reduced to v'_0 : then $\frac{p_0 v_0}{p'_0 v'_0} = 1 + \Delta p$, where Δp denotes the deviation from Boyle's law at the pressure p . If, now, while the pressure remains constant, the temperature be raised to t , and the volume v'_0 thereby increased to v , we shall have:

$$\frac{v}{v'_0} = 1 + a_p t;$$

where a_p is the coefficient of expansion under constant pressure p between 0° and t° . Assuming further:

$$\frac{p_0 v_0 a_0}{1 + \Delta p} = R_p; \text{ and } \frac{1}{a_p} = a_p,$$

we have:

$$pv = R_p (a_p + t),$$

where R_p and a_p vary with the pressure.

The values of R_p are as follow:—

	$p = 0$	0.76	1	5	10	15	20 met.
Air	$R_p = 29.222$	29.325	29.347	29.672	30.007	30.265	30.446
Carbon dioxide	$R_p = 19.239$	19.388	19.437	20.417	21.997	23.867	25.915

Now, according to Clausius (*Zamminer's Jahresh. f. Physik.* 1857, 36),

$$pv = \frac{u^2}{3g},$$

where g is the acceleration due to gravity, and u the mean velocity of the progressive motion of the molecules. Consequently,

$$u = \sqrt{3R_p (a_p + t)},$$

which formula differs from that of Clausius for perfect gases in this respect, that R_p and a_p are not constant, but functions of the pressure or volume.

For air and carbon dioxide observation has furnished the data required for calculating the following mean velocities in meters per second:—

Pressure in Meters	Air		Carbon Dioxide	
	$t = 4^{\circ}80$	$t = 100$	$t = 3^{\circ}3$	$t = 100^{\circ}$
0	485.1	566.0	393.3	459.7
0.76	484.4	566.9	392.1	459.2
1	484.8	566.9	391.8	459.0
5	483.8	566.9	385.0	456.4
10	482.8	566.9	374.5	452.8
15	482.0	566.9	362.9	449.4
20	481.4	566.9	350.4	446.2

The velocities found for the pressure 0 represent the ideal case of an infinitely expanded, that is, perfect gas, in which the molecular attractions are infinitely small (Blaserna, *Compt. rend.* lxxix. 134; *Jahresh. f. Chem.* 1869, 74).

GASES, VOLCANIC. The gases evolved from the solfataras of Vesuvius and the Campi Flegrei were examined by Deville in 1862 and by Fouqué in 1865. Goreix (*Compt. rend.* lxxv. 154) examined them in June 1869, collecting the gases as nearly as possible from the same points.

A small constant variation was observed in gas issuing from one and the same orifice, to such an extent that two consecutive analyses scarcely ever gave identical results; it was not probable, therefore, that any uniformity would be traceable in the gas from different centres of emanation, or that the present results would correspond closely with those of previous experimenters.

As a rule the gas evolved consisted mainly of carbon dioxide mixed with about 5 p.c. of hydrogen sulphides, less than 1 p.c. of oxygen, and from 5 to 10 p.c. of nitrogen: the percentage of the latter gas, however, varied greatly, sometimes increasing to the extent of 50 or 60 p.c. with a proportional decrease in the amount of carbon dioxide. In some instances small quantities of marsh-gas were detected.

At Lake Agnano, and at the *Grotta del Cane*, the gas which escaped was pure carbon dioxide; in the *Grotta d'Ammoniac* the hydrogen sulphide present in 1862 was no longer capable of being detected. At the *Grotta di Solf* the marsh-gas was mixed with a small quantity of hydrogen, but ethylene was absent, while the hydrogen sulphide, which had disappeared in 1865, was again present in notable proportions. At Castellamare this same gas had reappeared, and the proportion of carbon dioxide had considerably augmented.

On a subsequent occasion the following results were obtained:—

Source	CO ₂	H ₂ S	O	N	Temperature
Great Solfatara	88.8	7.0	0.7	4.5	110° to 120°
Stufa, E.	29.5	traces	13.2	57.3	25°
Lago d'Agnano	96.1	—	—	—	—
Grotta del Cane	77.0	—	—	—	—
Acqua ferrata del Pozello (Castellamare)	29.1	00.0	0.7	70.2	Air, 28° Water, 25°

At Vesuvius aqueous vapours containing carbon dioxide, besides dry emanations of hydrochloric acid and sulphurous oxide, without carbon dioxide, at a temperature of 225°, were evolved from the crater and from fissures on the sides. From the great Solfatara there issued with much noise, a mixture of steam, hydrogen sulphide, carbon dioxide, and air. The sides of the cavity were covered with crystals of sulphur and sulphide of arsenic.

Emanations from the Caldeira de Furnas, San Miguel, Azores: in 1867.—Janssen and C. Sainte-Clare Deville examined the gases evolved by the Grande Caldeira of Furnas, and found them to consist wholly of carbon dioxide, sulphuretted hydrogen, and a trace of nitrogen, hydrogen and other combustible gases being absent. The recent experiments of Fouqué corroborate the above results. The residue left after treating 2,500 c.c. of the gas with potash was less than 1 c.c. and was incom-
bustible.

It would seem, therefore, that the gaseous emanations of the Caldeiras differ materially in composition from those of the Geysers of Iceland, and from the Solfon of

Tuscany, since the latter invariably contain both hydrogen and carburetted hydrogen. They more closely resemble the solfataras of certain active volcanic districts (*Compt. rend.* lxxv. 1115).

Gases evolved from the Volcanic Island of Santoria (Grecian Archipelago) after the Eruption of 1866.—These gases have been analysed by Gorceix (*Compt. rend.* lxxv. 270-272), who found that, besides carbon dioxide, oxygen, and nitrogen, the proportions of which varied from day to day, and even from hour to hour (vide N in table), traces of hydrogen, sulphuric acid, and marsh-gas were detected. In April 1870, acid vapours (temp. about 115°), were still issuing at two points, the gas evolved having the following composition:—

Gas evolved on April 12, 1870.	Fumarole M	Fumarole N	
		Sample 1	Sample 2
Hydrochloric acid . . .	19.4	1.0	28.4
Sulphurous acid . . .	12.0	0.4	
Carbon dioxide . . .	68.5	98.5	
Oxygen . . .	nono	nono	14.0
Nitrogen . . .	nono	nono	57.3
	99.9	99.9	99.7

An analysis of the gas contained in the sea-water on the coast (date not stated) gave 25.5 p.c. CO₂, 10.1 O, and 64.3 N.

Gases evolved from the Volcano of Nisirois (Gorceix, Compt. rend. lxxvii. 597-601).—The gas collected during March 1873, from the fumaroles in the crater had the following composition:—

	<i>a</i>	<i>b</i>		<i>c</i>			<i>d</i>
Hydrogen sulphide . . .	65.0	74.0	77.0	74.0	71.7	70.0	8.6
Carbon dioxide . . .	30.0	21.6	18.0	21.6	24.0	25.3	90.2
Oxygen . . .	0.4	0.4	0.4	0.4	0.4	0.4	—
Residue . . .	4.6	4.0	4.6	3.7	3.9	3.8	1.2

a was from the older group of fumaroles: the residue was incombustible. *b* and *c* were from two apertures in the more recent group, the analyses being made at intervals of three days: the residue was combustible. *d* was from a solfatara in the island of Cos: the residue consisted of nitrogen.

The fumaroles are surrounded by deposits of sulphur, and the soil is impregnated with sulphuric acid.

GASTRIC JUICE (Kuhne, *Lehrbuch der physiologischen Chemie*). As the pepsin and hydrochloric acid of the gastric juice produce together effects on albuminous bodies which neither is capable of producing apart from the other, C. Schmidt has suggested that these substances unite to form a sort of conjugated acid, which he calls pepto-hydrochloric acid: that some such compound is formed is also rendered probable by the modification of the properties of the two substances which is seen in their mixture. Dilute hydrochloric acid, for instance, dissolves the calcareous salts out of bone, leaving behind the gelatinous matter, but gastric juice removes the gelatin and leaves a brittle mass consisting of the earthy salts. Pepsin, too, in a neutral solution is non-diffusible, but in the presence of dilute hydrochloric acid it dialyses readily.

The preparation of artificial gastric juice has been much simplified by Von Wittich's discovery that pepsin, its essential organic constituent, is soluble in glycerin. An active digestive fluid may be obtained by removing the mucous membrane from a fresh pig's stomach, except that portion near the pyloric orifice, cutting it into small pieces, placing them in alcohol for twenty-four hours, and then transferring into just sufficient glycerin to cover them; a little of the glycerin extract can be strained off when required, and a 0.1 p.c. solution of hydrochloric acid added to it. The hardening in alcohol before maceration in glycerin is not essential, but if it is omitted, the glycerin extract is very tenacious and difficult to strain, on account of its containing a large quantity of mucus. To obtain absolutely pure artificial gastric juice, pure pepsin must of course first be prepared, and then dissolved in the dilute acid (see Pepsin).

H. N. M.

GEIERITE. A mineral occurring at Wolfach in the Black Forest, in caespar or on antimonial silver, in crystals of the rhombic combination $\infty P. mP\infty$. It is silver-white, yields a sublimate of arsenic and sulphide of arsenic, and when heated on charcoal gives off arsenious oxide, sulphurous oxide, and vapour of antimony. Hardness = 5.5, sp. gr. = 6.550. The analysis, carried out by Petersen, leads approximately to the formula, $FeS \cdot 5(Fe; Co)(As.Sb)$:

S	As	Si	Fe	Co
5.18	62.29	4.37	24.33	4.40 = 100.57

The mineral also contains traces of manganese, zinc, nickel and lead (Sandberger, *Jahrbuch f. Mineralogie*, 1869, 315).

GELSEMIUM. The alcoholic extract of *Gelsemium sempervirens* yields, by evaporation, solution in water, acidulation, and agitation with ether, an acid which crystallises out in small quantity as the ether evaporates. This acid, called gelsemic acid, forms, after purification, colourless, scentless, and tasteless needles; unites with alkalis forming crystallisable salts; and dissolves in nitric acid with yellow or red colour becoming deep blood-red on addition of ammonia.

The alkaline solutions of the acid exhibit a yellow colour and blue fluorescence, to whatever degree they may be diluted. The acid sublimes at 100° .

The ethereal solution of gelsemium extract also contains an alkaloid, gelsemine, in larger quantity than the acid. This alkaloid, which may be extracted by addition of potash and agitation with chloroform, is, when purified, a white amorphous substance having an intensely bitter taste, slightly soluble in water, easily in chloroform, and in 25 pts. of ether; sulphuric acid dissolves it with red colour, changing to purple-red on heating. It melts below 100° . Alkalis precipitate it from the aqueous solutions of its salts; these salts also give precipitates with potassium dichromate, potassium sulphocyanate, picric acid, potassium iodide, hydrobromic acid, ferri-cyanide and ferrocyanide of potassium, &c. It is very poisonous. (Wormley, *Americ. J. Pharm.* 1870, 42.)

GERANIUM OIL. Indian geranium oil, as it occurs in commerce, exhibits considerable varieties of composition and properties. O. Jacobson (*Ann. Ch. Pharm.* clvii, 232) has examined two samples of it, both containing traces of copper, to which perhaps the greenish colour of the oil is due. One sample, of sp. gr. 0.887 at 20° , was found to be adulterated with about 8 p.c. of alcohol; the other, which was more viscid, and had a specific gravity of 0.910 at 29° , contained 20 p.c. of a fatty oil. The free acid, which was most abundant in the second oil, was separated by agitating the distillate obtained below 210° with potash-ley, and distilling the evaporated liquid with sulphuric acid; it proved to be valeric acid.

Geraniol, $C^{10}H^{18}O$.—This compound, isomeric with bornol, and with the essential constituents of the oils of eucyput, hops, coriander, and *Osmitopsis asteriscoides*, is obtained by repeated fractional distillation of the portion of the crude oil which passes over between 210° and 240° . It is a colourless, strongly refracting liquid, having a very fragrant smell of roses; not solidifying at 15° , and inactive to polarised light. It has a specific gravity of 0.8851 at 15° and 0.8813 at 21° , and boils at 232° – 233° , that is to say, at a higher temperature than either of its isomerides. It is insoluble in water, but mixes in all proportions with alcohol and ether. On heating it with recently fused and pulverised calcium chloride to 50° , at most, filtering the liquid in dry air, and then cooling it slowly to 10° , a crystallised compound $CaCl_2 \cdot C^{10}H^{18}O$ separates out, which is immediately decomposed at a higher temperature or by water.

Geraniol oxidises very slowly on exposure to the air, and then leaves on distillation a brown viscid mass, which is also left in variable quantities when crude geranium oil is distilled.

By dropping geraniol on melting *potassium hydrate*, potassium valerate is formed. Valeric acid is also produced in small quantity by prolonged boiling of geraniol with potash-ley or baryta-water. By oxidation with a cold, neutral solution of *potassium permanganate*, geraniol yields valeric acid together with fatty acids poorer in carbon, especially acetic acid, when the solution is allowed to become heated. With a hot solution of *potassium chromate and sulphuric acid* the principal product is acetic acid; valeric and succinic acids are also formed. *Nitric acid* produces nitrobenzene, hydrocyanic acid, oxalic acid, and a resin, but no analogue of camphoric acid.

Geranyl chloride, $C^{10}H^{17}Cl$, is formed by passing hydrochloric acid gas through geraniol, or by heating the latter to 80° – 90° for several hours with strong aqueous hydrochloric acid. It is a yellowish, oily, optically inactive liquid, having a peculiar camphorous aromatic odour, a specific gravity of 1.020 at 20° , not solidifying at 15° ,

decomposed by distillation; silver nitrate in alcoholic solution precipitates the chlorine immediately and completely, even at ordinary temperatures.

Geranyl bromide, $C^{10}H^{17}Br$, and *Geranyl iodide*, $C^{10}H^{17}I$, are produced by decomposing the chloride in alcoholic solution at ordinary temperatures with bromide or iodide of potassium. The *cyanide* and *sulphocyanate* may be obtained in a similar manner by means of the corresponding potassium salts; also the *valerate*, *succinate*, and *benzoate*, which are fragrant oily liquids, not solidifying at -10° , and not distillable without decomposition. The etherification may also be effected by heating geraniol to 200° for two hours with excess of cinnamic or benzoic acid, and washing with dilute solution of sodium carbonate.

Geranyl oxide, $C^{10}H^{16}O$, is produced by heating geranyl chloride with geraniol, or to 180° , 200° with three or four times its bulk of water, or over the water-bath for same time with alcoholic potash. When purified by repeated distillation, it is a colourless liquid which floats on water, has a peculiar odour of peppermint, and boils at 187° – 190° .

Geranyl sulphide, $C^{10}H^{16}S$, produced by treating the chloride with potassium sulphide in alcoholic solution, is a yellowish liquid, sinking in water and having a peculiar disagreeable odour. It unites with *mercuric chloride*, forming a compound insoluble in alcohol. When heated it gives off sulphurous oxide; and yields a distillate consisting chiefly of the terpene of geraniol.

The preceding reactions show that geraniol in its chemical relations, bears a great resemblance to borneol, and, like the latter, may be regarded as a monatomic alcohol, $C^{10}H^{17}OH$. The distinguishing physical characters, namely, that geraniol is liquid and has no action on polarised light, are repeated in almost all its derivatives.

Geranene, $C^{10}H^{16}$, is produced by distilling geraniol with phosphoric anhydride or zinc chloride. When purified by repeated rectification, finally over metallic sodium, it is a colourless, mobile, optically inactive liquid, having a specific gravity of 0.8225 at 20° , and vapour-density of 4.93 at 237° . In contact with the air it oxidises quickly, with abundant formation of ozone. It unites with *hydrochloric acid*, forming a liquid hydrochloride; does not appear to form a hydrate when treated by Wiggers' method for the preparation of terpin. With *nitric acid* it yields the same oxidation-products as the other terpenes.

GEYSERS. The valley of Furnas, in the eastern part of San Miguel, was disturbed about three centuries ago by volcanic eruptions, and the soil is now perforated by a number of geysers. The three largest and most active of these are called 'caldeiras.' Only one of these furnishes a continuous stream of water. Another sends forth intermittent currents; while the third emits only water-vapour and gas. Besides these boiling springs, there exist others which have a temperature of about $16^{\circ}C$. and whose waters are ferruginous. The water of some is very alkaline and but slightly sulphurous; others are not in the least sulphurous; many contain a considerable amount of hydroferrie carbonate and carbonic acid; and some, free sulphuric acid. These springs, especially those containing sulphuric acid, are used medicinally. All of them contain a large quantity of silica in solution, so large, indeed, that it is deposited at the mouth. Sodium salts and free carbonic acid are present in large quantity, while iron, lime, and magnesia are comparatively scarce. Several of the springs contain traces of bromides, iodides, and fluorides; boracic acid and arsenic are not present (T. du Fouqué, *Compt. rend.* lxxvi. 1361).

GIRONA RESIN. See RESINS.

GLASS. *Composition of various kinds.*—Crystalline glass from Dresden, easily fusible, and having a sp. gr. of 2.556 to 2.660, was found by H. Schwarz (*Dingl. pol. J.* ccc. 423) to have the composition $16SiO^2.2AlF^3.13RO$, the symbol RO including manganese oxide, lime, magnesia, soda, and potash. Amorphous glass of sp. gr. 2.611–2.648, exhibited nearly the same composition, viz.: $17SiO^2.2AlF^3.13RO$. These glasses contain large proportions of manganese oxide (5.60–6.30), which acts like lead oxide, rendering them easily fusible. The manganese residues from chlorine works, such as the compound of manganese oxide and lime obtained in Weldon's process, might be usefully employed in their preparation. Venetian Mosaic glass, opaque and of light blue colour, was found by Schwarz to contain 5.92 p.c. antimonious oxide, 9.76 lead oxide and 1.32 copper oxide.

Baryta glasses.—Benrath (*Dingl. pol. J.* cii. 422) has endeavoured to determine how far baryta can be advantageously used as a substitute for the alkalis. Setting out on the supposition that no glass which does not approach more nearly to the composition of $RO.3SiO^2$ than to $RO.2SiO^2$, can be of practical value, on account of its easy decomposability by water, &c., he has attempted to prepare glasses approaching the

former composition, in which more or less of the alkali has been replaced by baryta. A glass containing silica 58.48, baryta 30.56, potash 10.96—melted well—blew easily, had a medium hardness, and considerable lustre. As compared with a similar lime glass (*i.e.*, with an equivalent of lime in place of baryta), it was found to be of greater density and lustre, and more fusible; in resistance to chemical reagents it seemed to stand between lime and lead glass.

Attempts to increase the quantity of baryta in proportion to the other basic constituents, or to make the glass more acid, resulted in obtaining masses which became devitrified on cooling. Although glasses containing no alkali can be prepared from silica, lime, and baryta, they are practically infusible if they contain more silica than corresponds to $\text{RO} \cdot 2\text{SiO}_2$, and these are so easily decomposed as to be worthless.

It appears, then, that baryta can only be substituted for the lime, and not for the alkali of glass. See also Jenno (*ibid.* xciii. 259).

Ancient Jewish Glass. D. Campbell (*Chem. News*, xxiv. 283) examined a specimen of glass dug up in the neighbourhood of the Temple of Jerusalem at a depth of 20-80 feet. It was much weathered. Sp. gr. = 2.430. The least altered portions gave by analysis:

SiO_2	CaO	MgO	Na_2O	K_2O	Al_2O_3	Fe_2O_3	SnO_2	PbO	P_2O_5
69.30	8.50	0.55	13.79	1.49	3.20	2.00	0.29	trace	0.80 = 99.92.

Cryolite Glass. Milk Glass.—Cryolite glass from the works of the American Hot-cast Porcelain Company, having a sp. gr. of 2.471, milk-white in the middle, opalescent to transparent on the outer and inner surfaces, and like ordinary good glass in the other parts, was found by Benrath (*Dingl. polyt. J.* xcvi. 237) to contain

SiO_2	Al_2O_3	Fe_2O_3	MnO	CaO	Na_2O
67.07	10.99	1.02	1.09	trace	19.83 = 100.

Experiments in the glass furnace showed that a mixture of 1 part cryolite and 2 parts quartz-sand melted easily and became quite limpid, yielding a glass which remained transparent after rapid cooling, while at the bottom of the crucible, where the layer of glass was 5 mm. thick, the mass on cooling was completely converted into milk-glass. The glass, which was perfectly white, had a sp. gr. of 2.373, and gave by analysis 70.01 p.c. SiO_2 , 10.78 Al_2O_3 , and 19.21 Na_2O . Its formation may be represented by the equation:

The silicon fluoride, which is evolved in large quantity (74 pounds from 300 pounds of the mixture), might be converted into silicofluoric acid available for the preparation of potassium salts, by simply connecting the covered melting pots with absorption-chambers containing water.

C. P. Williams (*Journal of the Franklin Institute*, lvii. 252) has made five analyses of cryolite glass, from which it appears to contain, on the average,

SiO_2	Al_2O_3	Fe_2O_3	MnO	ZnO	CaO	MgO	Na_2O	F
68.34	7.86	1.50	1.12	6.99	1.86	0.25	10.51	8.05.

The sum of these constituents must be diminished by 3.39 p.c. oxygen, equivalent to the fluorine. From this composition Williams calculates the formula:

and infers, from the proportion of soda, that the original mass consists of 67.19 silica, 23.84 cryolite, and 8.97 zinc oxide, but loses 39 p.c. of its fluorine as silicon fluoride by the melting process. He supposes that the sodium silicofluoride in cryolite glass acts in the same manner as the calcium phosphate in ordinary milk glass. Cryolite glass is peculiarly well adapted for coloration by metallic oxides. According to W. J. Cheyney, calcium fluoride may be substituted for cryolite in its preparation.

E. Richters (*Dingl. pol. J.* xciii. 259) has made experiments on the use of calcium fluoride, obtained in the preparation of carbonate of soda from cryolite, in glass making instead of lime. He finds that it leads to a considerable saving (nearly one-half) of Glauber's salt, without involving any increased consumption of fuel, or time of melting, or diminished yield; but that the iron contained in this artificial fluor-spar renders it unavailable for the preparation of white glass.

Sodium aluminate has been found to be more advantageous than cryolite for the preparation of milk-glass, as it does not attack the melting pots so strongly. $1\frac{1}{2}$ cwt. of cryolite and $\frac{1}{15}$ cwt. of calcined sodium carbonate is replaced by 1 cwt. of sodium aluminate. This preparation has also the advantage of containing less iron than cryolite (Stolba, *Dingl. pol. J.* xcvi. 178).

A very hard 'alabaster glass' examined by Stollé (*loc. cit.*) was found to contain

SiO ²	Al ² O ³	CaO	K ² O	Na ² O	
82.3	3.2	3.3	5.7	5.6	= 100.1.

The turbidity of this glass is probably due to the large proportion of silica, which induces a tendency to devitrification.

Gold-ruby Glass.—The conditions under which this glass is produced have been examined by W. Müller (*Dingl. pol. J. cci. 117*). Previous researches had shown that its formation does not depend upon the use of any particular preparation of gold, but that all the gold-compounds used in its production give up the gold in the metallic state at a temperature much below that required for the fusion of the glass. The quantity of gold taken up by the glass does not exceed a small fraction per cent. The auriferous glass may be either turbid or transparent, and in the latter case may exhibit various colours. Immediately after fusion the glass is colourless or yellowish, and the red, which is the tarnish-colour (*Anlaufarbe*), appears only when the solidified mass is heated to the temperature at which it begins to soften; this tarnish is independent of the atmosphere and of everything else by which the glass is surrounded. By actual fusion the glass again becomes colourless. The changes of colour in gold-glass are entirely owing to allotropic modifications of the gold; silicates of gold are unknown, and the assumption of their formation in the preparation of gold-glass is scarcely admissible. It still, however, remains to be determined in what manner the gold is taken up by the glass; also why the gold-glass turns red when heated, and not as the mass cools down from the fused state. The conditions of formation of the auriferous glass, and of its changes of colour, are also but very imperfectly determined. Müller's experiments have led to the following results:—

One hundred-thousandth part of gold is sufficient to give the glass a rose colour; the half of this amount has no perceptible effect. Glass containing lead takes up more gold than that which is free from lead; lead silicates may be made to take up $\frac{1}{10000}$ of their weight of gold. The quantity of gold taken up affects the colour of the glass, but other circumstances influence it at the same time. Ordinary glasses, made by melting together lime, alkali and sand are not adapted for the preparation of gold-ruby. The addition of lead oxide has a very good effect on the colour of the ruby-glass, but it is limited by the inability of the melting pots to withstand the action of the lead oxide. Oxide of tin has no effect. An addition of *Vitrum antimonii* is said to make the colour less violet. To prepare an auriferous glass which shall take a good red colour, the temperature must be raised to the melting-point of cast-iron. If fused at a low temperature, the glass contains the gold in the separate state, and appears, not colourless, but yellow by reflected light, from the suspended gold-particles, and blue by transmitted light, exactly like a gold-solution from which the gold has been thrown down by ferrous sulphate. Gold-glass which reddens well can be obtained only by prolonged exposure to a high temperature for an hour and a half at the least. The melted glass will not take up gold if there is any 'glass-gall' floating on its surface. The addition of potassium sulphate or chloride to the glass immediately throws down the gold in spherules. Colourless gold-glass acquires the finest red colour when cooled as quickly as possible from fusion and then again heated. Sudden cooling leaves the glass colourless; slower cooling renders it turbid, part of the gold separating in granules, while that which remains in the glass does not impart to it the power of forming ruby-glass. Quenching the glass, that is pouring it into a large quantity of cold water, is especially resorted to in practice for producing a colourless glass capable of taking a good red colour. With regard to the colour of gold-glasses, those fluxes in which the gold is suspended in the glass must be distinguished from those in which it is really taken up or dissolved. The former may contain the gold as a black precipitate or a liver-brown mass according to the fineness of the suspended gold-particles. Those glasses in which the gold is taken up as a homogeneous constituent behave differently; and are colourless, yellow, or greenish-yellow before reheating, according to the quantity of the gold, the rapidity of cooling, &c.

The reddening of gold-glass takes place in various degrees. With good glass it begins at an incipient red heat, goes on quickly, and is completed by the time that the edges of the fragments begin to be rounded. In inferior glasses, the reddening takes place only at a higher temperature, when the glass begins to form drops, and sometimes so slowly that the glass must be repeatedly removed from the fire and reheated. The reddening succeeds better, in proportion to the quantity of gold taken up by the glass, the difference of temperature between the fused mass and the surrounding atmosphere, and the shortness of the time of cooling. It still remains to be explained why the same temperature acts differently on the auriferous glass accordingly as this temperature is attained by heating the glass, or by cooling it from the state of fusion.

In an appendix to Müller's paper, F. Knapp maintains that the gold in ruby-

glass is dissolved in the same manner as colouring matters are taken up by melted sugar and gelatin. Glass can also take up silver and copper in the same manner as gold. Colourless gold-glass is gradually reddened by light, even by diffused daylight, whence it appears that the allotropic modification of the gold may take place quite independently of the action of heat.

Devitrification of Glass.—Many kinds of glass when repeatedly heated become crystalline and more or less opaque. The change appears to be due to the crystallisation of silica, or of definite silicates rich in silica, previously held in solution in the amorphous glass, inasmuch as the amorphous portion is found to contain more alkali, while the crystallised or devitrified portion is richer in silica and lime. The addition of even a small quantity of sand to molten glass causes the formation of crystalline nodules, and when glass, towards the end of the melting, shows signs of crystallisation, the manufacturer knows that too much lime has been added. Glass is also especially apt to become crystalline when the crucibles are allowed to cool slowly. Henrivaux (*Bull. Soc. Chim.* [2], xix. 6) has analysed some of the crystalline nodules, and found that their composition is always different from that of the amorphous glass. Devitrified glass sweats in a damp atmosphere and gives up alkali to water (see *Chem. Soc. J.* [2], x. 387-386; xi. 244; xii. 543).

GLAUCONITE. A. Kupffer (*Jahresb. f. Chem.*, 1870, 1307) has analysed several Russian glauconites, of specific gravity 2.76-2.79:—1. From the Silurian limestone of the River Sibir, which forms the connection between Lakes Ladoga and Onega. 2. *a* and *b*. From the Silurian glauconite sand of Karyn-Oro near Ontika, Elisland. 3. From the Silurian limestone of the same locality: *a*, total analysis; *b*, after deduction of quartz. 4. From the Silurian limestone of Ballisehport, Elisland. 5. From the Silurian sandstone of the same. 6. From the tertiary sand of the green valley at Gadow:—

	SiO ₂	AlO ₂	FeO ₂	FeO	MgO	CaO	K ₂ O	Na ₂ O	H ₂ O	Quartz.	
(1).	49.42	10.23	16.01	3.00	3.78	0.31	7.91	0.26	8.05	0.80	= 99.80

GLAUCOPYRITE. A mineral from Guadalcanal in Andalusia, nearly related to the geleirite of Wolfach (p. 552). It occurs, together with fahl-ore, light red silver ore, and a small quantity of antimony-glance, in kidney-shaped masses composed of very thin scales. Twin and triple crystals also occur, formed on the type of coruscite; and apparently belonging to the rhombic combination $\infty P_{\infty} \cdot \infty P_{\infty} P_{\infty}$. Colour light lead-grey to tin-white, blackish at first, then acquiring a yellowish-brown and blue tarnish. Hardness = 4.5. Sp. gr. = 7.181. The analysis A, by R. Senfter, agrees approximately with the formula $\text{FeS}^{12} \cdot 12(\text{Fe}; \text{Co}; \text{Cu}^2)(\text{As}; \text{Sb})$ which requires the numbers given in B:

	S	As	Sb	Fe	Co	Cu
A.	2.36	66.90	3.59	21.38	4.67	1.14 = 100.04
B.	2.47	69.45	—	28.08	—	— = 100

(F. Sandberger, *J. pr. Chem.* [2], i. 230).

GLUCIC, or GLUCINIC ACID. This acid, produced by the action of alkalis or acids on glucose (ii. 848), has been lately examined by H. Reichardt (*Vierteljahrsschrift pr. Pharm.* xix. 384, 503; *Jenaische Zeitschr.* v. 307), who assigns to it the composition $\text{C}^{12}\text{H}^{22}\text{O}^{12}$, or $\text{C}^{12}\text{H}^{16}\text{O}^9 \cdot 3\text{H}^2\text{O}$, whereas the earlier experiments of Peligot, Rochleder a. Kawaller, and Mulder (ii. 848), led to the formula $\text{C}^{12}\text{H}^{16}\text{O}^9$, analogous to those of the carbohydrates.

When dextroglucose is heated with baryta-water, a precipitate is formed consisting of the barium salt of saccharamic acid, $\text{C}^{12}\text{H}^{16}\text{O}^{11}$, and the liquid filtered therefrom contains the barium salt of glucic acid. On mixing this solution with basic lead acetate, filtering from the coloured precipitate at first produced, and again precipitating with basic lead acetate, lead glucate is obtained; and on decomposing this salt with hydrogen sulphide and evaporating the filtrate at a gentle heat, glucic acid is obtained as a honey-yellow mass, which when dried over sulphuric acid, has the composition $\text{C}^{12}\text{H}^{22}\text{O}^{12}$ + aq. or $\text{C}^{12}\text{H}^{16}\text{O}^9 \cdot 3\text{H}^2\text{O}$ + aq. as further indicated by that of the lead-salt $\text{C}^{12}\text{H}^{16}\text{O}^9 \cdot 3\text{PbO}$ or $3\text{PbO} \cdot \text{C}^{12}\text{H}^{16}\text{O}^9$ thrown down from the neutralised solution of the acid by basic lead acetate, and dried at about 150°.

From a neutral or slightly alkaline solution of barium glucate, alcohol throws down the tribasic salt $3\text{BaO} \cdot 2\text{C}^{12}\text{H}^{16}\text{O}^9 + 6\text{H}^2\text{O}$. An acid barium salt, $\text{BaO} \cdot 2\text{C}^{12}\text{H}^{16}\text{O}^9 + 6\text{H}^2\text{O}$,

yellowish and very hygroscopic, is obtained by decomposing barium carbonate with glucic acid, and evaporating. The *acid calcium salt* is $\text{CaO} \cdot 2\text{C}^{\text{H}}\text{H}^{\text{O}} + 5\text{H}^{\text{O}}$. Magnesium carbonate is easily dissolved by glucic acid, and on evaporating the liquid a whitish-yellow easily friable mass is left, exhibiting when dried the composition $\text{MgO} \cdot \text{C}^{\text{H}}\text{H}^{\text{O}} + 3\text{H}^{\text{O}}$. The *sodium salt*, $3\text{Na}^{\text{O}} \cdot \text{O} \cdot \text{C}^{\text{H}}\text{H}^{\text{O}} + 9\text{H}^{\text{O}}$, obtained by neutralisation, is hygroscopic and melts at 100° . The *aluminium salt*, $\text{Al}^{\text{O}} \cdot 2\text{C}^{\text{H}}\text{H}^{\text{O}} + 3\text{H}^{\text{O}}$, obtained by solution and evaporation, is, when dried at 100° , yellowish-white and somewhat hygroscopic. The *ferrous salt*, $3\text{FeO} \cdot 2\text{C}^{\text{H}}\text{H}^{\text{O}} + 6\text{H}^{\text{O}}$, obtained by decomposing the tribasic salt with ferrous sulphate, is hygroscopic after drying at 100° , and forms a green solution.

Glucic acid is easily decomposed, by heating its aqueous solution, into apoglucic acid (ii. 848), formic acid, and an acid said to be isomeric with acetic acid, most probably acetic acid itself.

Apoglucic acid has the composition $\text{C}^{\text{H}}\text{H}^{\text{O}}$ when dried at 100° , and $\text{C}^{\text{H}}\text{H}^{\text{O}}$ at 140° . From the composition of the lead salt, $\text{C}^{\text{H}}\text{H}^{\text{O}} \cdot \text{PbO}$, or $\text{PbO} \cdot \text{C}^{\text{H}}\text{H}^{\text{O}}$, that of the acid dried at 100° is probably $\text{C}^{\text{H}}\text{H}^{\text{O}} \cdot 3\text{H}^{\text{O}}$ (H. Reichardt).

Since the acids, saccharic $\text{C}^{\text{H}}\text{H}^{\text{O}}$, and glucic $\text{C}^{\text{H}}\text{H}^{\text{O}}$, formed as above, both contain a larger proportion of oxygen than the sugar from which they are formed, and as no oxygen is absorbed during the reaction, products containing less oxygen ought to be formed at the same time. Numerous experiments, however, have brought to light nothing of this kind, except acetone $\text{C}^{\text{H}}\text{H}^{\text{O}}$, or other volatile bodies of similar character (E. Reichardt. *Vierteljahrsschrift pr. Pharm.* xix. 516).

GLUCINUM. The atomicity of this metal is still a matter of doubt. Klatzo, in 1868 (*J. pr. Chem.* cvi. 227; *Jahresb.* 1868, 205) described a number of double sulphates, from the examination of which he concluded that glucinum sulphate is capable of crystallising with the sulphates of the magnesium metals (Mg, Fe, Mn, Zn, Cu) in all proportions, and in forms determined by the predominant basic constituent, whereas he did not succeed in obtaining double sulphates of glucinum with aluminic, ferric, chromic, or manganic sulphate: hence he inferred that glucina must be regarded as a monoxide, GO , belonging to the magnesium group. Marignac, on the other hand (*Ann. Chim. Phys.* [4], xxx. 45), was unable to obtain any of the double salts described by Klatzo. He finds that mixtures of solutions of glucinum sulphate and a magnesium sulphate invariably deposit the two salts in separate crystals, each of which may always be obtained pure if due care be taken to free it from adhering mother-liquor and from enclosed crystals of the other salts. The same want of success was experienced in attempting to form double nitrates of glucinum with the nitrates of magnesium, lanthanum, and didymium. Marignac also points out that the argument in favour of the diatomicity of glucinum, founded on the isomorphism of glucina and zinc oxide, has but little force, inasmuch as glucina might with equal reason be regarded as isomorphous with alumina, and that, in fact, there is but one well-established fact of isomorphism tending to show that the formula is GO rather than GO^{O} , namely, the isomorphism of phenakite, $2\text{GO} \cdot \text{SiO}^{\text{O}}$, and willemite, $2\text{ZnO} \cdot \text{SiO}^{\text{O}}$. On the other hand, the weakness of glucina as a base, and its great tendency to form basic salts, together with the frequent recurrence of the number 3 in the formulae of its salts, —e.g. in the hydrates $3\text{GH}^{\text{O}} + 7\text{H}^{\text{O}}$ and $3\text{GH}^{\text{O}} + \text{H}^{\text{O}}$, the periodate $3\text{GO} \cdot \text{IO}^{\text{O}} + 11\text{H}^{\text{O}}$, and in solio-glucinic sulphate $3\text{GSO}^{\text{O}} \cdot 2\text{Na}^{\text{O}} \cdot \text{SO}^{\text{O}} + 12\text{H}^{\text{O}}$, —may be cited as arguments in favour of its triatomicity. On the whole, then, the question remains much in the same state as it was several years ago (compare ii. 849), and is likely to remain so, until we obtain a satisfactory determination of the vapour-density of glucinum chloride, or of the specific heat of the metal.

Elaborate investigations of the salts of glucinum have lately been published by Atterberg (*Bull. Soc. Chim.* [2], xix. 497; *Kongl. Vetenskaps. Akad. Handlingar*, Bd. 12; *Deut. Chem. Ges. Ber.* vii. 472). He finds that the composition of the basic salts is very variable. In addition to the easily-obtained bibasic salts, glucinum forms also tribasic and 7–8 basic up to 13–14 basic salts. Experiments on the precipitability or non-precipitability of different acids by solutions of bi- and tri-basic glucinum salts, have led to the following classification of acids with regard to their chemical relations to glucinum:—

1. Neutral salts, and likewise bi- and tri-basic salts, soluble: *hydrochloric, hydrobromic, hydriodic, sulphocyanic, nitric, chromic, perchloric, formic, and acetic acids.*
2. Neutral and bibasic salts, soluble; tribasic (insoluble or) decomposed by cold water: *sulphuric, selenic, iodic, oxalic, hydroferrihydric, tartaric, and citric acids.*
3. Neutral salts, soluble; bibasic, insoluble: *selenious, succinic, hydroferrocyanic, hydrofluoric, and hydrofluosilicic acids.*
4. Neutral salts, insoluble and easily prepared: *periodic, phosphoric, and benzoic acids.*

With regard to the rational constitution of the basic salts, an important point

established by Atterberg's experiments is that, when dried at 100° , they contain a quantity of water corresponding with the quantity of neutral salt and with the excess of oxide present; thus, in the 2-, 3-, and 8- basic sulphates:—

Hence Atterberg infers that the basic salts of glucinum (and probably, also, other basic salts) must be regarded as molecular compounds of the neutral salt and the hydrate.

Chlorides.—In addition to the neutral chloride, $\text{GCl}^2 + 4\text{H}^2\text{O}$, glucinum forms several basic chlorides or oxychlorides: e.g. $3\text{GCl}^2.2\text{GH}^2\text{O}^2$; $\text{GCl}^2.3\text{GH}^2\text{O}^2$; these, however, are definite only in solution, the former in dilute, the latter in concentrated solution. It also forms the insoluble oxychloride $\text{GCl}^2.12\text{GH}^2\text{O}^2 + 10\text{H}^2\text{O}$, and double salts with auric, mercuric, and stannic chloride (Atterberg).

The *platinochloride*, $\text{GCl}^2.\text{PtCl}^4$, prepared by dissolving glucinum hydrate in solution of platonic chloride, is very readily soluble in water, and separates from a hot concentrated solution as an orange-coloured crystalline powder. By slow evaporation it crystallises in short four- or six-sided prisms, with angles of 90° and 135° . Crystallised under the microscope, it forms four-, six-, or eight-sided tables, with the same angles, sometimes, also, octohedrons apparently belonging to the quadratic system.

These crystals have the composition $\text{GCl}^2.\text{PtCl}^4 + 9\text{H}^2\text{O}$. Crystallised glucinum platino-chloride does not therefore correspond, either in composition or in crystalline form, with the magnesium salts $\text{MgCl}^2.\text{PtCl}^4 + 6\text{H}^2\text{O}$ and $\text{MgCl}^2.\text{PtCl}^4 + 12\text{H}^2\text{O}$, but it agrees in composition with the calcium salt $\text{CaCl}^2.\text{PtCl}^4 + 9\text{H}^2\text{O}$; this last salt does not crystallise well, so that its form is not distinctly known. The crystallised glucinum salt gives off 5 mol. water at 120° , and may then be heated to 200° without further loss. The dried salt, $\text{GCl}^2.\text{PtCl}^4 + 4\text{H}^2\text{O}$, is analogous in composition to the barium salt (J. Thomsen, *Ann. Ch. Pharm.* clvii. 363).

Double Fluorides.—*Potassio-glucinic fluoride* was described by Berzelius (ii. 832) and afterwards by Awdejew (*Pogg. Ann.* lvi. 101). Klatzo, on the other hand (*loc. cit.*), did not succeed in preparing either this or the corresponding sodium salt. According to Marignac, however (*Ann. Chim. Phys.* [4], xxx. 45), they are easily obtained by concentrating the mixed solutions of glucinum fluoride and potassium or sodium fluoride, and may be recrystallised from water. The *potassium salt*, 2KF.GF^2 , generally forms hard mammellated crusts, but by cooling a somewhat dilute solution, it may be obtained in crystals derived from a right rhomboidal prism. They generally present the form of thin hexagonal plates, the basal planes being largely developed. When the solution contains excess of potassium fluoride, the crystals have the appearance of rectangular prisms, owing to the elongation of one of the secondary axes. The salt is soluble in 19 parts of boiling water or in 50 parts at 20° . When heated it decrepitates and melts at a low red heat: it contains no water. By concentrating a solution containing a large excess of glucinum fluoride, a second salt, KF.GF^2 , was obtained, forming a hard, vitreous, mammellated crust, from which no determinable crystals could be extracted; neither could it be recrystallised from water.

Sodio-glucinic Fluorides.—The compound 2NaF.GF^2 crystallises in two forms, one derived from a right and the other from an oblique rhomboidal prism. It is soluble in 34 parts of boiling water, or in 68 parts at 18° . After fusion at a red heat, it solidifies to a transparent glass, which falls to powder spontaneously. The compound NaF.GF^2 is very similar to the potassium salt.

The *ammonium salt*, $2\text{NH}^4\text{F.GF}^2$, forms prismatic crystals isomorphous with the potassium salt.

Cyanide of Glucinum appears to be capable of existing only in very dilute solution; barium cyanide, decomposed by glucinum sulphate, gives a solution containing traces only of glucinum cyanide. The *platinocyanide*, $\text{GCy}^2.\text{PtCy}^2$, is obtained by decomposing barium platinocyanide with glucinum sulphate, and purified by solution in alcohol and ether. Below 30° it contains water and is golden yellow; at 80° it becomes orange-coloured; at a higher temperature it appears red and green. *Glucinum-magnesium platinocyanide*, $\text{GMG}^2.\text{Pt}^2\text{Cy}^2 + 16\text{H}^2\text{O}$, crystallises from a mixture of magnesium and glucinum platinocyanides, in colourless crystals. At the same time other double compounds, which are dichroic, are produced (Toczynski, *Zeitschr. f. Chem.* [2], vii. 275).

Ferrocyanide.—Glucinum sulphate is not precipitated by potassium ferrocyanide, and on heating the liquid, Prussian blue separates out; a basic ferrocyanide is, however, obtained on addition of ammonia (Toczynski)

Oxygen-compounds of Glucinum (Atterberg, *loc. cit.*).—The hydrate recently precipitated by ammonia has the composition $3(\text{H}^{12}\text{O}^2 + 7\text{H}^2\text{O})$, and, after drying at 100° , GH^2O^2 ; from a boiling solution of glucina in potash it is precipitated as a compact powder containing $3\text{GH}^2\text{O}^2 + \text{H}^2\text{O}$.

Sulphates.—The normal salt $\text{GSO}^4 + 4\text{H}^2\text{O}$, gives off 2 mol. water at 100° , the third at 150° , the fourth at a higher temperature, and the whole of its acid when exposed to a prolonged red heat. It does not crystallise as a double sulphate with ferrous or cupric sulphate. Marignac describes a hex-hydrated sulphate obtained accidentally, in foliated prismatic crystals, which were very efflorescent and lost their brilliancy on removal from the mother-liquor.

Basic sulphates.—The salt $\text{GSO}^4.\text{GO}^2\text{H}^2 + 2\text{H}^2\text{O}$ is formed by dissolving glucinum hydrate or carbonate in a solution of the neutral sulphate. It is a transparent, amorphous mass, which, when dried at 100° , has the above composition. At 200° it loses two mols. of water.

$\text{GSO}^4.5\text{GO}^2\text{H}^2 + 2\text{H}^2\text{O}$ is produced when the solution in which it is formed is boiled.

Potassio-glucinic sulphates.— $\text{K}^2\text{G}(\text{SO}^4)^2 + 2\text{H}^2\text{O}$, is a white crystalline powder, slightly soluble in cold water, easily soluble in warm water.

$\text{K}^2\text{G}(\text{SO}^4)^2.2\text{KHSO}^4 + 4\text{H}^2\text{O}$ is precipitated on adding sulphuric acid to a mixed solution of the two sulphates. It gives off $4\text{H}^2\text{O}$ at 100° .

Sodio-glucinic sulphate, $2\text{Na}^2\text{SO}^4.3\text{GSO}^4 + 12\text{H}^2\text{O}$, forms needles grouped in stars, unalterable in the air, and giving off $7\text{H}^2\text{O}$ at 100° .

Ammonio-glucinic sulphate, $(\text{NH}^4)^2\text{SO}^4.\text{GSO}^4 + 2\text{H}^2\text{O}$, gives off two mol. water at 110° .

Sulphite.—When a solution of glucina in saturated aqueous sulphurous acid is evaporated, part of the acid escapes, and a viscous basic salt is obtained, probably having the composition $(\text{GSO}^2.\text{GO}^2\text{H}^2 + 2\text{H}^2\text{O})$.

The *hyposulphate* cannot be crystallised; its solution, when evaporated, evolves sulphurous acid.

Selenate, $\text{GSeO}^4 + 4\text{H}^2\text{O}$.—A very soluble salt which loses $2\text{H}^2\text{O}$ at 100° .

Selenite. A solution of glucina in selenious acid does not yield crystals by evaporation; but ammonia gives a white flaky precipitate of $2\text{GSeO}^2.\text{GO}^2\text{H}^2 + 5\text{H}^2\text{O}$, which loses $3\text{H}^2\text{O}$ at 100° .

Chromate.—A solution of glucina in chromic acid does not yield crystals by evaporation. The addition of neutral potassium chromate to a solution of glucinum sulphate precipitates a basic salt, which is decomposed by washing with water.

Molybdate, $\text{GMoO}^4.\text{GO}^2\text{H}^2 + 2\text{H}^2\text{O}$.—Obtained in fine needles, almost insoluble, by prolonged ebullition of glucinum hydrate with molybdic acid.

The neutral *nitrate* is decomposed, on evaporation, with formation of a basic salt. The *chlorate* is still more easily decomposed, with evolution of chlorine. The *perchlorate*, $\text{GClO}^4 + 4\text{H}^2\text{O}$, forms needle-shaped, deliquescent crystals. The *periodate*, $3\text{GO}^2.\text{I}^2\text{O}^2 + 13\text{H}^2\text{O}$, is nearly insoluble in pure water.

The *orthophosphate*, $\text{G}^3\text{P}^2\text{O}^8 + 7\text{H}^2\text{O}$, is precipitated on adding ordinary disodic phosphate to a solution of neutral glucinum sulphate.

Two basic *oxalates* have been obtained, one soluble, the other insoluble. The *neutral oxalate*, as well as the *succinate* and *tartrate*, crystallises with difficulty from a syrupy solution (Atterberg).

Potassio-glucinic Tartrates.—A solution of 2 mol. cream of tartar and 1 mol. glucinum hydrate deposits, on evaporation, first cream of tartar, and then the double salt $\text{C}^4\text{H}^2\text{K}^2\text{GO}^4$, in peculiar crystalline growths somewhat resembling yeast-cells. Another salt, $\text{C}^4\text{H}^2\text{K}^2\text{G}^2\text{O}^4 + 3\text{H}^2\text{O}$, is produced by boiling cream of tartar with excess of glucina (Toczynski, *loc. cit.*).

Double tartrates of glucinum and antimony are obtained as non-crystalline substances, by boiling together antimonious oxide, glucina, and tartaric acid (Toczynski).

GLUCONIC ACID, $\text{C}^6\text{H}^{12}\text{O}^7$. (Hlasiwetz u. Habermann, *Ann. Ch. Pharm.* clv. 120.) An acid produced by the oxidising action of chlorino-water on glucose or cane-sugar. A dilute solution of the sugar is treated with chlorino-gas as long as absorption takes place, the process going on for four or five days when a considerable quantity of the sugar-solution is employed. The chlorine is then expelled by a stream of carbonic anhydride; the liquid is warmed in a basin, and moist silver oxide is added till it becomes neutral; the solution is quickly filtered; the residue washed for some time with boiling water; the filtrates, which generally soon begin to become turbid and brown from reduced silver, are immediately treated with hydrogen sulphide; and the acid liquid is concentrated on the water-bath. The crude gluconic acid thus

obtained is neutralised with milk of lime; the resulting calcium salt converted into a lead salt; and the pure acid obtained from the latter by decomposition with hydrogen sulphide.

Gluconic acid is an acid syrup. Its calcium and barium salts and the ethylic ether crystallise well; the lead, cadmium and alkali-metal salts are amorphous.

Hlasiwetz and Habermann suppose that the formation of gluconic acid is preceded by that of a non-isolable chlorine-compound $C^6H^{12}O^4.Cl^2$, the two atoms of chlorine being subsequently replaced by one atom of oxygen.

Respecting the constitution and basicity of gluconic acid, different views have been advanced. Fittig (*Ueber die Constitution der sogenannten Kohlhydrate*, Tübingen, 1871) regards glucose as the aldehyde of a heptatonic alcohol $C^6H^7(OH)^7$ derived from the saturated hydrocarbon C^6H^{14} , and therefore as having the constitution

This, like all aldehydes, should yield by oxidation, an acid containing one atom of oxygen more, and differing from it in constitution only by having the last group CHO replaced by $CO(OH)$; gluconic acid should therefore have the structure

and should accordingly be monobasic.

Hlasiwetz, on the other hand (*Ann. Ch. Pharm.* clviii. 253), maintains that it is bibasic, and brings forward the following experiments in support of his view. When milk of lime is added to a moderately dilute lukewarm solution of monobasic calcium gluconate $Ca(C^6H^{11}O^7)^2$, as long as the lime dissolves quickly on agitation, the liquid then filtered, and the clear filtrate heated, the bibasic calcium salt $CaC^6H^{10}O^7$ (dried at 120°) separates immediately, and at the boiling heat almost completely, as a white indistinctly crystalline mud, which must be quickly filtered, washed and pressed. This salt dissolves easily in sal-ammoniac. The corresponding barium salt, $BaC^6H^{10}O^7$ (at 120°) is precipitated in white flocks on mixing the solution of monobasic calcium gluconate with baryta-water, and heating to the boiling point. The bibasic calcium and barium salts of lactonic acid, $C^6H^{10}O^8$, are obtained by similar processes.

Regarding therefore gluconic acid as bibasic, Hlasiwetz suggests that glucose and gluconic acid may be represented by the following formulæ:

Glucose being, according to this view, a simple polymeride of β -lactic acid,

which, according to the experiments of Hoppe-Seyler, is formed from glucose by the action of caustic soda.

Fittig, however (*Ann. Ch. Pharm.* clix. 111), still maintains the monobasicity of gluconic and lactonic acid. He points out that salicylic, paroxybenzoic acid, &c., exhibit exactly similar relations with lime and baryta, and that glycerin, mannite, glucose, cane-sugar, &c., form with lime and free bases in general, saline compounds, which are decomposed by carbonic acid, and that consequently the experiments of Hlasiwetz do not afford any satisfactory proof of the bibasicity of gluconic and lactonic acid. Both these acids, when treated with carbonates, exchange only 1 at. hydrogen for metal and therefore contain only one hydroxyl group in combination with oxidised carbon; in other words, they are monobasic.

GLUCOSE. See SUGARS.

GLUCOSIDES. Schützenberger (*Compt. rend.* lxx. 350) has attempted to produce glucosides synthetically by means of the acetyl derivatives of the sugars. When sodium-saligenin and acetyl-glucose are heated together in presence of benzene or alcohol, there is produced a small quantity of a substance which forms glucose and saliretin on boiling with diluted sulphuric acid; this is obtained pure by evaporation to dryness, solution in water, precipitation by lead acetate, and decomposition by sulphuretted hydrogen and finally, by evaporation to dryness *in vacuo*, there is obtained

an amorphous yellowish brittle mass, soluble in water and alcohol. The greater part of the substances employed, however, react differently, aceto-saliretin $C^{12}H^{11}(C^2H^3O)O^2(?)$, and sodium glucate or glucinate being formed: the former, which yields saliretin and sodium acetate on saponification, is likewise obtainable by the action of acetic anhydride on saliretin.

Diaceto-saccharose and *sodium-saligenin*, heated in an open vessel, together with absolute alcohol, also form a small quantity of a glucoside which splits into glucose and saliretin; the greater portion of the substances, however, is converted into aceto-saliretin and the sodium salt of an acid $C^{12}H^{10}O^3$, very similar to glucinic or glucic acid (p. 556), which may be termed *saccharinic acid*. This sodium salt, $C^{12}H^{10}NaO^3$, separates in small white crystals from boiling absolute alcohol; it is very soluble in water, gives with basic lead acetate a precipitate soluble in excess of the acetate, and yielding the acid itself by decomposition with sulphuretted hydrogen; the acid forms a very sour syrup.

The lead precipitate obtained by treating saligenin with lead acetate also yields, when heated with an aqueous solution of acetyl-glucose or -saccharose, a considerable quantity of a glucoside which splits into saliretin and glucose on treatment with acids; it is, however, uncrystallisable.

Rhamnetin (obtained by boiling rhamnegin, its glucoside, with dilute sulphuric acid) dissolved in caustic potash to saturation gives a precipitate with lead acetate; this precipitate heated in sealed tubes to 140° with solution of *diacetyl-saccharose*, gives a colourless liquid containing glucose, and a yellow insoluble portion which is a mixture of rhamnetin and the lead-compound of its glucoside; this portion treated with sulphuretted hydrogen, after thorough washing, yields a dark yellow liquid, from which an easily soluble amorphous dark yellow dye-stuff is obtainable by evaporation; this is extremely like rhamnegin in its properties, dyes the same tints, and splits on boiling with acids into glucose and rhamnetin, which is insoluble in water.

GLUCOSO-PHOSPHORIC ACID, $C^6H^{12}PO^3$ (Amato, *Gazzetta chimica italiana*, i. 56).—This acid was prepared from a strongly acid residue which Schiff obtained in the course of his researches on the constitution of salicin and helicin, by treating the latter substance with phosphorus oxychloride, digesting the resulting mass with alcohol, and evaporating. This residue—which must have been produced by the mutual action of hydrochloric acid, phosphoric acid, and glucose, resulting from the decomposition of helicin in presence of phosphorus oxychloride—was rendered slightly alkaline with sodium carbonate, then evaporated to a syrup, and digested with alcohol, which partly dissolved it, leaving a residue of chloride and phosphate of sodium. On distilling off the alcohol, evaporating the residue at a very gentle heat, and treating it with absolute alcohol, there remained a quantity of sodium phosphate nearly free from chloride. On again distilling off the alcohol and evaporating, a residue was obtained which dissolved completely in absolute alcohol; and this substance, when freed from alcohol and evaporated under the air-pump, formed an extremely hygroscopic mass, which became pasty on exposure to moist air, but was very friable and easily pulverised when dry.

This substance is very soluble in water and alcohol, but insoluble in ether; it has a yellowish tinge when first obtained, but may be rendered perfectly white by boiling with animal charcoal. It does not precipitate barium chloride or lead acetate, and may be purified from a small quantity of phosphoric acid, adhering to it in the form of sodium phosphate, by treating it with lead acetate, evaporating, dissolving the residue in absolute alcohol, evaporating off the alcohol, and precipitating the excess of lead with hydrogen sulphide.

The aqueous solution does not give the reaction of phosphoric acid with magnesium salts, ammonia and sul-ammoniac; neither does it exhibit the reaction of glucose with a cupro-potassic solution. But if it be previously boiled with a sufficient quantity of sulphuric acid, taking care not to carry the action so far as to destroy the glucose, the solution will then exhibit very plainly the reactions of phosphoric acid and of glucose. The presence of phosphoric acid may also be demonstrated by incinerating the substance, oxidising the residue with nitric acid, and testing as above with a magnesium salt and ammonia.

Quantitative determinations of the ash (sodium pyrophosphate) thus obtained, and of the phosphoric acid contained in it, show that the substance in question has the composition of disodic glucoso-phosphate:—

A lead salt was prepared by treating the sodium salt with excess of dilute sulphuric acid, digesting with alcohol to separate the acid sodium salt thereby produced, evaporating off the alcohol, neutralising with sodium carbonate, and finally with precipitated oxide of lead, and evaporating the filtered solution. A crystalline salt was thus obtained having an alkaline reaction, and yielding by incineration 75.4 p.c. ash, agreeing with the formula —

By treating sodium glucoso-phosphate with sulphuric acid, &c., in the same manner as above, excepting that the last traces of acidity were not neutralised with oxide of lead, a slightly acid crystalline lead salt was obtained, insoluble in ether, very soluble in water and in alcohol, and crystallising from the latter in magnificent setaceous needles, melting at 187°. This purified salt yielded 51.5 p.c. ash, agreeing with the formula $\text{C}^2\text{H}^2\text{O}^3\text{Pb}^2\text{PO}^4$. It may be supposed to be formed from 2 mol. of glucoso-phosphoric acid, which, under the influence of the lead salt, unite together, with elimination of 1 mol. water. Such a constitution is represented by the formula.—

In accordance with this, it is found that the ash gives the reactions of plumbic metaphosphate, whereas that of the former salt gives those of the pyrophosphate.

The last-described salt, heated to 150° in sealed tubes with ethyl iodide, was converted into lead phosphate and another substance, probably identical with that which Berthelot obtained by heating cane-sugar in sealed tubes with potash and ethyl bromide (*Jahresb. f. Chem.* 1860, 509).

GLUTAMIC ACID, $\text{C}^2\text{H}^2\text{NO}^4$, is produced, together with aspartic acid, by the action of boiling dilute sulphuric acid on vegetable proteids (p. 110). According to Masiwetz n. Habermann (*Chem. Centr.* 1872, 535) it is also produced from animal proteids by treating these bodies with hydrochloric acid, and decomposing the product with silver oxide. According to measurements by vom Rath, it crystallises in rhombic tetrahedrons having the axes $a : b : c = 0.80115 : 1 : 1.1788$. The right tetrahedron is usually present alone, sometimes, however, in combination with the left. Its specific rotatory power is $+34.7^\circ$ (Ritthausen, *J. pr. Chem.* [2], v. 354).

GLUTANIC ACID, $\text{C}^2\text{H}^2\text{O}^4$, the homologue of malic acid, which Ritthausen obtained by the action of nitrous acid on glutamic acid (1st Suppl. 637), is a substance possessing very few characteristic properties. It forms an indistinctly crystalline mass, and its salts are amorphous. The specific rotatory power of the acid is, according to Ritthausen, -9.15° .

Deoxyglutanic acid, $\text{C}^2\text{H}^2\text{O}^4$, is produced by heating glutanic acid with four times its weight of concentrated hydriodic acid to 120° for about eight hours. It is very readily soluble in water, alcohol, and ether, and crystallises exceedingly well, forming large, transparent monoclinic crystals, melting at about 97° and decomposing above 280° into water and the anhydride.

Acid ammonium deoxyglutamate, $\text{C}^2\text{H}^2\text{O}^4 \left\{ \begin{array}{l} \text{H} \\ \text{NH} \end{array} \right\}$, is obtained, by evaporating a strongly ammoniacal solution of the acid under an exsiccator, in transparent concentrically grouped crystals. **Calcium deoxyglutamate**, $\text{C}^2\text{H}^2\text{CaO}^4 + \text{H}^2\text{O}$, is sparingly soluble in water, and forms opaque laminae. **Barium deoxyglutamate**, $\text{C}^2\text{H}^2\text{BaO}^4 + 5\text{H}^2\text{O}$, crystallises in small transparent needles, readily soluble in water. **Lead deoxyglutamate**, $\text{C}^2\text{H}^2\text{PbO}^4$, is a white heavy precipitate, and the silver salt, $\text{C}^2\text{H}^2\text{AgO}^4$, a very bulky precipitate resembling alumina; it is but sparingly soluble in boiling water, and separates in the crystalline state on cooling. It may be obtained in distinct needles by boiling a dilute solution of the acid with silver carbonate; but the greater part of the salt remains behind with the excess of silver carbonate.

Deoxyglutanic acid is isomeric with pyrotartaric acid, from which it follows that glutamic acid is not identical with either of the three homomalic acids derived from aconitic acid, as these latter would yield pyrotartaric acid by reduction.

GLYCANILOSALHYDRANILIDE, $C^{23}H^{26}N^2O^3$.—A compound obtained by boiling helicin with anilino (see HELICIN).

GLYCERIC ACID, $C^3H^5O^3$. When this acid is treated with phosphorus pentachloride, and the resulting chloride is gradually decomposed by water, as by exposure to a moist atmosphere, an acid is obtained, the lead salt of which has nearly the composition of a basic salt of chloropropionic acid. On the other hand, when poured into water, it yields a mixture of two acids, one of which contains chlorine.

When in the preparation of the chloride any notable rise of temperature is avoided, a product is obtained, which gives a clear solution when poured into water. But when gradually heated to 150° , the resulting compound gives with water a white thick syrup. This syrup gradually assumes the consistence of honey, and becomes transparent. The honey-like body, decomposed by baryta-water, yields barium monochlorolactate.

The product of the decomposition of the chloride by alcohol, submitted to fractional distillation, gives a colourless aromatic liquid, boiling between 185° and 190° , besides two other fractions having an oily consistence. The analysis of the principal product, although giving very discordant numbers, showed that it was probably ethyl dichloropropionate (Werigo a. Okulitsch, *Ann. Ch. Pharm.* cxlvii. 49).

Ethyl Glycerate, $(C^2H^3(C^2H^3)O^2) = C^2H^3O(OH)^2(OC^2H^3)$, is obtained by heating concentrated glyceric acid with 3–4 vol. of absolute alcohol for some hours to 170° – 190° . It is a thick, sticky, colourless liquid, which boils at 230° – 240° , and has a bitter taste. On treating it with a mixture of nitric and sulphuric acids, the compound $(C^2H^3(OC^2H^3)(NO^2))^2$ is obtained, as a heavy colourless oil (L. Henry, *Deut. Chem. Ges. Ber.* iv. 701).

GLYCERIN, $C^3H^5(OH)^3$. This liquid boils without decomposition at 179.5° under a pressure of 12.5 mm., and at 210° under a pressure of 50 mm. It absorbs from the air varying quantities of water, up to 50° p. c. (Bolas, *Chem. Soc. J.* [2], ix. 84).

Analysis of Commercial Glycerin.—Commercial glycerin frequently contains glyceric ethers, volatile fatty acids, and other undetermined bodies. The action of nitro-sulphuric acid on these impurities is to convert them into bodies which are soluble in water, while the glycerin is transformed into nitroglycerin, which is insoluble. The nitroglycerin is washed, first with a dilute solution of caustic soda, afterwards with water, and subsequently dried in a water-bath. Before being dried it is mixed with its own bulk of wood-spirit, to assist in the volatilisation of the water present. From the weight of nitroglycerin found, may be calculated the amount of pure glycerin present in the sample. 100 grams of glycerin chemically pure, and concentrated at 120° – 150° *in vacuo* were found to yield 190 grams of pure nitroglycerin: the theoretical yield is 247. Careful attention to the strength of acid used, the temperature, and all other details are necessary to ensure constant results (Champion a. Pellet, *Bull. Soc. Chim.* [2], xix. 494).

Glycerin as a Solvent.—According to Klover (*Chem. Centr.* 1872, 434) 100 parts by weight of glycerin dissolve at ordinary temperatures—

Parts by weight		Parts by weight	
20	.. Arsenious oxide.	6.70	.. Cinchonine sulphate.
20	.. Arsenic oxide.	10	.. Cupric acetate.
10	.. Benzoic acid.	30	.. Cupric sulphate.
10	.. Boric acid.	7.50	.. Mercuric chloride.
15	.. Oxalic acid.	20	.. Morphine hydrochloride.
50	.. Tannic acid.	0.20	.. Phosphorus.

Oxidation.—In preparing glyceric acid by oxidising glycerin with nitric acid according to Beilstein's method (ii. 876), Heintz (*Ann. Ch. Pharm.* clii. 325) has obtained, as further products of the oxidation, racemic, formic, glycollic, and oxalic acids. The nitric acid of sp. gr. 1.5 and the glycerin having been left to mix gradually and then evaporated to a syrup over the water-bath, the crude glyceric acid thereby produced was gradually neutralised with lead oxide, and the precipitates obtained by partial precipitation were separately analysed. The first of these precipitates consisted of oxalate, the later ones of racemate. The glycollic acid is found, together with a considerable quantity of glycerin, in the mother-liquor from which the glycerate of lead has crystallised out. Heintz supposes that the glyceric acid, $\text{C}_3\text{H}_5\text{O}_6$, COOH , which is the first product of the oxidation of glycerin by nitric acid, takes up 1 atom of oxygen, whereby its middle term is removed as formic acid, while the two exterior terms unite to form glycollic acid. The latter is then successively oxidised to glyoxylic and oxalic acids.

The formation of racemic acid, $\text{C}^*\text{H}^*\text{O}^*$, from glycerin, which contains only 3 at. carbon, might be attributed to the simultaneous oxidation of glyceric and formic acid, according to the equation—

The occurrence of formic acid among the products of the oxidation of glycerin by nitric acid was observed, indeed, by Huppert (*Jahresb. f. Chem.* 1863, 502), and has been confirmed by Heintz. The latter, however, did not succeed in producing racemic acid by the direct action of nitric acid on a mixture of glyceric and formic acids, or by oxidising glycollic acid with nitric acid, whereby racemic acid might possibly be formed, according to the equation, $2\text{C}^*\text{H}^*\text{O}^3 + \text{O} = \text{H}^2\text{O} + \text{C}^*\text{H}^*\text{O}^6$.

Conversion of Glycerin into Acetone.—The product obtained by the action of bromine on dichlorhydrin consists, according to Carius, of dichlorodibromacetone. By acting upon it with zinc and dilute sulphuric acid, and heating from time to time, not above 40° , a slow reaction is set up, resulting in the formation of acetone and a bromine-compound (probably isopropyl bromide) not separable by distillation (O. Lange, *Deut. Chem. Ges. Ber.* vi. 98).

Metallic Derivatives of Glycerin. *Sodium-glycerin*, $\text{C}_3\text{H}_5\text{NaO}^3 = \text{C}_3\text{H}_5(\text{OH})(\text{ONa})$ (E. A. Letts, *Chem. Soc. J.* [2], x. 450). When a fragment of sodium is placed in glycerin, little or no action is observed; but on heating the mixture, a rapid extrication of hydrogen takes place, the sodium becomes red-hot, and the glycerin decomposed and charred, evolving fumes of acrolein. If however the sodium be diluted with mercury and then caused to act on glycerin, the action proceeds with more regularity, and finally sodium-glycerin is obtained as a gummy mass, which solidifies on cooling, and on addition of alcohol, crumbles down into a white crystalline powder. The same body may be obtained by heating glycerin with dry sodium-alcohol: in this case, alcohol is set free, and a solid white substance remains.

But the best method of preparing the compound, and one which yields it in any quantity, consists in dissolving sodium in alcohol and adding glycerin. At first no change is observed, but in a few minutes minute crystals consisting of radiating stars are formed, and in a short time a white crust is produced on the sides of the vessel. This crust is broken up, thrown on a filter, well washed with alcohol, and dried in a press between blotting paper. This must be done as quickly as possible, as the body is exceedingly deliquescent. The desiccation is afterwards completed over sulphuric acid, but not in a vacuum.

The product obtained by either of these processes is a compound of sodium-glycerin with alcohol $\text{C}_3\text{H}_5\text{NaO}^3 \cdot \text{C}^2\text{H}^5\text{O}$, which, when heated in a current of dry hydrogen, gives up its alcohol and leaves pure sodium-glycerin.

Sodium-glycerin is a white amorphous powder, attracting moisture with the greatest avidity from the air; by water it is constantly decomposed into glycerin and hydrate of sodium. On heating it to 245° , it shows signs of fusion, but appears to decompose at the same time. Bromine acts powerfully on it, giving small quantities of bromine-derivatives. It is remarkable that in this reaction a large quantity of water is produced. Pentachloride of phosphorus, after a few moments' contact, also reacts with great energy, producing so much heat as to char the compound.

The principal product of the decomposition of sodium-glycerin by heat appears to be acrolein.

2. Glyceri-manganous acids.—P. Schottländer (*Ann. Ch. Pharm.* cli. 230)

has obtained two compounds which he regards as the sodium and strontium salts of an etheric acid derived from manganese dioxide as acid, and glycerin as alcohol. To prepare the sodium-salt, a quantity (= 4 parts of dry substance) of hydrated manganese dioxide, recently precipitated from manganous acetate by chlorine, is introduced into a boiling mixture of 70 parts glycerin, sp. gr. 1.26, and 77 parts soda-ley, sp. gr. 1.38, and the boiling is continued for some minutes. The manganese oxide is thereby completely converted into the compound above-mentioned, which separates, for the most part, in the form of a precipitate, appearing chocolate-coloured under the violet another-liquor, but scarlet when removed, while the rest remains dissolved. To free this precipitate—which is very susceptible of the action of air containing carbonic acid, and of water—from the dissolved products, it is introduced into a flask which can be closed, and washed therein, first with spirit of 90 (vol.) p.c., then with highly rectified spirit, finally with absolute ether, and dried at 100°. The product amounts to 4 parts by weight.

The compound thus obtained is a yellowish-red mass, easily crumbled to a powder which feels like tale. After drying at 100°–110°, it loses nothing at 120°, but about $\frac{1}{2}$ p.c. of its weight at 160°, becoming at the same time somewhat darker in colour. At 170°–175° it decomposes with evolution of empyreumatic substances. When set on fire at one point, it glimmers throughout its whole mass. By exposure to the air, it is gradually converted into a black unctuous mass. This decomposition is accelerated by direct sunshine; light appears also to exert a decomposing action, even in the absence of moisture. The salt dissolves in cold water to a yellow-red liquid, which soon becomes turbid, from separation of manganese dioxide. The same change takes place instantly on boiling: the colourless filtrate contains soda and glycerin. From some approximate determinations of glycerin, giving about 26 p.c. C^3H^5 , and from the quantities of manganese and sodium given by analysis, the formula of the compound is inferred to be $(C^3H^5)^2Na^2MnO^6$. It is insoluble in alcohol, ether, chloroform, and ethyl acetate, sparingly soluble in alcoholic, easily in aqueous glycerin (1 : 1 vol.) The latter solution remains undecomposed for some hours at 15°. It forms dark-coloured precipitates, immediately with silver, lead, or mercurous nitrate, after some time with cupric sulphate and mercuric chloride. Its reactions with dilute sulphuric acid, concentrated nitric or hydrochloric or phosphoric acid, aqueous oxalic acid, and aqueous sulphurous acid, are very much what might be expected from a mixture of glycerin with MnO^2 or Mn^2O^3 .

The strontium salt, $(C^3H^5)^2SrMnO^6$, is obtained by dissolving 12 parts of crystallised strontium hydrate in 150 parts glycerin of sp. gr. 1.26, with aid of heat, boiling the solution with 3 parts of levigated hydrated manganese dioxide, till the latter is transformed, and washing the product in a closed vessel, as described for the sodium-compound. It is a light ochre-yellow powder, appearing crystalline under the microscope, and behaving with reagents like the sodium-compound.

Attempts to prepare the potassium, barium and calcium salts of glyceri-manganous acid did not succeed, the manganese dioxide dissolving in the corresponding hydrates to liquids which did not yield any solid compounds.

GLYCERYL CHLORONITROSULPHATE, $C^3H^5Cl(NO^2)(SO^2H)$. This is a thick glutinous liquid, insoluble in water, obtained by treating glyceryl chlorosulphate with fuming nitric acid, or by acting on epichlorhydrin with a mixture of nitric and sulphuric acids (L. Houry, *Dent. Chem. Ges. Ber.* iv. 703).

GLYCERYL OXIDE, or **GLYCERYL ETHER**, $C^3H^5O^2 = (C^3H^5)^2O^2$. This body is formed, together with acrolein, propionic aldehyde, acetone, allyl alcohol, and a small quantity of phenol, by heating glycerin with calcium chloride. The phenol and glycerin-ether are contained in the portion of the product which boils between 180° and 190°, and may be separated by caustic potash, which dissolves the phenol.

The glyceryl ether, which remains undissolved, is a somewhat thick colourless liquid, smelling like spearmint, boiling between 169° and 173°, and almost completely soluble in 20 parts of water. Heated with water for four hours to 160°, it is converted into glycerin. On heating it gently with dilute hydrochloric or sulphuric acid, or a little zinc chloride, a strong odour of aldehyde is developed, and the distillate reduces an ammoniacal silver-solution. By heating it with a concentrated solution of potash, phenol is formed, besides volatile acids: $C^3H^5O^2 + 2H^2O = C^3H^5O +$ (Linnemann a. von Zotta, *Ann. Ch. Pharm. Supplement-band*, viii. 254).

H. v. Gegerfeldt (*Dent. Chem. Ges. Ber.* iv. 919) by subjecting the residue left after the preparation of allyl alcohol from glycerin and oxalic acid, to distillation at a higher temperature, obtained a brown distillate, from which potash separated a liquid distilling between 160° and 280°, and yielding, after repeated rectification, a colourless somewhat viscid liquid, boiling between 170° and 172°, having a sp. gr. of 1.0007 at 18°, miscible in all proportions with alcohol and ether, and soluble in about its own volume of water. It agrees in composition and boiling-point with glyceryl ether, and

is regarded by v. Gegerfeldt as probably identical therewith: it appears, however, to be much more soluble in water than the product obtained by Linnemann a. von Zotta.

In some of its properties glyceryl ether resembles the monoallylin which Tollens obtained as a byo-product in the preparation of allyl alcohol from glycerin (p. 51); and indeed Linnemann a. von Zotta regard it as probably identical therewith. But monoallylin has the composition $C^3H^5O^3 = (C^3H^5)^m \left\{ \begin{matrix} (OH)^2 \\ C^3H^5 \end{matrix} \right.$, and boils at $225^\circ-240^\circ$.

Moreover, when distilled with water it yields allyl alcohol, together with a viscid residue, whereas glyceryl ether yields nothing but glycerin; and finally bromine has no action on glycerin-ether, whereas it unites with allylin, forming a dibromide (Tollens).

v. Gegerfeldt suggests that glyceryl-ether may be represented by one of the following constitutional formulæ:

GLYCERYL-SULPHONIC ACIDS. 1. Glyceryl-disulphonic acid,

$C^3H^5O(SO^2H)^2 = C^3H^5 \left\{ \begin{matrix} OH \\ (SO^2H)^2 \end{matrix} \right.$.—This acid is formed as a potassium salt by boiling dichlorhydrin for $1\frac{1}{2}$ hour with neutral potassium sulphite:

(Schäuffelen, *Ann. Ch. Pharm.* cxlviii. 111); and, in like manner, from epichlorhydrin:

The potassium hydrate formed in this latter case exerts a further action on the epichlorhydrin (Pazschke, *Zeitschr. f. Chem.* v. 613). Thirdly, it is produced by heating sodium chloromethylisethionate with neutral sodium sulphite in a flask with reversed condenser:

The sulphuric acid and excess of sulphurous acid are removed by baryta-water, and the glyceryl-disulphonic acid is precipitated as barium salt by mixing the concentrated filtrate with barium chloride and leaving it to stand (Pazschke, *ibid.* vi. 512).

Glyceryl-disulphonic acid separated from its lead salt by hydrogen sulphide forms a syrupy liquid which does not crystallise, even after long standing over sulphuric acid. The *potassium salt*, $C^3H^5O(SO^2K)^2 + 2H^2O$, forms transparent colourless crystals, which (according to measurements by G. Werner) belong to the rhombic system, with the axial ratio $0.41:0.48:1$, and predominant octohedral faces, together with the perpendicular end-face and the rhombic prism. The salt dissolves sparingly in cold, easily in warm water. On mixing its boiling solution with barium chloride, *barium glycerin-disulphonate*, $C^3H^5(OH)(SO^2)^2Ba$, separates as a white anhydrous crystalline powder. This salt dissolves slowly in water, and the solution, when left to evaporate, deposits a bihydrated barium salt in white nodules which dissolve more easily in water. The *calcium salt* forms small hard crystals insoluble in alcohol. By treating the barium salt with ammonium carbonate, the *ammonium salt* is obtained in white, hard, very soluble crystals. The *neutral lead salt*, obtained by decomposing the barium salt with sulphuric acid, and saturating with lead carbonate, forms large transparent crystals, $C^3H^5(OH)(SO^2)^2Pb + 2H^2O$, very soluble in water. If, on the other hand, the acid be saturated with lead hydrate, an uncrystallisable *basic lead salt* is obtained, having an alkaline reaction and easily soluble in water.

The *silver salt*, $C^3H^5(OH)(SO^2Ag)^2$, forms white warty crystals slightly blackened by light, easily soluble in anhydrous, slightly in aqueous alcohol. The *copper salt* forms light blue crystals easily soluble in water (Schäuffelen).

Glyceryl-trisulphonic acid, $C^3H^5(SO^2H)^3$, is prepared by prolonged boiling of trichlorhydrin with potassium sulphite. On evaporating the resulting solution, the potassium salt crystallises out mixed with potassium chloride, from which it cannot be separated by crystallisation. The solution must therefore be mixed with sulphuric acid, and evaporated down; the residue exhausted with alcohol, and the solution of the free acid saturated with barium carbonate after boiling with water. On cooling, *barium glyceryl-trisulphonate*, $[C^3H^5(SO^2)^3]^2Ba$, separates as a white, crystalline powder, slightly soluble in water. By leaving the solution to evaporate, the same salt is obtained in more soluble crystals containing water of crystallisation.

GLYCIDAMINE, C^3H^7NO (Claus, *Ann. Ch. Pharm.* clxviii. 29).—A base produced, together with diamidohydrin (p. 319), by the action of alcoholic ammonium (containing 1 p.c. NH^3) on dichlorohydrin. The *hydrochloride*, $C^3H^7NO.HCl$, which is the direct product of the reaction, may be obtained in crystals by precipitating the alcoholic solution with ether; it is very hygroscopic. The *platinochloride*, $2(C^3H^7NO.HCl).PtCl_4$, crystallises in transparent shining needles.

Glycidamine may be represented by the constitutional formula:—

It is probably identical with Berthelot a. De Luca's *glyceramine*, which they obtained by a similar process, and represented by the formula $C^3H^7NO^2$.

GLYCOCHOLIC ACID. For the preparation of this acid, Gorup-Besanez (*Ann. Ch. Pharm.* clvii. 286) recommends the following process as easier and more productive than those given by Strecker and by Hoppe-Seyler.

Ox-gall, fresh from the gall-bladder, is evaporated nearly to dryness in the water-bath, and the residue is exhausted with alcohol of 90 p.c. The alcohol is evaporated or distilled off; the residue, diluted, if necessary, with water, is treated with milk of lime and gently warmed, whereupon the greater part of the colouring matter is carried down with the lime; and the liquid is filtered and left to cool.

The filtrate, generally of a faint wine-yellow colour, is treated with dilute sulphuric acid, avoiding excess, till a permanent turbidity is produced. If it be then left at rest, the whole solidifies in a few hours to a mass of crystals of glycocholic acid, which is to be thrown on a filter (the filtration being best effected by the use of a water air-pump), washed with cold water, and pressed, first between blotting-paper, and then in a wooden screw-press. The acid thus obtained, which is generally colourless, may be further purified by dissolving it in a large quantity of lime-water, and adding dilute sulphuric acid till a permanent turbidity is produced. Perfectly pure glycocholic acid then separates out in needles of dazzling whiteness.

Hoppe-Seyler leaves the alcoholic solution of the acid to evaporate spontaneously, and purifies the residue by recrystallisation from alcohol. Gorup-Besanez, as well as Strecker, never obtained crystals in this way, but always a resinous mass. By his own method it sometimes happens that several hours after a permanent turbidity has been produced by sulphuric acid in the filtrate from the lime precipitate, a thickish oily mass is found at the bottom of the vessel, while the liquid above becomes gradually clear. After a few days or weeks, however, this mass becomes converted into crystals of glycocholic acid. The conditions which determine this anomaly have not been discovered.

GLYCOGEN (Kuhne, *Lehrbuch der Physiologischen Chemie*, Leipzig, 1866). Glycogen is best obtained pure by Brucke's method (*Wiener Acad. Berichte*, 1871), which readily separates all proteids from it. A solution of potassio-mercuric iodide is prepared by precipitating mercuric chloride with potassium iodide, washing the precipitate and then saturating a boiling solution of potassium iodide with it. A watery solution of glycogen, mixed with albuminous matters, is prepared in the ordinary way by cutting a perfectly fresh liver into pieces about the size of a hazel-nut, and throwing them into boiling water for a couple of minutes, so as to destroy the liver ferment, which would otherwise convert the glycogen into grape-sugar; the pieces are then bruised in a mortar and extracted with boiling water, and the solution is filtered. As soon as the filtrate is cold it is treated alternately with hydrochloric acid and the potassio-mercuric iodide solution as long as these agents produce any precipitate, and after standing for five minutes the solution is again filtered. Alcohol is then added until about 60 p.c. of absolute alcohol is present in the fluid: this throws down the glycogen alone, but more alcohol precipitates other bodies with it. The precipitate is collected on a filter, washed first with weak, then with 90 p.c. alcohol, and finally with ether, and is then transferred to a tile to dry. Glycogen is thus obtained as a snow-white amorphous powder; if impure or not quite dry, it forms a semi-transparent brittle mass.

The opalescent watery solution of glycogen passes unchanged through animal charcoal; it is four times more dextro-rotatory than solution of grape-sugar of the same strength. With solution of potassium iodide containing free iodine, it gives a deep red colour, which is removed by excess of glycogen; the colour also disappears on heating, but returns on cooling. Strong solution of caustic potash clears away the opalescence of the watery solution of glycogen, but produces no other change in it; the clear solution thus obtained dissolves cupric oxide, forming a deep blue solution

which is not reduced on boiling. Boiling with dilute nitric acid turns glycogen into oxalic acid, but similar treatment with sulphuric or hydrochloric acids converts it into grape-sugar; it is also turned into glucose by the action of saliva, pancreatic juice, blood-serum, and cold-water liver extract, all of which act most rapidly at a temperature of about 35°. The glucose is in each case preceded by a form of dextrin which has not yet been thoroughly examined.

Schetscherbakoff (*Deut. Chem. Ges. Ber.*, 1870) maintains that the glycogen which accumulates in the liver of an animal fed on mixed diet is not a single body, but a mixture of four substances, which can be separated by fractional precipitation with alcohol and ether, and differ in their rotatory power and their reactions with iodine and copper oxide. He calls them the *A*, *B*, *C*, and *D* forms. The last, treated with dilute sulphuric acid yields glucose; *C* gives *D* and glucose; *B* gives *C* and glucose, and *A* gives *B* and glucose. From these decompositions he concludes that the molecular formula of glycogen is at least $C^{30}H^{50}O^{22}$.

The question as to the origin and functions of glycogen in the organism is still far from settled; it seems to be present wherever active growth is going on, being found in most of the tissues of the young fetus, but, curiously, not in the liver. Dareste and Bernard (*Compt. rend.* 1871 and 1873) have both described its formation in the developing hen's egg, and state that it exists there in the form of granules much like those of vegetable starch. Glycogen would also appear to have some relation to the functional activity of the contractile organs; it exists in the muscles (McDonnell, Limpriht, Weiss, *Wien. Akad. Ber.* 1871) in considerable quantity, and partially disappears during muscular activity; alteration of diet and starvation affect its quantity in the muscles much later than in the liver; it also exists in the white blood-corpuscles as long as they exhibit their amoeboid movements, but is replaced by sugar as soon as the movements cease (Hoppe-Seyler, *Med. Chem. Unters.* 1871). There can be little doubt that the glycogen formed in the liver is constantly being converted into glucose during life, and carried off by the hepatic veins. The objections brought against this view are two: (1) the supposed absence of sugar in the perfectly fresh liver, and (2) the statement that as much sugar exists in the portal as in the hepatic blood. We know, however, that the kidneys, which certainly excrete urea, hardly contain a trace of that substance, a very small quantity only being present in them at any one moment, and we may expect to find the same true of the liver: that the latter organ, even in its freshest state, contains some sugar, has been shown by Dalton (*Trans. New York Acad. of Med.* 1871), who found that, though he could detect no sugar by Fehling's reagent in such quantities as from 100 to 150 grains of fresh dog's liver, yet that if he took 1,000 or 1,500 grains it could always be found. There is great contradiction among observers as to whether the blood of the hepatic veins contains more sugar than that of the portal vein; but probably one great cause of this error lies in the neglect of the precaution of ligaturing the portal vein close to the liver before taking the blood from it for analysis. If this is not done, on account of the free communication of the two systems, much blood from the hepatic veins is sure to flow back into the portal vein during the disturbance caused by the operation. When the portal vein is previously tied, most observers agree in stating that hepatic blood contains much more glucose than portal blood, the latter indeed containing none at all in animals fed on a purely albuminous food. Though the liver itself contains a ferment capable of transforming glycogen into glucose, this change would appear to be chiefly effected by the ferment in the blood: for it is much hastened by increased blood-flow through the organ, and it is probably chiefly thus that operations which cause paralysis of the vaso-motor nerves of the organ bring about artificial diabetes, more sugar passing then into the blood than can be used up by the organism. Experiment has shown that the introduction of grape-sugar into the blood of a rabbit in the proportion of 2 grams for each kilogram of the body-weight, will cause diabetes.

That the glycogen of the liver is formed, or at any rate can be formed, in that organ itself, from materials containing no sugar or starchy matters, has long been known; but the nature of the chemical changes which are concerned in its production is obscure. Whether or no it is normally formed from proteid food-stuffs, it certainly is formed from such when animals are fed on them alone, so that the idea suggests itself that these matters split up in the liver into a highly nitrogenised portion and glycogen. In support of this view, several observers have stated that the liver contains much urea, or, in the case of birds, uric acid (Meissner, Cyon), and have supposed these bodies to be in the main formed in that organ, and merely afterwards separated from the blood by the kidneys. This agrees with the fact that in many diseases of the liver, as acute atrophy, urea almost disappears from the urine. Cyon (*Centrbl. f. d. Med. Wiss.* 1870) passed defibrinated blood to and fro through the vessels of a fresh liver kept warm, and found the quantity of urea much increased by its passage; some doubt, however, attaches to his mode of determination of the quantity of urea, and Gscheidlen

(*Stud. über d. Ursprung d. Harnstoffs in Thierkörper*) found that, though the glycogen increases in quantity in a liver cut out and left to itself, the urea does not; he therefore concludes that the formation of the two substances goes on independently. Glycogen is also abundantly formed in the livers of animals fed on starchy and saccharine food. As much fat then accumulates in the liver, it has been suggested that sugar may be decomposed in the organ, forming fats and glycogen.

Triacetyl-glycogen, heated to 150° with excess of acetic anhydride, swells up without dissolving, and the product, after washing with water, consists of white amorphous triacetyl-glycogen, $C^6H^4(C^2H^3O)^3O^3$, insoluble in water, alcohol, ether, and acetic acid, and reconverted into glycogen by saponification (Schützenberger u. Naudin, *Deut. Chem. Ges. Ber.* ii. 163).

H. N. M.

GLYCOL, DICHLORONAPHTHYDENCIC. See NAPHTHALENE COMPOUNDS.

GLYCOL, TOLYLENIC. See TOLYLENE COMPOUNDS.

GLYCOLLIC ACID, $C^2H^3O^3$. This acid is formed, together with glyoxylic and tartaric acids, by the action of sodium-amalgam on an alcoholic solution of ethyl oxalate:—

The acid $C^2H^3O^3$, called *glycollic acid*, said by Friedländer to be produced in this reaction, appears to have no existence (Dobus, *Chem. Soc. J.* [2], x. 365).

Glycollic acid is also produced by the action of chlorine and water at ordinary temperatures on sorbin and levulose: $C^6H^{12}O^8 + O^2 = 3C^2H^3O^3$ (Hlasiwicz u. Habermann, *Jahresb.* 1870, 840).

Identity of Glycollic Acid from Different Sources.—The experiments of Wurtz, Drechsel, Kolbe, and Kekulé (ii. 910), had indicated the probable existence of two modifications of the acid $C^2H^3O^3$, one crystallisable and non-deliquescent, the other liquid at ordinary temperatures, or at all events very deliquescent; and Kolbe suggested that these acids might be respectively—

To throw further light on this question, Fahlberg (*J. pr. Chem.* [2], vii. 329) has prepared glycollic acid from the mother-liquor of fulminating mercury, said by Cloez to be syrupy and uncrystallisable, and compared it with the acid obtained from other sources. The liquors were treated successively with sulphuretted hydrogen and milk of lime to remove mercury, oxalic acid, and glyoxylic acid, the latter being decomposed by boiling the liquid into glycollic and oxalic acids; carbonic acid gas was then passed through the liquid to precipitate the excess of lime, and the filtrate was evaporated to a syrup. Calcium glycolate then either separated in crystals or was thrown down by addition of alcohol, freed from acetate, formate, &c., by pressure, and purified by recrystallisation. By decomposing this salt with oxalic acid, mixing the filtered solution with lead carbonate, decomposing the resulting solution of lead glycolate with hydrogen sulphide, and evaporating the filtrate, glycollic acid is obtained in radiate groups of needles; and by dissolving these crystals in ether free from alcohol, and leaving the solution to evaporate in a vacuum, beautiful anhydrous laminae are obtained which melt at 80°, and are not at all deliquescent. If, however, too strong a heat is employed in the evaporation, or if the ether used as a solvent contains alcohol, no crystals are obtained, the crystallisation being prevented by the presence of glycollic anhydride (diglycollic acid) in the first case, and of ethyl glycolate in the second. In like manner the glycollic acid obtained from monochloroacetic acid (ii. 909) which, when separated from the silver salt, is very deliquescent, and when separated from the potassium salt appears quite uncrystallisable, may be obtained in fine permanent crystals by converting it into the calcium salt and separating it as above described. Hence it appears most probable that the syrupy or deliquescent acid obtained by several experimenters was more or less impure, and that there is actually but one glycollic acid.

Glycollic acid, from whatever source it may be prepared, is acted upon in the same manner by *phosphorus pentachloride*, yielding at ordinary temperatures glycollic

chloride, $\text{CH}^2\text{OH}.\text{COCl}$, and at 120° , chloroacetyl chloride, $\text{CH}^2\text{Cl}.\text{COCl}$ (Fahlberg).

The action of hydrochloric acid on pure glycollic acid does not yield chloroacetic acid; the acid obtained by Kekulé's process from silver or potassium chloroacetate, however, yields chloroacetic acid in this way; but Fahlberg finds that this is simply *precontained* in the impure glycollic acid employed. Kekulé's production of bromoacetic acid by the action of hydrobromic acid on this impure glycollic acid is due to the reaction of the hydrobromic acid on the chloroacetic acid actually present. By heating glycollic acid with alcohol saturated with hydrochloric acid to 150° , glycollic ether is formed, but no chloroacetic acid.

Metallic Glycollates.—The calcium salt, $\text{Ca}(\text{C}^2\text{H}^3\text{O}^2)^2$, crystallises from concentrated solution in hard, translucent crystals, the form of which resembles that of the diglycollate. From dilute solutions it separates in concentrically grouped needles containing $2\text{H}_2\text{O}$, and soluble in 19 pts. water at 15° . The copper salt, $\text{Cu}(\text{C}^2\text{H}^3\text{O}^2)^2$, prepared by digesting the aqueous acid with cupric oxide and evaporating, forms splendid blue crystals sparingly soluble in cold, more soluble in hot water. The thallous salt, $\text{TlO}(\text{C}^2\text{H}^3\text{O}^2)$, prepared by treating the carbonate with aqueous glycollic acid, crystallises in anhydrous long-pointed needles. The zinc salt, $\text{Zn}(\text{C}^2\text{H}^3\text{O}^2)^2 + 2\text{H}_2\text{O}$, prepared in like manner, separates, after sufficient concentration, in warty groups of needles, soluble in 26 parts of cold water. The neutral and basic lead salts have the properties described in vol. ii. p. 911 (Fahlberg).

Ethyl Glycollate. $\text{C}^2\text{H}^3.\text{C}^2\text{H}^3\text{O}^2$, is prepared: 1. By heating equivalent quantities of calcium glycollate and potassium ethyl-sulphate to 170° (Fahlberg). 2. By gradually adding a solution of sodium ethylate to monochloroacetic acid, and heating the mixture for some time in a vessel with reversed condenser:

(L. Henry, *Dent. Chem. Ges. Ber.* iv. 706.) When purified by fractional distillation it is colourless, boils at 150° and has a sp. gr. of 1.033 (at what temperature?) (Fahlberg); 0.9770 at 150° (Henry). It is decomposed by water into alcohol and glycollic acid, and unites with calcium chloride, on which account anhydrous cupric sulphate must be employed for its dehydration (Fahlberg).

Glycollic Anhydride, or Diglycollic Acid, $\text{C}^2\text{H}^3\text{O}^2 = \text{O}$, is formed
 $\text{CO}.\text{CH}^2\text{OH}$
 $\text{CO}.\text{CH}^2\text{OH}$

by heating glycollic acid—in which case, however, the greater part of it suffers further decomposition, yielding the isomeric compounds, glycollide and dioxymethylene, $\text{C}^2\text{H}^3\text{O}^2$ (ii. 912);—or better, by exposing the acid to the vapours of sulphuric anhydride. After a few days the anhydride is obtained as a lustreless powder which may be purified from glycollic acid by washing with water. It is insoluble in alcohol, ether, and cold water; boiling water reconverts it into glycollic acid and dissolves it. It melts at 128° – 130° , that is to say, at a temperature midway between the melting points of glycollic acid (80°) and glycollide (180°). The presence of a small quantity of this compound prevents, as already observed, the crystallisation of glycollic acid (Fahlberg).

GLYCOL-NITRINS. See NITRINS.

GLYCOL-METHYL-GUANIDINE. See GUANIDINE.

GLYCOSALHYDRANIDE, $\text{C}^6\text{H}^{11}\text{NO}^6$. A compound obtained by gently heating helicin with aniline (see HELICIN).

GLYCYRRHIZIN. To prepare this substance from its aqueous infusion, J. M. Hirsch (*Pharm. J. Trans.* [3], i. 749) adds acetic acid, evaporates to dryness, dissolves the residue in alcohol, and treats the solution with sodium carbonate, whereupon sodium acetate crystallises out, while glycyrrhizin remains in solution. Another method is to heat the alcoholic infusion of the root to boiling, filter, evaporate nearly to dryness, redissolve in alcohol, and again evaporate: the residue is nearly pure glycyrrhizin.

GLYOXAL, $\text{C}^2\text{H}^2\text{O}^2$. H. Schiff (*Gazzetta chimica italiana*, iv. 16) has prepared a condensation-product of this compound by the following process:—

When hydrochloric acid gas is passed for some time through a solution of glyoxal in five or six times its volume of strong acetic acid, and the liquid is then exposed in a closed vessel to a moderate heat, as by placing it near a lighted stove, a white crystalline substance separates in the course of the next day, on the sides of the vessel, and

gradually fills the whole of the liquid. By pumping out the liquid, washing the residue with water, and drying it, a very white, microcrystalline powder is obtained, which, when agglomerated in lumps, is very much like potato-starch, crunches between the fingers, swells up in acetic acid, and, like starch, exhibits the greatest indifference to solvents and other reagents.

This substance is free from chlorine; after washing with water and drying, it gives by analysis 39.8 p.c. carbon and 3.6 hydrogen, agreeing with the formula, $C^2H^4O^{12}$, which is that of hydro-hexglyoxal, formed by the condensation of 6 molecules of glyoxal, with addition of 1 molecule water:

Hydro-hexglyoxal is insoluble in water, ether, benzene, petroleum, chloroform, and acetone; sparingly soluble in boiling alcohol. rather more soluble in concentrated acetic, sulphuric, and nitric acid; and is precipitated unaltered on addition of water. Heated with sulphuric acid, it gives off carbon monoxide, without a trace of acetic acid; neither does it yield acetic ether when heated with sulphuric acid and alcohol; it therefore does not contain any acetic residue. A further proof of this is afforded by the fact that it may be formed, though more slowly, by passing hydrochloric acid gas through a solution of glyoxalic ether. By prolonged boiling with water it acquires an acid reaction, and dissolves in the form of glycollic, and perhaps also of glyoxalic acid. The same transformation is produced much more rapidly by caustic alkalis, even in very dilute solution, and likewise by magnesia. No acetate is produced in either case.

Hydro-hexglyoxal, as already observed, is a very stable substance, and in particular does not exhibit any aldehydic reaction. Hence it cannot be supposed to contain the group, $-CHO$. To explain its stability, we must suppose that the aldehydic groups in glyoxal have undergone a change of structure, the oxygen- as well as the carbon-atoms having become united together, *e.g.* :-

Several of these groups may be supposed to unite together by virtue of their free affinities, the molecule of water at the same time serving to satisfy the two units of affinity which remain free, whatever may be the number of the aldehydic groups thus connected. In this manner compounds may be formed, represented by the formulæ:--

The first of these formulæ contains only one hydroxyl, whereas the second contains two. Now when hydro-hexglyoxal is boiled with excess of acetic anhydride, it partly dissolves, and the solution deposits, partly on cooling, further, on addition of water, a white powder, which gives off acetic ether when heated with sulphuric acid and alcohol, acetic acid when boiled with sulphuric acid alone; yields an alkaline acetate when boiled with dilute alkali; and gives by analysis (mean) 41.26 p.c. carbon and 3.98 hydrogen, agreeing very nearly with the formula, $C^{12}H^{12}(C^2H^4O)^4$; it is, therefore mono-aceto-hydro-hexglyoxal. Prolonged boiling with acetic anhydride did not produce any derivative containing a larger proportion of carbon.

A corresponding *benzoyl derivative*, $C^{12}H^{12}(C^7H^5O)^4$, is formed by digesting hydro-hexglyoxal with benzoyl chloride.

These results show that hydro-hexglyoxal contains only one atom of hydrogen replaceable by acid radicals: it may therefore be regarded as a mono-acid alcohol.

Attempts to fix hydrogen upon it by the action of sodium-amalgam and of zinc and sulphuric acid were unsuccessful; concentrated hydriodic acid acts upon it, but the products of the reaction appear to be very complicated.

Hexglycolide or hexglycollic anhydride—

would be isomeric with hydro-hexglyoxal, but it has not yet been obtained.

GÖTHITE. Chrysoberyl, göthite, manganite and diasporo form an isomorphous group (rhombic) represented by the general formula $M''(R^2)^nO^4$, in which, for chrysoberyl, $M = G, Fe$; $R = Al, Cr$, while the others contain H^2 instead of M'' . Parallel with this rhombic group, and represented by the same formula, is the spinel group in the regular system (Kayser, *Jahresb. f. Chem.* 1870, 1281).

GOLD. Analyses of native gold from various localities in the British Isles are given by D. Forbes (*Phil. Mag.* [4], xxxiv. 331; xxxviii. 321):

A, from the Clogau quartz-vein No. 2, in Wales; B, wash-gold from the Mawddach river near Gwyn-fynydd. C, from St. Austell Moor, Cornwall. D, wash-gold from Wicklow in Ireland. E, *a* and *b*, from the Kildonan Valley, Sutherlandshire:—

The analyses A agree with the formula Au^4Ag . The remarkably low specific gravity of the gold from Wicklow (D) is due to the porosity of the specimens examined.

All these native golds are found in granite and in the copper pyrites, galena, and silver fahl-ore contained in it. The ores of the Poltimore mines in Devonshire, which contain gold to the amount of 30 to 60 grams per ton, appear also to be products of the oxidation of metallic sulphides, especially iron sulphide.

Gold from Venezuela was found by Williams (*Chem. News*, xxi. 84) to contain

Au	Ag	Fe	Cu	
93.58	3.69	1.60	0.65	= 90.53.

Specimens of gold from Vancouver Island and West Africa have been described and analysed by F. Wibel (*Jahrbuch f. Mineralogie*, 1873, 244). The specimen from Vancouver Island is a crystal about 7 mm. long, weighing 26.7 grams and having the form of a rhombic dodecahedron (∞O) prismatically elongated in the direction of one of its axes, as in a specimen from the Ural described by G. Rose. Sp. gr. 18.5 at 22°. Its analysis gave—

Gold.	Silver.	Copper.	Iron.	
91.86	6.63	1.00	0.51	= 100.

No mercury, lead, or other metals were found in it.

The specimens from West Africa, analysed by K. Wibel, consisted—*a*. Of gold in grains; *b*. Of gold-dust; *c*. Of gold obtained by washing from a flesh-coloured clay in the neighbourhood of Elmina:—

	<i>a</i> .		<i>b</i> .			<i>c</i> .
Gold	89.40	87.91	97.23	96.40	92.03	97.81
Silver	10.07	11.40	2.77	3.60	5.82	2.19
Copper	0.53	0.69	—	—	2.15	—
	100.00	100.00	100.00	100.00	100.00	100.00
Sp. gr.	14.63	16.20				

Other specimens of West African gold, containing 4.15 and 25 p.c. of copper, and variable quantities of zinc, tin, and lead, were found to be adulterated with brass.

R. Brough Smith (*Sill. Am. J.* xlix. 263) gives a description of the Gold Fields of Victoria in Australia, in which he maintains, in opposition to Murchison, that the richness in gold of the quartz-veins, as well as their thickness, increases with their depth below the surface.

Extraction.—Rivot (*Ann. Min.* [6], viii. 1), describes the occurrence of gold and silver ores in California, and the mode of working them for the extraction of these metals. The gold occurs partly in quartz-veins, partly associated with quartz and pyrites. In the former, the whole of the gold is metallic; the latter ores do not yield up the whole of their gold to the amalgamation process—a proof that part of it is in a state of combination.

The silver ores, occurring in beds of slate, quartz, and heavy spar, rarely in calc spar, contain the silver in combination with sulphur, with arsenic and sulphur, or with antimony and sulphur, and are accompanied by varying quantities of blende, galena, iron pyrites, arsenical pyrites, bournonite, fahlore, grey antimony ore, &c.

The processes employed at the present time in America for the extraction of gold and silver from mineral veins are: (1) Amalgamation in heaps; (2) amalgamation at 100° C. in copper pans; (3) direct amalgamation in pans by the aid of water, a process which is inexpensive, as it can be effected without material loss of mercury, but which does not yield so much gold and silver; and (4) amalgamation, preceded by the roasting of refractory ores with common salt. The yield of gold and silver from pyritical ores does not exceed 65 p. c. of the assay, which in itself is open to losses. According to many synthetical experiments, the loss is greater in assays of richer than of poor ores, amounting always to more than 30 p.c., and with fahlore and ores containing arsenical pyrites to more than 50 p.c. The loss incurred when working on a large scale is less than in laboratory assays. The difference between the yield on the large scale and the percentage indicated by the assay may exceed 30 p.c. even when the metallurgical method is quite perfect; but as the American methods are far from perfect, the difference is still greater.

A new process, devised by Rivot, has been worked in California with good results, and is said to be applicable to ores of every kind, giving at a small cost nearly the whole of the metal. It consists in roasting the ores with superheated steam before amalgamation. The action is somewhat sluggish in the case of pyrites and pyritiferous ores, but may be accelerated by addition of oxidising agents such as ferric oxides, roasted pyrites and black oxide of manganese.

The several stages of the process on the large scale are as follows:—

1. Roasting of the pyrites in heaps, or in reverberatory furnaces, in such a manner as to almost completely oxidise the metallic sulphides, and reduce the formation of sulphates to a minimum.
2. Pulverising and mixing of the roasted pyrites with the ores.
3. Roasting of the mixed mass with superheated steam in a revolving furnace, with exclusion of air.
4. Amalgamation in vortical mills, which are capable of a great out-turn, and of working wet or dry as may be desired, divide the mercury well, and effect a more speedy and complete amalgamation, owing to the pressure of the millstones.
5. Separation of the mercury from the residues.
6. Squeezing of the mercury through coarse linen bags, or wooden cylinders.
7. Distillation of the amalgam in cast-iron tubes provided with receivers cooled by water.

8. Smelting of the metals recovered by amalgamation in blacklead crucibles, and casting in iron moulds.

In the case of silver chloride and copper pyrites, the process has to be modified by the addition of iron pyrites. The several stages are then:

1. Mixing of the ores with iron pyrites, a small quantity sufficing for the chloriferous ores, whereas copper pyrites requires to be mixed with an equal weight of iron pyrites.
2. Roasting the mixture at a low red heat with superheated steam as long as sulphuretted hydrogen continues to escape.
3. Amalgamation of the roasted ores, with addition of water.
4. Separation of the amalgam, expression and distillation of the mercury, fusion of the noble metals, &c.
5. Working of the ore, after treatment with mercury, for copper in the usual way.

W. Skye (*Chem. News*, xxii. 282) has observed that grains of gold often resist the amalgamating action of mercury, in consequence of the gold becoming united on the surface with sulphur. Direct experiments showed that gold immersed in moist hydrogen sulphide or in a solution of ammonium sulphide, becomes converted on the surface into gold sulphide without any alteration in the colour of the metal. In the working of auriferous sand, the hydrogen sulphide which produces this change may be produced by the action of ferrous sulphate on various metallic sulphides. The gold thus altered may be rendered capable of amalgamation with mercury by ignition, especially if it does not contain any considerable quantity of copper (more than 7 p.c.). Gold may also be freed from its layer of sulphide by treatment with potassium cyanide, chromic acid, nitric acid, or an acid solution of calcium chloride.

A process devised by Tossé du Mothay for extracting gold and silver from arsenio-sulphides of lead, copper, &c., is described by G. Widemann (*Chemical News*, xxxiii. 126). The following are its main features:—

1. The sulphur ores are roasted with silicates, litharge being added to complete the oxidation.
2. The easily fusible scoria thus obtained is run on to a bath of molten lead, with which it is thoroughly mixed by mechanical means. The molten lead is said to dissolve out the whole of the gold and silver. The scoria is then removed, and fresh charges of the fusible silicates are added until the lead becomes sufficiently rich for cupellation.

3. The siliceous scoria is reduced by charcoal and iron, and an alloy of lead and antimony obtained.

4. This alloy is freed from antimony by acting on it at a high temperature with steam, which oxidizes the antimony. The lead is freed from all traces of antimony by means of a small quantity of lead sulphate.

Should the alloy contain copper instead of antimony, lead sulphide is added, and the resulting scoria of copper sulphide is removed. The pure lead thus obtained is either sold or used in the treatment of fresh ore.

Reduction of Gold.—Daintree first observed that when gold is introduced into a solution of auric chloride and the latter is reduced by organic substances, all the precipitated gold is deposited on the immersed metal. C. Wilkinson afterwards found that gold is precipitated under similar circumstances on the sulphides of copper, iron, arsenic, lead, zinc, molybdenum, and tungsten. According to Skoy (*Chem. News*, xxiii. 232) this latter result is due to the fact that all the sulphides above-mentioned, when immersed in a solution of gold, become covered with a thin film of gold and then act like an immersed bar of the metal. He finds also that this reduction may be effected by the sulphides of tin, mercury, bismuth, platinum, and gold. Instead of auric chloride, a solution of auric oxide in potash, sodium bicarbonate, or an alkaline silicate may be used. A solution of auric oxide in ammonia is not reduced below 200° F. A solution of gold sulphide remains unattacked under all circumstances.

Spongy Gold.—Gold may be precipitated in the spongy state by saturating a cold 10 p.c. solution of auric chloride with potassium bicarbonate, then adding 1 mol. bicarbonate and 5 mol. oxalic acid, and boiling (Prat, *Dingl. pol. J.* cxvi. 583).

Detection and Estimation of Gold.—In substances containing very small quantities of gold, the detection and estimation of the metal may be effected by means of tincture of iodine or bromine-water. The substance under examination is brought in contact with an equal volume of either of these reagents, and after some time filtering paper is soaked with the clear supernatant liquid. This paper when dried and burnt, leaves, if gold is present, a red ash. This process is particularly well adapted to the separation of gold from sulphides, inasmuch as these compounds are rendered so porous by the previous roasting that the solvent easily takes up the whole of the gold, while only very small quantities of either substance pass into solution (W. Skoy, *Chem. News*, xxii. 245).

Detection of Gold in Sea-Water (Sonstadt, *Chem. News*, xxvi. 150).—Experiments made on specimens of sea-water collected at various times at Ramsey Bay, Isle of Man, prove that gold exists therein, but as the quantity is certainly less than one grain in a ton, it is too small to admit of separation, or even detection, by the usual tests. Besides the difficulty of detection arising from the small quantity of gold present, there is another difficulty of a graver kind, due to a continuous redissolution of the gold after it has been separated in the metallic state. This redissolution is owing to the separation of iodine under the influence of reducing agents upon the iodate of calcium, which Sonstadt has previously shown to exist in sea-water. Even if the reducing agent is added in large excess, oxidation takes place so rapidly under the continuous reproducing power of calcium iodate, that, sooner or later, according to the excess of reducing agent added, the stage arrives at which the iodine is set free, and the suspended gold is redissolved.

Of three entirely different methods employed, the following is one which may be performed upon so small a quantity of sea-water as 150 to 200 c.c. Two or three decigrams of pure ferrous sulphate are dissolved in the water, which is acidulated with two or three drops of hydrochloric acid. The solution is heated in a clean and well-glazed porcelain dish, over a small flame, so managed that the flame may touch the under part of the dish without causing ebullition. Under these circumstances a lustrous film of ferric oxide forms in the dish, commencing from the portion directly heated by the flame. The heat is continued without boiling, until the sea-water is evaporated to about half, or so long as the film increases in extent and in lustre. The liquid is then poured off, the strongly adherent film is rinsed with a little water, and then about 50 c.c. of strong chlorine-water is allowed to stand in the dish for an hour or two, after which it is slowly evaporated down (over the film) to a few drops, a drop of dilute hydrochloric acid being added towards the end of the evaporation. The liquid, which should be nearly colourless, is then poured into a test-glass containing a few drops of solution of stannous chloride, when, after a few minutes, it takes a bluish or purplish tint, which may be exactly matched by a drop or two of a suitably diluted solution of gold added to a corresponding proportion of tin-salt in another glass. The formation of the film depends upon the iron being in a particular state of oxidation, and it is best, after adding the ferrous sulphate and hydrochloric acid to the sea-water, to leave it exposed to the air for a few hours before heat-

ing the liquid to obtain the film. The chlorine-solution of the sea-water films may be dried up in a porcelain crucible with precipitated lead, and gold beads obtained by cupellation, after fusing the lead into a button with borax; but for this experiment at least half a litre of sea-water should be taken, and even then the bead obtained is too small to be weighed. Similar experiments in the same vessels, and with the same reagents, upon simple water, and on water containing chloride of sodium and alkaline sulphates, never yielded the slightest coloration with stannous chloride.

Separation of Gold from Copper.—The solution of the two metals in aqua regia is evaporated to dryness, the residue dissolved in water, the solution mixed with oxalic acid, then after standing for 48 hours, heated to the boiling point and neutralised by caustic potash added at short intervals. The potassium oxalate thus formed unites with the copper oxalate, forming a soluble double salt, and the gold in it is left in the pure state. Gold precipitated by oxalic acid from an acid solution containing copper is always contaminated with cupric oxalate (E. Pargotti, *Zeitschr. anal. Chem.* ix. 127).

Separation of Gold from Silver Chloride.—The silver chloride formed in the purification of argentiferous gold by means of chlorine gas, contains an appreciable amount of gold, to such an extent indeed, that the silver bullion obtained by the reduction of the chloride often contain as much as 18 p.c. of gold. The processes generally adopted for the removal of this gold do not give satisfactory results, but the separation may be advantageously effected as follows. The fused chloride is covered with a layer of borax, one-eighth to one-quarter inch in thickness, and sodium carbonate is gradually added on the top of this layer, in quantity varying from 16 to 20 oz. per 230 oz. of silver chloride operated on. The chloride is not stirred, but the metallic gold is allowed to subside to the bottom of the receptacle. 20 oz. of soda will generally produce a gold button weighing about 35 oz., assaying from 870 to 880, while the silver bullion subsequently obtained will contain 2 to 5 parts of gold in 10,000 parts. A second treatment with a much smaller quantity of soda renders the silver perfectly free from gold (Loebius, *Chem. News*, xxvii. 128).

Gold Monochloride, or Aurous Chloride, AuCl. The directions usually given for the preparation of this compound, and the descriptions of its properties are somewhat discordant. According to Leuchs (*J. pr. Chem.* [2], vi. 156) these discrepancies arise from decomposition taking place during the preparation. He finds that when trichloride of gold is heated, the evolution of chlorine does not cease as soon as the whole of the trichloride is converted into monochloride, as commonly stated, but may go on till the gold is completely reduced to the metallic state. This result he attributes to the action of moisture in the air, which, being absorbed by the hygroscopic trichloride, decomposes some of the monochloride already formed into metallic gold and trichloride, the moisture again acting upon fresh portions of monochloride, and so on. To prevent this decomposition he adopts the following process. Trichloride of gold is heated to 200°–300° on a sand-bath, care being taken to crush all lumps, and to bring fresh portions of the material constantly in contact with the basin by trituration with a pestle. The evolution of chlorine is very rapid: the liquefied red chloride becomes first brownish-red, then dirty brown, yellowish-brown and dry, afterwards greenish, and ultimately pure yellow. When the mass acquires a greenish colour, the temperature is lowered gradually to 180°. The evolution of chlorine still continues, and the end of the operation can be judged of only by the changes of colour. As soon as the powder appears of a pure full yellow, it is removed from the sand-bath, trituated till it ceases to smell of chlorine, and at once transferred to closed glass vessels. The product, after cooling, is pure yellowish-white.

A chloride, intermediate in composition between the mono- and tri-chloride, is formed by heating spongy gold with a solution of auric chloride, or by heating aurous and auric chlorides together (Prat, 1st Suppl. 653).

Iodides. Aurous iodide, prepared with aqueous hydriodic acid, dissolves in hydriodic acid saturated with iodine, and the solution, when evaporated at a gentle heat, deposits small rhombohedral crystals of auric iodide, AuI_3 (Prat, *Compt. rend.* lxx. 840).

Oxides. When gold is treated with a quantity of aqua regia not sufficient to dissolve it, but containing excess of hydrochloric acid, and the solution is saturated with such a quantity of potassium bicarbonate that the precipitate redissolves, an orange-yellow solution is obtained which begins to show turbidity at 55°, deposits at 60° a light olive-green hydrate, and at 65°–95° a dark olive-green hydrate, the former containing 8 p.c. the latter 7.74 p.c. oxygen, answering to the composition Au_2O_3 . This intermediate oxide of gold gives up its water of hydration on exposure to the air, and is converted into a nearly black, hard, heavy mass, having a conchoidal shining

fracture. It is not altered by light, gives off its oxygen at about 250° , dissolves very easily in hydriacids, and forms a dark-green solution with cold hydrochloric acid. It also unites, especially when heated with oxygen-acids; hydrofluoric acid combines with it, but does not dissolve it. When a solution of gold in excess of aqua regia in which the nitric acid predominates is supersaturated with potassium bicarbonate and heated, an oxide is obtained, orange-coloured when freshly precipitated, ochre-coloured after washing and drying, and containing 15 p.c. oxygen, which answers to the formula AuO^2 . It is not altered by light, but gives up its oxygen, with sparkling, when heated to about 200° (Prat, *loc. cit.*).

Oxy-salts. *Aurous Sulphate (?)* When spongy gold is heated with a mixture of sulphuric and iodic acids ($3\text{HI} \cdot \text{SO}^4 : 2\text{HIO}^3$) till the mixture has acquired a dark orange-colour, which takes place at 300° , the whole of the gold is oxidised, and the product, when dissolved in fuming nitric acid, gives, on dilution with water and heating, a copious brown precipitate, consisting of a gold sulphate, which is quickly altered by light, is very difficult to crystallise, has a dark purple-red colour when dry, and appears remarkably stable when heated. It is very hygroscopic, and is decomposed by a large quantity of water into insoluble aurous sulphate and auric sulphate, which remains dissolved (Prat). This last decomposition would seem to show that the salt is an auroso-auric sulphate.

Auric Sulphate and Nitrate.—It is stated by Gmelin and other authorities that a solution of auric oxide in nitric or sulphuric acid is rapidly and completely decomposed on dilution with water. From the experiments of A. H. Allen, however (*Chem. News*, xxv. 85), it would appear that the oxacid salts of gold are more definite and more stable in solution than they are usually supposed to be.

A solution of auric oxide in nitric acid gave, on dilution with water, a perfectly clear solution which answered to all the tests for gold. It decomposed very gradually by keeping, the oxide being deposited.

In like manner an aqueous solution of auric sulphate deposited but very slowly a portion of the metal, the decomposition in many instances being very slight, and never wholly complete, even after a long interval.

Finely divided gold, when heated with solid potassium permanganate and concentrated sulphuric acid, is rapidly dissolved, yielding a solution which is not precipitated at all on dilution, but gives, when tested with oxalic acid or ferrous sulphate, abundant evidence of the presence of gold. There would appear, then, to be no doubt that the gold exists in this solution in the state of sulphate.

When nitric acid is substituted for sulphuric acid, the gold is completely precipitated on the addition of water. Reynolds and Spiller are of opinion that in this latter reaction auric nitrate is not produced. Allen objects to this conclusion, and points out that the true cause of the reduction is the presence in the solution of nitrous acid, since, if a small quantity of permanganate be added before dilution, or if the acid liquor be boiled with a crystal of ammonium sulphate, precipitation of the gold does not take place.

This explanation is further strengthened by the fact that it is possible, by adding a few drops of fuming acid to a pure solution of auric nitrate, to cause an instantaneous precipitation of the metal.

Gold and Silver Sulphide, $2\text{Au}^2\text{S}^3 \cdot 5\text{Ag}^2\text{S}$. This sulphide is formed by the action of melted sulphur on a mixture of gold and silver in the fused state. It is a dark grey crystalline substance of sp. gr. 8.159, decomposed by heating in a stream of hydrogen. Fused with sodium carbonate it gives sodium sulphide, and apparently an alloy of gold and silver (Muir, *Chem. News*, xxv. 654).

Gold Purple, or Purple of Cassius. Macquer having observed that the purple of Cassius was deeper in colour the more gold it contained, considered it to be a mixture of stannic hydrate and metallic gold. But Proust, finding that when moist it dissolved in ammonia, and that it did not yield gold when treated with mercury, looked upon it as a true combination, consisting of aurostannous stannate mixed with varying proportions of stannic hydrate. Debray (*Compt. rend.* lxxv. 1026) considers both views to be wrong, and regards the purple as a 'lake' of stannic acid coloured by metallic gold, the gold being prevented by its union with the acid from being dissolved out by mercury, just as ordinary lakes will not yield up their colours to water.

Instead of preparing the purple in the usual way, it may be obtained by first precipitating stannic oxide by boiling together stannic chloride and sodium acetate, then adding gold chloride and potassium oxalate, and again boiling, when metallic gold will be precipitated upon the oxide. A similar colour is produced if alumina be substituted for stannic oxide. This seems to show that the purple is simply an oxide coloured by gold. That the purple should be soluble in ammonia is not surprising if it be admitted

to be chiefly made up of stannic oxide, which is soluble in ammonia in the cold. Elevation of temperature and desiccation diminish the solubility both of stannic oxide and of the purple. Moreover, the solution, which always appears turbid by reflected light, slowly deposits metallic gold. The latter could not, therefore, have been present as an oxide, since ammonia, in acting upon oxides of the precious metals, gives rise to products more or less complex, but the metal is never set free.

In the assay of silver containing a little gold and tin, there is often observed, on dissolving the metal in nitric acid, a substance very similar in appearance to the purple of Cassius. It is not, however, soluble in ammonia, and Debray thought that this might be due to the metal having been dissolved in hot acid, just as stannic oxide obtained by oxidising tin with hot acid, is also insoluble in ammonia. He therefore attacked, with nitric acid, at a very gentle heat, an alloy of silver, gold, and tin, and obtained a purple residue quite soluble in ammonia, showing the identity of this residue with the ordinary purple.

Debray appears to consider a 'lake' as standing midway between a mixture and a chemical combination.

GOLDEN SEAL. See HYDRASTIS.

GRAIN, ANALYSIS OF. The methods hitherto employed for the determination of starch and cellulose in grain give very discordant results. When the starch is dissolved by a solution of malt (Oudemans' method), much nitrogenous matter remains with the cellulose, and is not perfectly removed by treatment with potash, which, moreover, dissolves cellulose to an appreciable extent. Purified cotton-wool lost 4.54 p.c. when boiled with a 1.25 p.c. solution of potash, and afterwards with dilute acetic acid; and on repetition of the treatment, suffered a further loss of 2.6 p.c. When vegetable matter is acted upon in the cold by potassium chlorate and nitric acid (F. Schulze's method), the cellulose obtained is very pure; but purified cotton-wool loses 3.6 p.c. when treated in this manner. To avoid those sources of error, W. Pillitz (*Zeitschr. anal. Chem.* xi. 46) determines the vegetable fibre in grain by heating the flour with very dilute sulphuric acid in sealed tubes at 140°-145°; under such treatment cotton-wool loses only 0.4 p.c. His plan of analysis is as follows:—

8-10 grams of the flour are exhausted as quickly as possible with 1 litre of cold water, by means of a Reul's press, in which the flour lies on a filter-bed, and water is forced through it by means of a column 7 feet high. In the watery solution the total solid matter, ash, nitrogen, and sugar are determined. The undissolved flour is quickly dried, first in a vacuum, then, after being finely powdered, at 100°. 1 to 1.2 gram of the dried mass is then treated with 40 c.c. of very dilute sulphuric acid (3 to 3.5 c.c. of acid sp. gr. 1.16 diluted to 1 litre), and heated in a sealed tube for eight hours at 140°-145°. The cellulose is then collected on a weighed filter, washed with water, alcohol, and ether, dried, weighed, and its ash deducted; it contains only traces of nitrogen. In the solution sugar is determined by Fehling's method, and the amount found is calculated as starch. The heating in the sealed tube is repeated with 1 to 1.2 gram of the original meal. The sugar thus obtained represents starch plus sugar and dextrin; and by subtracting the starch and sugar previously determined, the amount of dextrin is found. Fat, total nitrogen, and ash are determined in the usual manner.

The following are analyses made by this method. The millet, buckwheat, and spelt, were free from their external shells; the other grains were in their ordinary marketable condition:—

100 parts dried at 100° contain. —	Prince Albert Wheat	Browick's Wheat	Spelt	Rye	Millet	Barley	Oats	Maize	Rice	Buckwheat

2nd Sup.

GRANITE. From an examination of English and Irish granites, S. Haughton (*Proc. Roy. Soc.* xvii. 209) concludes that they are either eruptive rocks belonging to the formations from the Silurian to the carbonaceous, or metamorphic rocks. The eruptive granites contain orthoclase and albite, but no lime felspar; the metamorphic granites, on the other hand, contain orthoclase and a lime felspar, viz., oligoclase, but no albite.

The granites of central and western Scotland are metamorphic, like those of Donegal and Norway, with which, in fact, they are geologically identical; eruptive granite is met with only occasionally, as near Peterhead. The felspars are the same as in the English and Irish granites (Haughton, *Jahrbuch f. Mineralogie*, 1871, 83).

J. Lemberg (*Zeitschr. geol. Gesellsch.* xxii. 85) has analysed several series of the decomposition-products of Finland felspars and granites. The results show that, in the process of weathering, the bases RO, and especially CaO, diminish in proportion to Al_2O_3 , whereas H_2O , Fe_2O_3 , and MgO , are taken up; or that, under the influence of water containing potash and magnesia, CaO and K_2O are exchanged for MgO ; Na_2O and CaO for K_2O . For the analyses, see *Jahresb. f. Chem.* 1870, 1353.

GRANULITE. Scheerer (*Jahrbuch f. Mineralogie*, 1873, 673-691). The true granulites form a class of rocks, sharply characterised by their petrographic constitution, which may be regarded as co-ordinate with that of the gneisses, consisting mainly of a fine-grained mixture of felspar and quartz, and distinguished by admixture of garnet (sometimes also of cyanite): they exhibit for the most part, notwithstanding their characteristic deficiency in mica, the parallel structure, and therefore the character, of a stratified rock. They may in fact be regarded as gneisses containing little or no mica, and having that mineral replaced by garnet.

In chemical constitution also, the granulites are sufficiently near to the gneisses to admit of their division into groups corresponding with the red, middle, and grey gneisses (or upper middle and lower plutonites). Scheerer has shown (*Zeitschr. d. Deutschen geologischen Gesellschaft*, xiv. 23-150), that the chemical constitution of these gneisses may be represented by the following formulae, and by the oxygen-ratios, degrees of silicatisation (ratio of number of molecules of silica to number of molecules of base) and percentage of silica, thence deduced:—

	Upper plutonite Red Gneiss	Middle plutonite Middle Gneiss	Lower plutonite Grey Gneiss
Chemical formula	$4RO.9SiO_2$	$4RO.9SiO_2 + 2(2RO.3SiO_2)$	$2RO.3SiO_2$
Oxygen ratio RO : SiO_2 }	1 : 4.5	1 : 3.75	1 : 3
Degree of sili- entisation }	2.25	1.875	1.5
Percentage of silica Mean	76-74 75	71-69 70	66-64 65

The following are analyses of seven Saxon granulites:—1. Reddish granulite from Penig, containing, in a fine-grained eutectic ground-mass, numerous small crystals and granules of red garnet; no perceptible trace of mica. 2. Greyish flesh-red granulite from Neudörfchen, similar in structure to the preceding, but containing also small granules of quartz and crystalline felspar. 3. Greyish-white granulite from Limbach; ground-mass fine-grained to compact, with splintery fracture, and containing, besides pale-red garnet, granules of an unknown black mineral, to which the greyish colour is due. 4. Grey granulite from Penig, similar to 3, but containing more of the black mineral. 5. Dark grey granulite from Burgstadt, containing brown granules of garnet and black scales of mica. 6. Light-grey granulite from Neudörfchen, rather fine-grained, containing granules of quartz and crystalline felspar, together with scattered crystals of garnet, and here and there scales of pinchbeck-brown mica, with traces of the black-mineral. 7. Greyish-white slaty granulite from Steinä near Hartha, shows distinct parallel structure. The ground-mass appears under the magnifying glass to be made up of parallel layers of quartz and felspar with brown garnet and scales of pinchbeck-brown and black mica imbedded. According to Förster's observations, this rock is the most abundant of all the true granulites, and, together with gneiss-granulite and trap-granulite, makes up by far the greater part of the granulite field of Saxony:—

Analyses of Saxon Granulites.

	SiO ²	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	H ₂ O	
1. . . .	76.33	12.89	2.35	0.45	0.35	7.59	—	0.22	= 100.18
2. . . .	75.80	12.09	2.42	1.45	0.38	4.27	2.72	0.39	= 99.52
3. . . .	75.46	12.09	3.75	1.22	0.66	3.96	2.46	0.25	= 99.85
4. . . .	72.97	12.69	4.55	2.33	0.63	3.46	3.16	0.13	= 99.92
5. . . .	71.25	14.28	4.32	2.84	0.92	3.02	2.76	0.16	= 99.55
6. . . .	73.47	14.86	3.64	1.62	0.67	3.95	1.80	0.21	= 100.22
7. . . .	73.37	14.09	3.31	1.54	0.76	4.25	2.49	0.27	= 100.08

From these analyses may be deduced the following oxygen-ratios, RO : SiO₂, and degrees of silicatisation:—

	Oxygen ratio			Degree of silicatisation		
	Found	Normal	Difference	Found	Normal	Difference
1. . .	1 : 4.74	1 : 4.50	+ 0.24	1.58	1.50	+ 0.08
2. . .	1 : 4.64	"	+ 0.14	1.55	"	+ 0.05
3. . .	1 : 4.47	"	— 0.03	1.49	"	— 0.01
4. . .	1 : 3.93	1 : 3.75	+ 0.18	1.31	1.25	+ 0.06
5. . .	1 : 3.56	"	— 0.19	1.19	"	— 0.06
6. . .	1 : 3.83	"	+ 0.08	1.28	"	+ 0.03
7. . .	1 : 3.90	"	+ 0.15	1.30	"	+ 0.05

These numbers show that the normal granulites are co-ordinate, partly with the upper plutonite (red gneiss), partly with the middle plutonite (middle gneiss), but they do not indicate the existence of any granulite representatives of the lower plutonite (grey gneiss). Granulites of the last-mentioned variety (with 64–66 p.c. silica) appear indeed to occur much more rarely and in less extent than the two more highly silicated classes, but not to be altogether wanting. At Ehrenberg in the Zschopenthal, for example, there occurs a grey-black granulite containing 65.4 p.c. silica; and a very dark grey-black granulite from Waldheim has been found to contain 65.5 p.c. silica. The latter contains, together with a large quantity of garnet, a small quantity of pinchbeck-brown mica; the former, on the other hand, contains garnet without mica, and its dark colour appears to be due to the black mineral. Parallel structure is visible in the latter, but not in the former.

On comparing the analyses of the granulites with those of the gneisses which they most nearly resemble, it is seen that they differ considerably from the latter in their amount of water. In the granulites 1–3, the average amount of water is 0.29 p.c., and in the granulites 4–7, it is only 0.19 p.c., whereas the average proportions of water in the normal upper and middle plutonites are respectively 1 and 1.5 p.c. This deficiency of water in the granulites is a simple consequence of the almost total absence of mica. The several species of mica are indeed the only hydrated constituents of plutonic silicious rocks, the proportion of water contained in them being between 4 and 5 p.c. Where they are absent, in rocks which have not undergone alteration, water is either absent or present in small quantity only; in the latter case its presence may be due to small scattered particles of mica imperceptible to observation, or to an incipient weathering of the felspar.

These facts lead to the conclusion that granulites have been formed from gneisses (plutonites) by a process of transformation which has removed the chemically-combined water of the latter. That this process has consisted in a more or less complete remelting, or at least in a softening of the mass by heat, may be inferred from the occurrence of crystalline garnet, which has been formed by dehydration of mica. Garnets, indeed, having the composition expressed by the general formula $3(2\text{RO} \cdot \text{SiO}_2) + 2\text{R}'\text{O} \cdot 3\text{SiO}_2$, may have derived their constituents from the micas, their formation being accompanied by that of felspar and cyanite, or one of the two, according to the composition of the mica. Certain dark magnesia micas having the composition $3(2\text{RO} \cdot \text{SiO}_2) + 2\text{R}'\text{O} \cdot 3\text{SiO}_2$, differ indeed from garnet only by the water included in the first member; and in the case of other magnesia micas, $2(2\text{RO} \cdot \text{SiO}_2) + 2(\text{R}'\text{O} \cdot 3\text{SiO}_2)$, the formation of garnet is nearly as simple. Less simple is the derivation of garnet from the more silicious potash micas; but even in this case it is possible, taking into account the

simultaneous formation of the minerals above mentioned, or perhaps of the black mineral before alluded to as occurring especially in the granulites 3 and 6, most probably as a product of the decomposition of mica.

In the granulite district of Saxony there occur, together with the true granulites above considered, chiefly the following rocks:—*a.* Gneiss-granulites (and granulitic gneisses), i.e., rocks more or less fine-grained and micaceous, but likewise containing garnet, forming, indeed, transition-stages between gneiss and granulite. *b.* Gneissos (and gneiss-granites). *c.* Granitos (together with granulitic granite, granitic granulite, and Förster's granular normal granulite. *d.* Trap-rocks, the so-called trap-granulites (together with gabbro).

From the oxygen-ratios and degrees of silicatisation of these rocks it is inferred (*a*) that the gneiss granulites, like the true granulites, are co-ordinate with the upper and middle plutonites; the gneiss-granulites of Waldheim, however, which contains 66.3 p.c. silica, is a representative of the lower plutonite or grey gneiss; (*b*) that the gneisses, which occur but sparingly, belong to the middle and lower plutonite; (*c*) that the granites, which occupy a large portion of the district, belong to the upper and middle plutonite; (*d*) that the trap-granulites, including gabbro and hypersthénite, which, as already observed, form, together with slaty normal granulite and gneiss-granulite, by far the greater part of the whole granulite field, exhibit oxygen-ratios $2\text{RO} : 3\text{SiO}_2$ included between 1 : 1.49 and 1 : 1.36, that is to say, they are similar in constitution to the corresponding rocks in other localities.

From all the facts above detailed Scherer infers that, in the formation of granulite from gneiss, the rocks chiefly concerned have been the red and middle gneisses (upper and middle plutonites). The eruptive rock which has brought about the remelting and consequently dehydration of the gneiss—or which has been thrown up simultaneously with the granulites—cannot have been granite, although this rock traverses and intersects the whole granulite district in numerous veins. The remelting must, in fact, be assigned to a much later geological period, as indicated by the occurrence of the trap-granulites, i.e., especially of the gabbro and hypersthénite rocks. But whether any other eruptive rocks have taken part in the metamorphosis or not, the view—first advanced by Naumann from a purely geognostic standpoint—that the granulites themselves are eruptive rocks, is fully confirmed by their chemical constitution.

Analyses of the Saxon granulites have also been made by A. Stelzner (*Jahrbuch f. Mineralogie*, 1871, 244; *Chem. Soc. J.* [2], ix. 807), who regards them, not as eruptive, but as metamorphic rocks.

GRAPES. Researches on the ripening of grapes have been made by E. Pollucci (*Gazzetta chimica italiana*, ii. 392). A comparison of the amount of sugar and of acid in the external and internal portions of the flesh of the fruit, shows that the part nearest the centre contains more of the acid principle, and is, consequently, the last to ripen. During the ripening, the amount of sugar goes on increasing to a certain point, and then remains stationary, whilst the proportion of acid still continues to decrease, so that the grape must be considered to be ripe, not, as heretofore, when the amount of sugar ceases to increase, but rather when the acidity no longer diminishes.

GRAPE-SUGAR. See SUGAR.

GREENSTONE (Th. Petersen, *J. pr. Chem.* [2], vi. 197). The greenstones may be divided into two classes, viz.: (1.) The amphibolitic or hornblende greenstones; (2.) The pyroxenic or augitic greenstones.

To the hornblende group belong diorite, with its varieties and congeners, the essential constituents of which are hornblende and a triclinic alkali-felspar. Sometimes also quartz is present, in which case the rock approximates to the trachytic series, and may even pass into syenite if it also contains orthoclase. The augitic greenstones are the true basic rocks. They all contain a plagioclastic alkali- or lime-felspar, but no quartz. They may be conveniently divided into two groups, the older and the younger.

The older division, which is developed chiefly in the transition formation, includes the rocks of the diabase family, to which belong: (*a*.) True diabase. (*b*.) Melaphyr and augitic porphyry, which contain true augite and are very much alike. (*c*.) Hypersthénite, containing ferruginous hypersthène, which, according to the recent investigations of Descloizeaux, crystallises in the rhombic system. (*d*.) Gabbro, containing comparatively light-coloured non-ferruginous enstatite, diallage, or smaragdite. All these rocks may be conveniently designated as 'true greenstones.'

To the later division of the augitic rocks belong those of the basaltic family: basalt, diorite, and basaltic lavas, for which, as proposed by Naumann, the collective name 'trap' may be retained.

The basic greenstones, and especially those containing augite, exhibit on the whole a considerable resemblance to one another, and their percentage composition is also nearly the same. The alkaline silicates are more variously developed in the basaltic than in the diabasic rocks, which latter do not contain glassy felspar, nepheline, &c. In the former, on the other hand, the augitic substance has in the course of ages been more or less altered and converted into chlorite. Titaniferous magnetic iron ore (in some cases also titaniferous iron), and in small quantity apatite, is common to both groups.

The most important Constituents of the Basic Rocks.—It has long been questioned whether any triclinic felspar is a regular constituent of diabases. Petersen finds that oligoclase is usually present, whereas lime-felspar occurs in considerably smaller proportion, or is altogether wanting. In the younger greenstones, especially the basaltites, the oligoclase is sometimes replaced by orthoclase. Zeolites, mostly of comparatively recent formation, are diffused through all greenstones, especially the basaltites.

Augite and Hornblende.—The constitution of these minerals, and especially the part which alumina and ferric oxide play in them, has not yet been satisfactorily explained. Most of the analyses agree with the formula of a bisilicate, the excess of base which some of them exhibit being due to the iron, which is often present as magnetic oxide. Augite and hornblende sometimes occur together in greenstones, the augite, however, generally predominating.

Chlorite.—The constitution of minerals of the chlorite family is but imperfectly understood, the obscurity arising chiefly from the fact that they are products of the more or less advanced transformation of augitic minerals, and therefore difficult to obtain pure. Their mean composition is best expressed by Rammelsberg's formula $2(3\text{RO} \cdot \text{SiO}_2) + \text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + 4\text{H}_2\text{O}$. In the diabases ferruginous chlorite is almost always present, the augite being sometimes completely converted into this mineral. It is often accompanied by a large quantity of finely-divided magnetic iron ore.

Magnetic and Titaniferous Iron Ores.—Magnetic iron oxide is a regular constituent of the basic rocks, both old and new, especially of the augitic greenstones. It often contains titanous acid. Titaniferous iron is of frequent occurrence in the dolerites. Titanic acid occurs in basic rocks, sometimes isolated, more frequently, however, as titaniferous iron.

Apatite, to the amount of several units per cent. is rarely absent from basic rocks, and is frequently met with in other rocks of plutonic origin, especially trachytes and lavas.

Formation of Serpentine.—Greenstones are not unfrequently serpentinised. Serpentine more or less distinctly stratified is often found amongst crystalline rocks, as gneiss, granite, diorite, gabbro, diabase, &c., but also nearest to those which contain a considerable quantity of magnesia. Silica and magnesia appear therefore to have a peculiar tendency to unite into a mass exhibiting the character of serpentine.

The Greenstones as Matrices of useful Minerals and Ores.—The beds of ore of Wittichen in Baden, appear to owe their existence to neighbouring hornblende slates containing nickel, cobalt, arsenic, bismuth, and silver. Many iron and copper ores, particularly the copper schist of Oberhessen, also the nickel and copper ores of the Dillenburg district, are probably derived from diabase. The origin of the important deposits of phosphorite in Nassau must also be assigned to diabase, which is everywhere rich in apatite.

GUAIAACUM. E. Schaer (*Zeitschr. anal. Chem.* ix. 430) prepares tincture of guaiacum by dissolving 1 part of the recently pulverised resin in 100 parts of absolute alcohol, and keeps it in black glasses, in which it will remain unaltered for a long time.

The reaction of this tincture with copper salts in presence of hydrocyanic acid and with various cyanogen compounds of copper has been already noticed (p. 383). Schaer either pours the guaiacum tincture on the liquid to be tested, or mixes it with the latter till a strong opalescence is produced. In the former case a blue zone becoming continually broader makes its appearance at the surface of contact; in the latter the resinous precipitate assumes in a few minutes a light blue colour.

The true homologues of hydrocyanic acid, viz.: acetonitril, propionitril, capronitril, &c., produce a very distinct blueing, even when they have been completely freed from isocyanides or carbamides by repeated treatment with dilute hydrochloric acid. Of the carbamides, only the toluyl-compound was examined, which, whether in the state of liquid or of vapour, does not produce any blueing, either with tincture of guaiacum containing copper, or on guaiac paper moistened with a very weak solution of a copper salt. Schaer does not, however, infer from this that the entire group of carbamides is incapable of producing this reaction, inasmuch as the action of benzene derivatives may be much weaker than that of methyl-, ethyl-, or amyl-compounds. Normal sulphonyl cyanates, as those of ethyl and amyl, blue the guaiac-copper solution as strongly

as their isomerides, the mustard-oils or sulphocarbimides. The blueing produced by these sulphocyanates, especially in the state of vapour, is much weaker than that developed by the normal cyanides. Methyl-, ethyl-, amyl-, and phenyl-sulphocarbimides behave in the same manner as ordinary mustard-oil. The amyl-compound, however, is distinguished from the rest by its much stronger action in the state of vapour. Phenyl-sulphocarbimide, on the other hand, exerts but a very feeble action, especially in the state of vapour.

Schönn (*Zeitschr. anal. Chem.* 1870, 209) observes that great care is necessary in the use of tincture of guaiacum for the detection of hydrocyanic acid, chromic acid, and ozone, inasmuch as the same effect may be produced by other substances. Guaiacum-paper moistened with solution of cupric sulphate is turned blue by ammonia, as well as by hydrocyanic acid. Tincture of guaiacum, in presence of sulphuric acid, is rendered blue, not only by chromic acid, but also by ferric chloride, potassium ferricyanide, gold chloride, potassium permanganate, molybdic acid, potassium nitrate, and potassium nitrite. Guaiacum resin assumes a blue colour with oxidising substances, and with potassium antimonate, barium carbonate and hydrochloric acid, lead acetate, calcium chloride, manganese chloride, copper nitroprusside, mercurous nitrate, and sodium sulphocyanate. Copper salts also colour tincture of guaiacum blue when very dilute. The reaction is more sensitive in presence of ammonium chloride, barium chloride, ammonium bromide, potassium iodide or cyanide, or ammonium fluoride.

GUANAPITE. See GUANO.

GUANIDINE, $\text{CH}_3\text{N}^+ = \text{C} \begin{Bmatrix} \text{NH}^2 \\ \text{NH} \\ \text{NH}^2 \end{Bmatrix}$. Erlemmeyer obtained this base by the action

of cyanogen chloride on ammonia (i.e. of cyanamide on ammonium chloride, 1st *Suppl.* 654). According to Bannow (*Deut. Chem. Ges. Ber.* iv. 161) the chloride of cyanogen may be conveniently replaced by the iodide. The solubility of ammonium iodide in alcohol appears to hasten the formation of guanidine. Iodide of cyanogen with three times its weight of alcoholic ammonia (of 10 p.c.), heated in a sealed tube in the water-bath for three hours, gave almost the theoretical quantity of nearly pure guanidine salt. According to Ossikovsky, however (*Bull. Soc. Chim.* [2], xviii. 161), other products, including a volatile fatty acid are formed at the same time.

G. Bouchardat (*Compt. rend.* lxi. 961) by passing 150 litres of phosgene gas into ammonia, obtained, together with sal-ammoniac and urea, small quantities of guanidine, ammelide, and cyanuric acid.

Guanidine boiled with dilute sulphuric acid, or with baryta-water, assimilates the elements of water, and gives ammonia and urea, or the products of its decomposition.

Substituted Guanidines. *Dibenzyl-guanidine*, $\text{CH}_2(\text{C}_6\text{H}_5)_2\text{N}^+ = \text{C} \begin{Bmatrix} \text{NH.C}_6\text{H}_5 \\ \text{NH} \\ \text{NH.C}_6\text{H}_5 \end{Bmatrix}$

The hydrochloride of this base is formed by boiling an alcoholic solution of cyanbenzylamide (p. 182) with benzylamine hydrochloride, and the free base is formed by the action of dry cyanogen chloride on pure dry benzylamine. The hydrochloride crystallises in laminae melting at 176° , slightly soluble in water, more freely in alcohol. The *platinohydrochloride* is crystalline. On adding caustic soda to a solution of the hydrochloride, dibenzylguanidine separates as an oil which soon solidifies, and crystallises from alcohol in colourless laminae or plates which melt at 100° , and dissolve freely in water, alcohol and ether (*Strakosch, Deut. Chem. Ges. Ber.* v. 692).

Phenyl-, tolyl-, and methyl-guanidine may be formed by the action of cyanamide on the hydrochlorides of aniline, toluidine, and methylamine respectively (Erlenmeyer, *Deut. Chem. Ges. Ber.* iii. 806); the last also by the action of methyl-cyanamide on ammonium chloride (Tawildarow, *ibid.* 477).

Methyl-guanidine, $\text{CH}_3(\text{CH}_3)_2\text{N}^+ = \text{C} \begin{Bmatrix} \text{NH.CH}_3 \\ \text{NH} \\ \text{NH}^2 \end{Bmatrix}$, appears to be identical with

methyluramine—which Dessaignes obtained by boiling an aqueous solution of creatine or creatinine with mercuric oxide (iii. 1009)—in every respect excepting in the form of its platinum salt, that of methyluramine crystallising, according to Sérarmont, in rhombohedrons, whereas, according to v. Kobell's measurements, that of methyl-guanidine crystallises in monoclinic forms (Erlenmeyer).

Glycolyl-methyl-guanidine, $\text{C}_2\text{H}_4\text{N}^2\text{O}^2$, is formed by the action of monochloroacetic acid at the boiling heat on methyl-guanidine, the action being analogous to that which the same acid exerts on triethylamine, triethylphosphine, piperidine, and strychnine:

When an aqueous solution of chloracetate of methyl-guanidine is heated to 120°, the product boiled with lead hydrate, the lead precipitated by hydrogen sulphide, and the filtrate evaporated to a thin syrup, glycolyl-methyl-guanidine is obtained in colourless, thick, rhombic tablets, which soon agglomerate in irregular groups. These crystals are easily soluble in water, and are neutral to litmus-paper. When strongly heated they melt without subliming. Glycolyl-methyl-guanidine unites with gaseous hydrochloric acid, forming the salt $C^4H^{11}N^3O^2.HCl$, which cannot be prepared with the aqueous acid. With *platinic chloride* and *silver nitrate* it yields respectively the compounds $C^4H^{11}N^3O^2.H^2PtCl^6$ and $C^4H^{11}N^3O^2.Ag^2O$. The hydrochloride melts below 100°, and if gaseous hydrochloric acid be passed over it at 100°, 2 mols. of the salt give up 1 mol. water, leaving the compound $C^4H^{10}N^3O^2.2HCl$.

Triphenyl-guanidine, $C(C^6H^5)^3H^2N^3$, is formed by the action of mercuric chloride on sulphocarbamide. When equal parts of these two substances in the dry state are heated together in an oil-bath to 140°–150°, the mass first melts, then froths and gives off hydrochloric and sulphydric acids. The fused mass, which smells like phenyl-sulphocarbamide, is lixiviated, first with boiling water and then with alcohol. The aqueous extracts, treated with soda-ley, yield yellow and white precipitates of triphenyl-guanidine, which, after recrystallisation from alcohol, melts at 145°. It crystallises in thin needles which, according to Groth's measurements, are rhombic six-sided prisms, having the axial ratio $a : b : c = 0.6703 : 1 : 0.5575$ (H. L. Buff, *Deut. Chem. Ges. Ber.* ii. 498; *Zeitschr. f. Chem.* 1870, 54).

The alcoholic extract of the fused mass obtained in the above reaction yielded long, shining, strongly refractive needles of diphenylurea, melting at 235° and solidifying at 210°.

Cyantriphenyl-guanidine, $C^3H^{11}N^5 = CH^2(C^6H^5)^3N^3.2CN$, is formed, together with cyananiline, by the action of cyanogen on aniline. When purified it forms beautiful aurea-red crystals having a violet iridescence. Heated with dilute alcohol it gives off ammonia and aniline, and yields diphenyl-parabanic acid:

When its alcoholic solution is boiled with hydrochloric acid, the diphenyl-parabanic acid is likewise decomposed, the products being ammonia, aniline, carbon dioxide, and oxalic acid:

(Hofmann, *Deut. Chem. Ges. Ber.* iii. 763).

A compound isomeric with the above is obtained by the action of cyanogen on an alcoholic solution of triphenyl-guanidine. It forms yellowish-white crystals which, in contact with hydrochloric acid, turn red and are quickly resolved into ammonia and oxalyl-triphenyl-guanidine, $C(C^6H^5)^3(C^2O^2)^2N^3$. This latter, boiled with alcohol and hydrochloric acid, yields diphenyl-parabanic acid and its products of decomposition (Hofmann, *ibid.* 764).

Naphthyl-diphenyl-guanidine, $C^2H^{10}N^3 = C(C^6H^5)(C^6H^5)^2H^2N^3$.—When diphenyl-sulphocarbamide and naphthylamine in equal numbers of molecules are boiled in alcoholic solution with lead oxide till the whole of the sulphur is precipitated, the filtrate then evaporated, the residue dissolved in dilute hydrochloric acid, and concentrated hydrochloric acid added to the solution, *hydrochloride* of *naphthyl-diphenyl-guanidine* separates in indistinct crystals which form a crystalline double salt with platinic chloride. The *nitrate* is sparingly soluble. The free base forms crystalline crusts which melt at 155 (F. Tiemann, *Deut. Chem. Ges. Ber.* iii. 6; *Zeitschr. f. Chem.* [2], vi. 309).

Naphthyl-tolyl-phenyl-guanidine, $C^4H^{12}N^3 = C(C^6H^5)(C^6H^5)(C^6H^5)H^2N^3$, is prepared, like the preceding compounds, from phenyl-tolyl-sulphocarbamide and naphthylamine. In the free state it forms a clear, brittle resin, melting below 60°. The *nitrate* is sparingly soluble and crystalline; the *hydrochloride* is crystalline, and forms a sparingly soluble double salt with platinic chloride (Tiemann).

Tetraphenyl-tolylene diguanidine, or *Dicarbo-tetraphenyl-tolylene-hexamine*, $C^6H^{12}N^6 = C^2(C^6H^5)^4(C^6H^5)^2H^4.N^6$, is obtained in the manner above described from 2 mols. diphenyl-sulphocarbamide and 1 mol. toluylene-diamine. The free base forms a clear resin which melts at 76° and dissolves in chloroform, ether, alcohol, and benzene. The *platinichloride* has the composition $C^6H^{12}N^6.2HCl$; the *nitrate* is sparingly soluble (Tiemann).

GUANINE. This base has been found in the excrement of a heron fed partly on fish, partly on flesh (Hoppe-Seyler, *Med.-Chem. Untersuchungen*, 1871, 582).

GUANO. According to Chevreul (*Compt. rend.* lxxvii. 463, 569, 901) the crystal-

lissable material dissolved from guano by cold water, consists mainly of ammonium oxalate mixed with yellow, red, and brown organic colouring matters. The residue left after complete extraction of guano with cold water yields avic acid to hot alcohol, although the residue originally possessed no smell of the acid. Prolonged washing does not remove the whole of the ammonium carbonate from the insoluble residue of guano. The bones of birds found in guano have entirely lost their cohesion, being reduced by trituration with water to orange flocks, the water at the same time becoming acid and dissolving some calcium phosphate. One example of guano yielded a salt containing calcium, ammonium, potassium, and oxalic acid, soluble in a little water, but decomposed by a larger quantity with precipitation of calcium oxalate. Chevreul concludes that these crystalline substances have been formed by a slow action in the absence of any notable proportion of water.

On the composition and properties of guano, see further, Chevreul (*Compt. rend.* lxxvi. 1376, 1500; lxxvii. 155; *Chem. Soc. J.* [2], xi. 1052; xii. 90).

Guano from Malden Island.—This guano is in the form of a coarse powder, of bright brown colour, and has the following composition:—

FeO ^s	K ² O	Na ² O	MgO	CaO	P ² O ⁵	SO ³	CO ³	Cl	Sand	Organic matter	Water	N
·26	·28	1·71	1·86	43·51	37·58	·22	2·61	·82	·01	6·61	4·70	·29 = 100·40

It is similar to that from Baker Island, and is well adapted for the manufacture of superphosphate (J. Fittbogen, *Ann. d. Landwirtschaft, Wochenblatt*, 1872, 310).

Minerals found in Guano.—C. U. Shepard (*Sill. Am. J.* [2], i. 273) describes two new minerals—the homogeneity of which is perhaps doubtful—from the guano of Guanapo Island, north-east of the Chincha Islands, Peru. One of them, guanapite, occurs in nodules and veins, has a rhombic cleavage, and gives off ammonia in contact with the air. Hardness = 1·5; sp. gr. = 2·3. The other, guanoxalite, is a product of transformation of a bird's egg. It is milk-white, slightly translucent, has a nacreous lustre, and forms laminae with rhombic cleavage. Hardness less than 2; sp. gr. = 1·58. When heated it swells up, blackens, and melts, giving off a large quantity of ammonia, and leaving a white residue. The composition of these minerals is as follows:—

	Guanapite.	Guanoxalite.
Potassium sulphate	67·75	40·20
Ammonium sulphate	27·88	—
Ammonium oxalate	3·75	29·25
Water	—	30·46
	99·38	99·91

Shepard also enumerates five other minerals found in the vertebral column and the stomach of a bird imbedded in the guano, viz.: *Taylorite* (calcium oxalate), *Oxammite* (ammonium oxalate), *Phosphammite*, and *Diphosphammite* (ammonium phosphate in different stages of saturation).

GUARANINE. For the preparation of this substance from guarana, the following process is recommended by C. J. Williams (*Chem. News*, xxvi. 97). Finely-powdered guarana is mixed with one-third of its weight of hydrate of lime, and moistened with water. After an hour or two, it is placed in a drying closet, and completely dried at a moderate heat. It is then exhausted with boiling benzene, filtered, and the benzene distilled off. A small quantity of light-coloured oily matter is left, which is treated with boiling water, and again digested over a water-bath, until all traces of benzene have been dissipated, then filtered through a wetted filter so as to keep back the oil; the aqueous portion evaporated to a small bulk, and set aside for twenty-four hours, yields the guaranine white and pure, and requiring no further purification.

GÜMBELITE. A mineral occurring at Nordhalben, near Steben, in Upper Franconia, in thin fibrous layers on clay slate, or on the iron pyrites which occurs in small flattened masses. It is greyish-white, of a soapy to pearly lustre, translucent, soft, and pliant, and feels, when rubbed, like fine asbestos. It intumesces before the blow-pipe, and the fine fibres fuse into a mass resembling porcelain. It gives off water when heated, and resists the action of acids. Its analysis gave the following numbers:—

SiO ²	Al ² O ³	FeO	MgO	K ² O	H ² O	Undecomposed substance
50·62	31·64	3·00	1·88	3·18	7·00	1·46 = 98·05

(v. Kobell, *Jahrb. f. Mineralogie*, 1871, 174).

GUM. The compound obtained by heating gum-arabic to 150° with 2 parts of acetic anhydride, and regarded by Schützenberger & Naudin (*1st Suppl.* 658) as diacetyl-arabin, $C^6H^4(C^2H^3O)^2O^2$, appears from more recent experiments by Schützenberger (*Ann. Chim. Phys.* [4], xxi. 235) to be tetracetyl-diarabin, $C^{12}H^{12}(C^2H^3O)^4O^{10}$, inasmuch as the saturated acetyl derivative obtained by heating gum to 180° for five or six hours with 6 to 8 parts of acetic anhydride, has the composition $C^{12}H^{12}(C^2H^3O)^4O^{10}$. Both these acetyl-derivatives are white amorphous powders.

Distinction of Gum-arabic from Dextrin.—According to Hager (*Zeitschr. anal. Chem.* xi. 350) these bodies may be distinguished from one another by the following characters:

Gum contains no dextroglucose, which, however, is present in dextrin, and may be found by Trommsdorff's sugar-test.

Gum contains a lime-compound: hence its solution is rendered turbid and milky by oxalic acid, whilst a solution of dextrin remains almost clear.

Gum gives a slimy yellow deposit when its solution is mixed with a neutral ferric salt.

Distinction between Gum-arabic and Sennar Gum.—The presence of the cheaper Sennar gum in gum-arabic may be detected by dissolving 3 grams of the gum in 15 grams of cold distilled water, and adding 30 grams of basic lead acetate in several portions, with constant stirring and filtering. Pure gum-arabic filters easily, yielding in an hour 18 to 20 grams of scarcely opalescent filtrate, and leaving on the filter a residue which is no longer fluid. When 6 grams of the filtrate are mixed with 5 grams of water and $1\frac{1}{2}$ gram of ammonia is added, the liquid remains almost clear. Gum-Sennar behaves in a similar manner. Sennar gum, on the other hand, gives a milky filtrate, and the filtration goes on for 24 hours till the filtrate weighs from 18 to 20 grams, after which the residue on the filter still appears fluid. When 6 grams of the filtrate clarified by a second filtration are diluted with 5 grams of water and mixed with the above specified quantity of ammonia, a white gelatinous mass is formed on agitation. By this character a mixture of the two kinds of gum may easily be recognised (Schlosser, *Chem. News*, xx. 120).

Gum mixed with dextrin exhibits the same characters as when mixed with Sennar gum; but dextrin solution alone is merely clouded by basic lead acetate, so that the smaller quantity of the precipitate produced by this reagent, is sufficient of itself to indicate the presence of dextrin. Characteristic of dextrin also is the peculiar smell of bread which is emitted on dissolving it in hot water (Schlosser).

Estimation and Separation of Gum and Dextrin. (J. Roussin, *J. Pharm.* [4], vii. 251).—These substances may be separated by means of ferric chloride, which precipitates the gum and not the dextrin. The liquid containing them is evaporated to a syrup, mixed with 10 times its volume of 90 p.c. spirit, and the resulting precipitate is washed with spirit of the same strength and dried. One gram of the residue is then dissolved in 10 c.c. of water; the solution is mixed with 30 c.c. spirit of 56 p.c., 4 drops of ferric chloride solution (containing 25 p.c. of the anhydrous chloride) and a few decigrams of pounded chalk; and after stirring briskly and leaving the liquid at rest for three or four minutes, the whole is thrown on a filter. The precipitate is washed with spirit of 56 p.c. and from the filtrate the dextrin is precipitated by spirit of 90, or better 95 p.c. After 24 hours the alcoholic liquid is decanted, and the dextrin is dissolved in a small quantity of water, then dried on the water-bath and weighed. The compound of gum with ferric chloride must be dissolved in dilute hydrochloric acid, the gum separated by precipitation with alcohol of 95 p.c. and after washing likewise dissolved in water, dried and weighed.

The precipitation of gum from the slightly alcoholic liquid by ferric chloride with addition of chalk is so complete that nothing but calcium chloride can be found in the filtrate. On the other hand, the precipitate of ferric oxide separated from pure dextrin solutions, does not contain a trace of dextrin, the whole of that substance being found in the filtrate. If a precipitate is formed on addition of ferric chloride alone the presence of gum is demonstrated; the clouding of the filtrate by addition of 8 or 10 times its volume of 90 p.c. spirit indicates the presence of dextrin.

GUMMIC ACID. A. Claus (*J. pr. Chem.* [2], iv. 63) in continuing his examination of the products of decomposition of grapo-sugar by potash in alkaline solution (*1st Suppl.* 659), has arrived at the somewhat modified view that the acid obtained by Reichardt from the so-called gummates (ii. 956) was a mixture of tartronic acid with several other syrupy or difficultly crystallisable acids, while the crystallised acid analysed by Reichardt, was tolerably pure tartronic acid, which had separated in small quantity from the evaporated mixture of acids.

GUNPOWDER. Important researches on the products of combustion of gun-

powder fired under circumstances similar to those which exist when it is exploded in guns or mines have recently been published by Captain Noble and Mr. F. A. Abel.

The gunpowder used in the experiments included five kinds, viz. pebble powder, rifle large-grain (cannon) powder, fine-grain powder, and rifle fine-grain powder (all of Waltham-Abbey manufacture), and also a spherical pellet powder of Spanish manufacture, specially selected for experiment as presenting considerable difference in composition from the English powders. The composition of these powders is shown in the following Table:—

TABLE I.
Results of Analysis of Gunpowders employed.

Components, per cent.	Description of Gunpowders employed in Experiments

Ash	0.23	0.25	0.24	0.17	0.63
Water	0.95	1.11	0.80	1.48	0.65

The apparatus consisted of a mild steel vessel, of great strength, carefully tempered in oil, in the chamber of which the charge to be exploded was placed. The main orifice of the chamber was closed by a screwed plug, called the firing-plug, fitted and ground into its place with great exactness. In the firing-plug itself was a conical hole, stopped by a plug, also ground into its place with great accuracy, and for purposes of insulation, covered with the finest tissue-paper. Two wires (one in the insulated cone, the other in the plug) were inserted, and joined by a very fine platinum wire passing through a small glass tube filled with mealed powder. By completing connection with a Daniell's battery, the charge could be fired.

There were two other apertures in the chamber—one communicating with the arrangement for letting the gases escape, the other containing the crusher-apparatus for determining the tension at the moment of explosion.

The pressures actually observed with this apparatus varied from over 36 tons on the square inch to about 1 ton on the square inch.

On opening the explosion-vessel after the gases had been allowed to escape, the solid products were found collected at the bottom in a hard compact mass extremely difficult to remove, there being generally an exceedingly thin (in fact, with large charges, quite an inappreciable) deposit on the sides.

The surface of the deposit was generally perfectly smooth and of a very dark grey, almost black, colour. This colour, however, was only superficial, and through the black could be perceived what was probably the real colour of the surface, a dark olive-green. The surface of the deposit and the sides of the cylinders had a somewhat greasy appearance, and were indeed greasy to the touch.

The deposit always smelt powerfully of sulphuretted hydrogen, and often strongly of ammonia. It was always exceedingly deliquescent, and after a short exposure to the air became black on the surface, gradually passing over into an inky-looking pasty mass.

As regards the proportions of total solid and gaseous products furnished by the several powders, remarkable uniformity was exhibited by the results of explosion of the same powder at different pressures, and no very considerable difference existed between the proportions furnished by the three powders chiefly used in the researches. The largest grain, or pebble powder, yielded most gas; the quantity furnished by R.L.G. powder was not greatly inferior, but was decidedly more considerable than that yielded by the smallest powder (F.G.).

The composition of the gas furnished by the explosion of all the English powders

was throughout remarkably uniform, but presented certain apparently well-defined small variations, regulated by the pressure under which the products were developed, the chief being a steady increase in the proportion of carbonic anhydride, and decrease in that of carbonic oxide, in proportion as the pressure was increased. The composition of the *solid* products exhibited much greater variations, chiefly in regard to the state of combination in which the sulphur existed. These variations were exhibited, not merely by the products obtained from the different powders, but also, and to as great an extent, by those which one and the same powder furnished at different pressures, and apparently without reference to the pressure, excepting in the case of the very lowest (the powder occupying 10 per cent. of the total space in the chamber).

The reactions which occur among the powder-constituents, in addition to those which result in the development of gas of fairly uniform composition (and very uniform as regards the proportions which it bears to the solid), from powders not differing widely in constitution from each other, are susceptible of very considerable variations, regarding the causes of which it appears only possible to form conjectures. Any attempt to express, even in a comparatively complicated chemical equation, the nature of the metamorphosis which a gunpowder of average composition may be considered to undergo when exploded in a confined space, would therefore only be calculated to convey an erroneous impression as to the simplicity or the definite nature of the chemical results, and their uniformity under different conditions, while it would in reality possess no important bearing upon the elucidation of the theory of explosion of gunpowder. But the experiments under consideration show decidedly that the chemical theory of the decomposition of gunpowder, as based upon the results of Bunsen & Schischkoff, and accepted in recent text-books, is as far from representing the general metamorphosis of gunpowder as was the old and long-accepted theory, according to which the primary products were simply potassium sulphide, carbonic anhydride, and nitrogen.

The principal results of the investigation are summarized as follows, and for convenience are computed upon 1 gram of powder, occupying 1 c.c. :—

(a) *First, with regard to powder fired in a close vessel.*

1. On explosion, the products of combustion consist of about 57 hundredths by weight of matter which ultimately assumes the solid form, and 43 hundredths by weight of permanent gases.
2. At the moment of explosion, the fluid products of combustion, doubtless in a very finely divided state, occupy a volume of about 0.6 c.c.
3. At the same instant the permanent gases occupy a volume of 0.4 c.c., so that both the fluid and gaseous matter are of approximately the same specific gravity.
4. The permanent gases generated by the explosion of a gram of powder are such that, at 0° C. and 760 mm. barometric pressure, they occupy about 280 c.c., and therefore about 280 times the volume of the original powder.
5. The constituents of the solid and gaseous products are as shown in Tables II. and III. :—

6. The tension of the products of combustion, when the powder fills entirely the space in which it is fired, is about 6,400 atmospheres, or about 42 tons per square inch.

7. The tension varies with the mean density of the products of combustion, according to the law given in the equation:

$$p = \text{const.} \times \frac{\delta}{1 - \alpha \delta} \quad (1)$$

where α is a constant determined from the experiments. The close agreement of the results of calculation from this form and those of experiment, is shown in the following Table:—

TABLE IV.

Showing the comparison, in tons per square inch, between the pressures actually observed in a close vessel and those calculated from the formula (1).

Density of products of combustion	Value of p deduced from direct observation	Value of p deduced from equation (1) $\alpha = .65$	Density of products of combustion	Value of p deduced from direct observation	Value of p deduced from equation (1) $\alpha = .65$
	Tons per square inch	Tons per square inch		Tons per square inch	Tons per square inch
.10	1.47	1.56	.60	14.30	14.59
.20	3.26	3.36	.70	19.09	18.79

8. About 705 gram-units of heat are developed by the decomposition of 1 gram of powder, such as used in the experiments.

9. The temperature of explosion is about 2200°C .

(b) *When powder is fired in the bore of a gun.*

1. The products of explosion, at all events as far as regards the proportions of total solid and gaseous matters, are the same as in the case of powder fired in a close vessel.

2. The work on the projectile is effected by the elastic force due to the permanent gases.

3. The reduction of temperature and pressure due to the expansion of the permanent gases is in a great measure compensated by the heat stored up in the liquid residue.

4. The law connecting the tension of the products of explosion with the volume they occupy is stated in the equation :

$$p = p_0 \left\{ \frac{v_0(1-\alpha)}{v-\alpha v_0} \right\}^{\frac{c_p + \beta\lambda}{c_v + \beta\lambda}}; \quad . \quad . \quad . \quad (2)$$

in which p denotes the tension and v the volume of the products of explosion; α the proportion occupied by the solid products; c_v and c_p the specific heats of the permanent gases at constant temperature and pressure; λ the mean specific heat of the non-gaseous products; β the ratio between the weights of the gaseous and non-gaseous portions of the charge.

5. The work that gunpowder is capable of performing in expanding in a vessel impervious to heat is given by the equation :

$$W = \frac{p_0 v_0 (1-\alpha) (C_p + \beta\lambda)}{C_p - C_v} \left\{ 1 - \left(\frac{v_0(1-\alpha)}{v-\alpha v_0} \right)^{\frac{C_p - C_v}{C_p + \beta\lambda}} \right\}. \quad . \quad . \quad (3)$$

and the temperature during expansion by the equation :

$$t = t_0 \left(\frac{v_0(1-\alpha)}{v-\alpha v_0} \right)^{\frac{C_p - C_v}{C_p + \beta\lambda}}. \quad . \quad . \quad . \quad (4)$$

6. The total theoretic work of gunpowder, when indefinitely expanded, is about 332,000 gram-met. per gram of powder, or 486 foot-tons per lb. of powder.

With regard to one or two other points to which attention was specially directed, the results appear to warrant the following conclusions :—

1. Very small-grain powders, such as F. G. and R. F. G., furnish very decidedly smaller proportions of gaseous products than a large-grain powder (R. L. G.); while the latter, again, furnishes somewhat smaller proportions than a still larger powder (pebble), though the difference between the total gaseous products of these two powders is comparatively inconsiderable.

2. The variations in the composition of the products of explosion furnished, in close chambers, by one and the same powder under *different* conditions as regards pressure, and by two powders of similar composition under the *same* conditions as regards pressure, are so considerable, that no value whatever can be attached to any attempt to give a general chemical expression to the metamorphosis of a gunpowder of normal composition.

3. The proportions in which the several constituents of solid powder-residue are formed are quite as much affected by slight accidental variations in the conditions which attend the explosion of one and the same powder in different experiments, as by decided differences in the composition as well as in the size of grain of different powders.

4. In all but very exceptional results, the solid residue furnished by the explosion of gunpowder contains, as important constituents, potassium carbonate, sulphate, thio-sulphate, and sulphide, the proportion of carbonate being very much higher, and that of sulphate very much lower, than stated by recent investigators.

GYPSUM. Schott (*Dingl. pol. J.* cxvii. 357) has examined the reaction of gypsum with potassium sulphate. In the first place he has verified the previously observed fact, that even unburnt gypsum, when mixed with solutions of certain salts, especially potassium sulphate, hardens like burnt gypsum with water. Equal parts by weight (corresponding with equal numbers of molecules) of pulverised selenite and potassium sulphate solidify, when made into a paste with water, more quickly than burnt gypsum with water. A hardening, though slower, may also be observed when only $\frac{1}{10}$ mol. potassium sulphate is mixed with 1 mol. gypsum. The hardening of burnt gypsum is very much accelerated by the addition of potassium sulphate to the water used. When the two salts are mixed in molecular proportions, and stirred up with a small quantity of water, the mixture solidifies before it can be poured out of the vessel.

With equal weights of water and the mixture of salts just mentioned, a paste is obtained which may be poured out just before it solidifies, and in solidifying exudes crusts of potassium sulphate. Burnt gypsum, mixed with a cold-saturated solution of potassium sulphate, solidifies instantly, and the mixture cannot be poured out of the vessel if the weight of the solution is less than about double of that of the gypsum. If the quantity of water is greater, the mixtures solidify more slowly, always, however, more quickly than gypsum with water. The casts become curved in solidifying. When burnt gypsum is mixed with a solution of potassium sulphate saturated at the boiling heat, the mixture can scarcely be completed before solidification takes place. The casts made with gypsum and potassium sulphate are not more compact than those made with water, since a large quantity of water is required to make a mixture that will pour out, and this makes the solidified masses of looser texture. But the casts obtained with potassium sulphate solution have a nacreous and satiny lustre, and are altogether handsomer than the chalky products obtained with gypsum and water.

Schott confirms the suggestion of L. Gmelin that double sulphates of calcium and potassium are formed in this process. When pulverised selenite is added to a solution of potassium sulphate, and the liquid quickly stirred and filtered, the filtrate deposits satiny laminae having the composition $\text{CaSO}_4 \cdot \text{K}^2\text{SO}_4 \cdot \text{H}_2\text{O}$.

Potassium carbonate, stirred up with gypsum and water, produces potassium sulphate, which then acts as above. Sodium sulphate does not produce the same effect.

A solution of cream of tartar does not bring about the solidification of unburnt gypsum, but burnt gypsum mixed with the same solution hardens very quickly. The formation of the above-mentioned double salt, however, does not appear to take place, the casts being merely mixtures of gypsum and crystals of cream of tartar.

On crystals of gypsum from various localities, see *Jahrbuch für Mineralogie*, 1871, 572, 881; *Jahresb. f. Chem.* 1869, 1240; 1870, 1328; 1871, 1180.

Gypsum as a Fertiliser.—The power of gypsum to augment the fertility of soils may doubtless be ascribed in great measure to its property of facilitating the decomposition of complex rocks containing alkaline silicates, and thereby bringing the alkalis into a condition favourable to their ready absorption by the roots of plants.

To estimate the intensity of this decomposing action, A. Cossa (*Gazzetta chimica italiana*, iii. 185) has compared the quantity of matter dissolved, in a given time and within given ranges of temperature, from various rocks, by a saturated solution of gypsum, with the quantities dissolved out of the same rocks under similar conditions by pure distilled water. He finds that 1,000 parts of pure water dissolve 2.19 parts of pure crystallised gypsum at $16^\circ.25$ and 2.352 at 22° , numbers agreeing nearly with those obtained by other experimenters.

The rocks were reduced to very fine powder, and left for twenty days in contact with a saturated solution of gypsum at temperatures ranging from 16° to 22° . The results are given in the following Table, together with those obtained in like manner with pure water:—

	Matter dissolved out	
	By pure water	By a saturated solution of gypsum
	Per cent.	Per cent.
Gneiss, containing undecomposed orthoclase and potash mica	0.125	0.463
Trachyte, decomposing, from Monte Chioja, Vicenza	0.0937	0.2562
Trachyte, undecomposed, from Monte Ortona (Euganian Hills)	0.0871	0.138
Trachyte, porphyroidal, decomposing (containing sanidine, mica, hornblende), from San Pietro	0.0567	0.0927
Montagnone (Euganian Hills)		0.1630
Trachyte from San Daniele	0.0750	
Granite (albite, quartz, mica), from Montorfano, Lago Maggiore	0.0727	0.207
Granite (orthoclase, mica containing a trace of lithia, quartz), from Baveno, Lago Maggiore	0.0990	0.2875
Felspar, white, compact, in veins in Diorite: from Mosso, Biella	0.350	0.714
Basalt, compact, of Monte Nuova (Euganian Hills)	0.1271	0.394
Perlite, from Monte Sieva (Euganian Hills)	0.0624	0.1963

The solvent action exercised by gypsum on rocks containing alkaline silicates may perhaps give rise to the presence of potash, soda, and lithia in certain mineral waters, especially in sulphuretted waters.

H.

HÆMATEIN. See HÆMATOXYLIN.

HÆMATIN,

HÆMATOLIN,

HÆMATOPORPHYRIN,

} See BLOOD (p. 201).

HÆMATOXYLIN, $C^{16}H^{10}O^8 = C^{16}H^8(OH)^8$ (F. Reim, *Deut. Chem. Ges. Ber.* iv. 329). This compound, treated with oxidising agents, yields nothing but oxalic acid; and it does not form any nitro-derivatives. With chlorine, bromine, phosphorus pentachloride, potassium chlorate and hydrochloric acid, and with hydriodic or hydrobromic acid, it yields only resinous products not admitting of purification. Treated with sodium-amalgam, or with zinc and sulphuric acid, it does not take up hydrogen. Heated with zinc-dust, it yields only a very small quantity of a crystallisable body suspended in an oily liquid.

Acetyl chloride acts easily on hæmatoxylin; and on evaporating the product over the water-bath, pouring the remaining syrupy mass into water, quickly collecting the curdy precipitate on a filter, and dissolving it, after washing, in gently heated alcohol or in acetic acid, the solution on cooling deposits the hexacetyl-compound, $C^{16}H^8(C^2H^3O)^6O^8$, in the form of extremely fine, soft, silky, crystalline tufts which, after pressing, may be kept without sensible alteration, but become coloured on exposure to the air when moist. This compound may be dried at 100° without decomposition. A similar substitution-product is formed with *benzoyl chloride*.

When an ethereal solution of hæmatoxylin is mixed with a few drops of strong nitric acid, hæmatein, $C^{16}H^{12}O^8 \cdot 3H^2O$ (iii. 1), separates in small brown-red tufts of crystals, which give off 2 mols. water over oil of vitriol and the whole when heated to 130° . By boiling it with zinc and sulphuric acid, or better with sulphurous acid, till it is decolorised, it is reconverted into hæmatoxylin.

Hæmatoxylin fused with potash yields pyrogallic acid. This reaction shows that it belongs to the aromatic group, and the formation of its hexacetyl and hexbenzoyl derivatives shows that it contains six hydroxyl groups.

HÆMOCHROMOGEN. See BLOOD (p. 202).

HÆMOGLOBIN. See BLOOD (p. 198). Observations on the variations in the amount of hæmoglobin in the blood according to the age of the animal and its position in the zoological series have been made by Quinquaud (*Concept. rend.* lxxvii. 487). He finds that—

1. The progressive diminution in the amount of hæmoglobin contained in equal volumes of the blood, follows, as a rule, the steps of the animal scale.

2. The blood of young animals contains less hæmoglobin than that of adults. The amount decreases slightly during the first few days of extra-uterine life, rises during childhood, remains stationary during adult life, and finally falls slowly during old age.

3. The blood of birds is much less rich in hæmoglobin than that of mammals, but the weight of the globules is rather greater in the former than in the latter, though the mammalian globules contain only a third of the quantity of albuminous material present in those of birds.

4. As a rule, the females have less hæmoglobin than the males.

5. The lymph of crustaceans contains 4 to 5 cubic centimeters of oxygen in 100, whereas ordinary water in the middle of winter, when completely saturated, contains only 1 cubic centimeter in 100.

Quinquaud also finds that there is an exact relation between the quantity of oxygen which blood can absorb and the amount of hæmoglobin it contains, so that the latter can be determined by ascertaining the former. The quantity of oxygen absorbed by 100 cubic centimeters of human blood is 260 c.c., of ox-blood 240 c.c., and of duck's

blood 170 c.c. The quantities of iron in 1,000 grams of these kinds of blood are 0.53, 0.48, and 0.34 grm. respectively. According to Hoppe-Seyler's computation, that 0.43 grm. of iron corresponds with 100 grams of hæmoglobin, the quantities of this substance in 1,000 grams of these kinds of blood are 125, 120, and 52 grams respectively. The numbers obtained by Preyer from observations with the spectroscopes are a little higher, but bear the same proportions. The amount of hæmoglobin in the blood of the fowl is nearly the same as in that of the duck (*Compt. rend.* lxxi. 1486).

HALLOYSITE (iii. 6). A specimen of this mineral from Elba analysed by A. d'Achiardi (*Sill. Am. J.* [4], xlix. 402) was found to contain:

SiO ²	Al ² O ³	MgO	CaO	K ² O	H ² O
55.15	27.72	5.10		1.15	10.20 = 99.32.

It is milk-white with black and flesh-coloured spots, opaque, but becomes translucent when immersed in water.

HALOGENS, OXYGEN-ACIDS of (Kümmerer, *Pogg. Ann.* cxxxviii. 390). Kümmerer proposes to designate these acids, together with hydrochloric acid, as follows:—

Cl	.	.	.	Chlorine
ClH	.	.	.	Chloric acid (Hydrochloric acid)
ClHO	.	.	.	Oxychloric (Hypochlorous) acid
ClHO ²	.	.	.	Dioxychloric acid
ClHO ³	.	.	.	Trioxychloric (Chloric) acid
ClHO ⁴	.	.	.	Tetroxychloric (Perchloric) acid.

Similar names are given to the acids of bromine and iodine.

Bromic (Trioxylbromic) Acid, BrHO³. According to Henry, potassium bromide is converted into bromate by fusion with the chlorate. Rammelsberg did not succeed in obtaining the bromate by this process. Kümmerer, on the other hand, finds that the formation of the bromate really takes place, but that on account of the decomposibility of the salt it is not easy to carry the process to a successful issue. The best result was obtained by fusing 10 grams of potassium chlorate in a porcelain crucible at the lowest possible temperature and adding, with stirring, the calculated quantity (or better, rather less) of potassium bromide by small portions at a time, and heating till the mass had become pasty and began to give off large bubbles. Many experiments failed, however, in spite of all precautions, and the yield was always below the calculated amount. Addition of potassium hydrate or sodium carbonate, and the use of sodium bromide or barium bromide, did not improve the result. The potassium bromate may be obtained pure by repeated crystallisation from water. A better and surer method of preparing it is by the action of bromine on chloric acid or its potassium salt. Chlorine is passed into a solution of potassium carbonate (6K²CO³) till effervescence begins, and bromine (2Br) is then added. The hypochlorous acid formed in the first instance serves to oxidise the bromine:—

and the chlorine thereby set free acts on the still undecomposed potassium carbonate, again producing chloric acid, carbon dioxide, and potassium chloride. To prepare free bromic acid HBrO³, either a slow stream of hypochlorous anhydride, Cl²O, is passed into bromine under water, or bromine is added to silver bromate suspended in water till it no longer disappears. The acid obtained by this latter process is quite pure. Evaporated in an open dish till decomposition began (formation of bromine and free oxygen), it exhibited a strength of 4.26 p.c. HBrO³. On distilling it in a retort, the distillate mostly exhibited an amount of oxygen somewhat less in proportion to the bromine than that required by the formula HBrO³. It appears, therefore, that bromic acid is not volatile under ordinary pressures, but splits up, on distillation, like chloric acid, probably yielding a lower oxygen-compound of bromine, which is perhaps resolved, by prolonged contact with water, into bromic acid and bromine, or hydrobromic acid. The boiling points of the several solutions of the acid could not be determined, on account of its great tendency to decompose; the thermometer, however, never rose above 100°. When concentrated in a vacuum till it begins to decompose, it contains 50.50 p.c. HBrO³, corresponding exactly with the formula HBrO³ + 7H²O.

Chloric (Trioxylchloric) Acid, HClO³.—The aqueous solution of this acid likewise exhibits, when concentrated in a vacuum, the composition HClO³ + 7H²O. The

specific gravity of this hydrate at 14.2° is 1.282. If left longer in the vacuum over sulphuric acid, it finally attains a degree of concentration at which tumultuous evolution of gas takes place. Just before this point is attained the liquid has the composition $2\text{HClO}^3 + 9\text{H}^2\text{O}$.

Iodic (Trioxiodic) Acid, HIO^3 , was prepared by decomposing its silver salt* with iodine, as the acid separated from the barium salt by dilute sulphuric acid always contains either barium or sulphuric acid. All solutions of this acid, the most concentrated as well as the most dilute, were found to boil exactly at 100°. At 13° one part of water dissolves 1.874 pt., I^2O^5 . This solution is viscid, cannot be filtered through paper, on which indeed it acts like strong sulphuric acid, converting it into a kind of vegetable parchment. It crystallises at -17°, apparently in hexagonal plates, melts constantly at -15°, and has the composition $2\text{HIO}^3 + 6\text{H}^2\text{O}$, analogous to that of the second hydrate of chloric acid; sp. gr. = 2.1269 at 13°. The anhydride, I^2O^5 , has a specific gravity of 4.7987 at 9°; Millhol found it to be 4.250. According to Kämmerer's number, the atomic volume is 69.60. Further determinations of specific gravity showed that the atomic volumes of the corresponding hydrates of chloric and iodic acid are equal.

Formula of the Hydrate	Amount of Anhydride per cent.	Atomic Weight	Specific Gravity	Atomic Volume
$\text{HClO}^3 + 7\text{H}^2\text{O}$	35.73	210.5	1.262	166.7
$\text{HIO}^3 + 7\text{H}^2\text{O}$	55.30	304	1.8256	165.4
$\text{HClO}^3 + 15\text{H}^2\text{O}$	21.29	351.5	1.161	305.2
$\text{HIO}^3 + 15\text{H}^2\text{O}$	37.44	446	1.486	200.5
$\text{HClO}^3 + 20\text{H}^2\text{O}$	16.98	444.5	1.128	394.2
$\text{HIO}^3 + 20\text{H}^2\text{O}$	31.16	536.0	1.389	391.6

The corresponding solutions of the hydrogen-compounds did not exhibit this relation.

Periodic (Tetra-oxiodic) Acid, HIO^4 .—When a hot aqueous solution of the salt, KIO^4 , is mixed with a hot solution of barium nitrate, and the mixture heated for a short time, no precipitate is formed, even after cooling, but the liquid exhibits a strong acid reaction. If, however, the acid solution be mixed with an equivalent quantity of potassium or sodium acetate, a precipitate is immediately formed, perfectly amorphous and not quite insoluble in water. This precipitate has the composition of Langlois' salt, BaH^2IO^6 , and not that assigned to it by Rammelsberg, viz., $\text{Ba}^2\text{I}^2\text{O}^9 + 34\text{H}^2\text{O}$. Its formation is represented by the equation:—

This salt is not decomposed either by the carbonate or the sulphate of potassium or ammonium. The reaction between potassium periodate and lead nitrate takes place as represented by the equation—

In preparing the acid, HIO^4 , from the brown silver salt, it is better to decompose this salt with chlorine or bromine than with nitric acid.

The polybasicity of periodic acid shows that iodine must be a polyatomic element, since, if it is regarded as only monatomic, the acid in question must be represented by the formula $\text{I}-\text{O}-\text{O}-\text{O}-\text{O}-\text{H}$, which is that of a monobasic acid.

Relations of Affinity of the Halogen Elements in their Oxygen-compounds.—The order of affinity of the three elements, chlorine, bromine, and iodine, is not the same in their oxygen-compounds as in their hydrogen-compounds. In the latter, as is well known, chlorine is displaced by bromine, and bromine by chlorine; in the oxygen-compounds, on the other hand, chloric acid, for example, chlorine is displaced by iodine. To throw further light on these relations, Kämmerer has studied the following reactions:—

- Br on HClO . . . this action has been already described.
- Br on HClO^2 . . . no action in aqueous solution.
- Br on ClO^2 . . . no action, even in presence of water,

This salt was prepared from the well-crystallised ammonium salt which is formed by the action of ammonium carbonate on barium iodate even at ordinary temperatures.

2nd Sup.

I on ClO^2	.	.	no action in the dry state, and very little in presence of water.
Br on HClO^2	.	.	production of HBrO^2 , but in very small quantity.
Br on HClO^4	.	.	production of HBrO^4 , but only under peculiar conditions, not easy to determine.
I on HClO^4	.	.	$\text{HClO}^4 + \text{I} = \text{Cl} + \text{HIO}^4$, the reaction complete on heating.
Cl on HBrO^2	.	.	no action.
I on HBrO^2	.	.	$\text{HBrO}^2 + \text{I} = \text{Br} + \text{HIO}^2$.
Cl on HIO^2	.	.	no action.
Cl on HIO^4	.	.	no action.
Br on HIO^4	.	.	no action.

HAMARTITE. The mineral from the Bastnäs mine, near Riddarhyttan in Sweden, called *Hydrofluocerite*, and represented, according to Hisinger's analysis (1838), by the formula $\text{Ce}^2\text{F}^2\text{O}^2 + 4\text{H}^2\text{O}$ (i. 834), appears, from an analysis by A. E. Nördenskjöld (*Pogg. Ann.* cxxvi. 628), to be a mixture of a carbonate with a fluoride having the composition $2(\text{LaO} ; \text{CeO})\text{CO}^2 + \text{CeF}^2$.

	LaO	CeO	CO^2	H^2O	F and O (Loss)
Found . . .	45.77	28.49	19.50	1.00	5.23
Calculated . . .	46.15	28.60	20.20	—	5.05

Nördenskjöld proposes to replace the old name, now become inapplicable, by the name *Hamartite*. The mineral occurs, between crystals of allanite, in small wax-yellow druses having a fatty lustre; it exhibits cleavage-planes, probably parallel to the faces of a rhombic prism, and two pairs of faces. Sp. gr. = 4.93; hardness = 4. Before the blowpipe it blackens and gives off a very small quantity of water, then becomes whitish-yellow, fissured, and opaque, but does not melt. Fused with potassium sulphate, it gives a distinct fluorine reaction. After ignition it dissolves easily in sulphuric acid with evolution of hydrofluoric acid.

HARTITE. This fossil resin, from the lignite of Oberdorf, near Voitsberg in Styria, occurs sometimes in small fragments or as a coating, sometimes in crystals having a magnitude of 6 to 8 and 4 to 6 mm. The crystals are triclinic, having the axial angles, $cb = 74^\circ$, $ca = 86^\circ$, and $ab = 80^\circ 15'$, where $a < b < c$. The observed faces, in the order of their predominance, are: ∞P^∞ . ∞P^∞ . oP . P' . ∞P . $\infty P'u$. The prisms sometimes exhibit homimorphism. The pinacoids are often curved, even to the shape of hooks. Cleavage parallel to the pinacoids. Sp. gr. = 1.051. It melts at 74° , and at 150° gives off bubbles of vapour, the temperature, however, not becoming stationary even at 340° ; it solidifies from fusion at 65° , becomes negatively electric by friction. Its composition, according to analyses by F. Ullik, and that of Schrötter already given (iii. 14), agrees with the formula C^8H^{10} , which requires 87.8 p.c. carbon and 12.2 hydrogen (*J. Rumpf, J. pr. Chem.* cvii. 189).

HAUYNE. Kennigott (*ibid.* cvi. 65) has endeavoured to bring the different analyses of this mineral into accordance without the assumption of isomorphous replacement between Na^2O and CaO . In explanation of the differences between the analyses, he adduces the fact that water extracts from pulverised hauyne a substance which remains in small crystals as the water evaporates, and appears, from his observations, to be sodium sulphate. Presuming that a similar process takes place in nature, he supposes that all the analyses of the mineral have been made with substance which had previously lost soda and sulphuric acid. He therefore makes up the amount of Na^2O to 1 molecule for every 2SiO^2 , and adds to the quantity of SO^2 , found by analysis, a quantity equivalent to this additional quantity of Na^2O . According to this method of recalculation, the four most exact analyses of hauyne give very nearly the proportion:

leading to the formula $3(\text{Na}^2\text{O}.\text{SiO}^2 + \text{Al}^2\text{O}^3.\text{SiO}^2) + 2(\text{CaO}.\text{SO}^2)$.

HAUYNOPHYTE. The microscopic structure of this lava from the Valtaro near Meli has been examined by F. Zirkel (*Jahrbuch für Mineralogie*, 1870, 818). The hauynes, whose actual substance is either colourless or blue, are essentially altered in colour by numerous gas-pores and imbedded pieces of glassy substance, also by lamellae of ferric oxide. The rock also contains leucite rich in enclosed liquids; nephelin without foreign enclosures; augite, melilite, magnetic iron ore, and apatite. Olivine and feldspar are absent.

HAY. See FODDER.

HEAT. *Calorimetry.*—Bunsen (*Pogg. Ann.* cxli. 1; *Phil. Mag.* [4], xli. 61; *Chem. Soc. J.* [2], ix. 180) has devised a new method of calorimetry, which is appli-

cable to small quantities of material, and thus facilitates the estimation of the specific heat of rare substances.

It depends on the principle of measuring the quantity of ice melted by a heated body by the diminution of volume which the ice undergoes in melting.

The instrument consists of a glass vessel *a* (fig. 16) in the form of a test-tube, fused into a vessel *b*, which terminates in the bent tube *c*. Into the upper extremity of this tube a graduated tube *s* of small calibre is inserted, and luted with fine sealing-wax into a cork *k*. An iron collar *d* serves the double purpose of containing mercury to render the joint perfect, and affording the means of clamping the instrument to a firm support.

The inner vessel *a* is filled with boiled water from μ to α , as also is the outer vessel from β to λ . The rest of the apparatus from β to γ is filled with boiled mercury.

A cylinder of ice is formed in the vessel *b* by surrounding the whole instrument with snow. When the water congeals, the mercury is driven out through the tube *c*. The scale-tube *s* is inserted into its place, and the mercury thread adjusted to the desired position either by depressing the cork, or in a manner which will be described further on. The substance to be examined, after it has been heated sufficiently and its temperature noted, is allowed to drop into the water in the tube *a*. In the bottom of this tube a piece of cotton-wool is placed and kept in position by means of a piece of platinum wire coiled round it. This prevents breakage, and facilitates the extraction of the substance after the operation is completed. The tube *a* is closed with a cork, to prevent change of air.

FIG. 16.

When the heated body under examination is introduced into the vessel *a*, some of the surrounding ice is melted, and the volume becomes less. The mercury below rises, and indicates its rise by the retraction in the graduated tube *s*. For relative measurements of the amount of heat given up by substances, it is sufficient to observe the number of divisions through which the mercury is drawn back. To convert these readings into thermal units they must be multiplied by a constant to be determined for each instrument by a method described in Bunsen's paper.

As the cylinder of ice surrounding the inner vessel weighs from 40 to 50 grams, and the quantity of ice melted in a single determination of specific heat does not exceed about 0.35 gram, it is easily seen that one cylinder of ice will suffice for about 100 such determinations, so that the apparatus once set up in the manner above described, may be used for weeks if the snow surrounding it be renewed every morning and evening. The accuracy of the determinations depends in great part on the care with which the water and mercury in the instruments have been freed from absorbed air. The delicacy of the instrument is shown by the fact that the rise of temperature, produced by immersing in the water 0.4 gram of brass at 37°, which would amount to only 0.07° of the centigrade thermometer, will move the quicksilver thread of the calorimeter through 20 divisions of the scale, each measuring a millimeter.

Specific Heat. For Bunsen's determinations of the specific heats of elementary bodies by the method above described, see *First Supplement*, p. 665.

Specific Heat of Carbon.—The numbers found by different observers for the specific heat of the allotropic modifications of carbon agree, as the following table shows, so little with each other, that their difference cannot be explained by the different methods of observation, or by the impurities of the substances employed:—

Observer	Charcoal	Gas Carbon	Natural Graphite	Blast Furnace Graphite	Diamond	Interval of temperature
Rognault	0.2415	0.2036	0.2010	0.1970	0.1469	8°—08°
De la Rive and Marce	0.2009	—	—	—	0.1146	3°—14°
Kopp	—	0.185	0.174	0.165	—	22°—52°
Willner and Bettendorf	—	—	0.1919	—	0.1452	22°—70°

These differences may, however, be accounted for by the rapid increase of the specific heat of carbon with the temperature. II. F. Weber (*Deut. Chem. Ges. Ber.* v. 303) finds indeed that the specific heat of this element increases with the temperature far more rapidly than that of any other substance; the specific heat of the diamond, for example, becoming three times as great when the temperature rises from 0° to 200°.

Weber has determined the specific heat of the diamond for twelve different temperatures at about equal intervals between 0° and 200°, and finds that the mean specific heat C_{0-t} , between 0° and the temperature t , may be calculated by the formula—

$$C_{0-t} = 0.0947 + 0.000497t - 0.00000012t^2 \quad . \quad . \quad . \quad (1)$$

This rapid variation with the temperatures, however, renders the *mean* specific heat of but little value, and it becomes necessary to calculate from it the *true* specific heat for the temperature t , that is to say, the quantity of heat required to increase the unit of weight of the substance at t° by 1 degree. This true specific heat γ_t may be calculated from the formula—

$$t.C_{0-t} = \int_0^t \gamma_t dt \quad . \quad . \quad . \quad (2)$$

whence by differentiation—

$$\gamma_t = 0.0947 + 0.000994t - 0.00000036t^2 \quad . \quad . \quad . \quad (3)$$

This formula gives the following values for the specific heats at intervals of 50° between 0° and 200°—

Temperatures	0°	50°	100°	150°	200°
Actual specific heats	0.0947	0.1435	0.1905	0.2357	0.2791

The specific heat of graphite was found to be 0.1439, between 0° and 34°, and = 0.1967 between 0° and 100°, whenever its mean specific heat between 0° and any temperature t can be calculated from the formula—

$$C_{0-t} = 0.1167 + 0.0008t,$$

and its true specific heat at any definite temperature t from—

$$\gamma_t = 0.1167 + 0.0016t.$$

Finally, the specific heat of charcoal was found by De la Rive and Marcet to be 0.2009 between 3° and 14°, and by Regnault = 0.2415 between 8° and 18°, whence it appears that the porous varieties of carbon exhibit variations in their specific heat similar to those observed in graphite and diamond.

The great increase in the specific heat of carbon as its temperature rises is quite sufficient to account for its deviation from the law of Dulong and Petit. If, however, the equation (3) be supposed to hold good for diamond up to the temperature of 500° (which is probably not strictly true), the specific heat of diamond at about 525° would be 0.52, which would be quite in accordance with the law in question, since $0.52 \times 12 = 6.24$.

The specific heat of carbon at temperatures considerably above those above mentioned has been determined by Dewar (*Phil. Mag.* [4], xlv. 461). To determine the mean specific heat between 20° and 1040°, gas-carbon, graphite, cocoa-nut charcoal and diamond were heated in an iron tube in boiling zinc (temp. about 1040°) and then plunged into a water-calorimeter. The mean value of the specific heat deduced from the results was 0.32.

To determine it at much higher temperatures, a cubical block of lime 2 inches in the side was pierced to the centre with two channels a quarter of an inch wide, and in directions at right angles to each other. Generally only one of the channels passed entirely through the mass. Two powerful oxy-hydrogen flames were caused to play into these holes till the interior was at a white heat. The carbon was then placed at the point of meeting of the holes, and kept exposed to the oxy-hydrogen flame for a considerable time, whereby it was exposed to a heat estimated at 2100°, after which it was allowed to drop from the mass of lime into the calorimeter.

The mean specific heat deduced from these experiments was 0.42, and Dewar is of opinion that the true specific heat at about 2000° must be at least 0.5. If it be so, carbon conforms at these high temperatures also to the law of Dulong and Petit.

Specific Heat of Solutions.—J. Thomsen (*Pogg. Ann.* cxlii. 337) has determined the specific heats of the aqueous solutions of several acids, alkalis, and salts by observing the rise of temperature produced in about 1000 cub. cent. of the solution contained in a calorimeter by the combustion of a given volume of hydrogen, and comparing the result with the rise produced under like conditions in a known weight of water.

The results are given in the following table, in which column 1 gives the number of molecules of water (n) present in the solution for one molecule of the substance dissolved; column 2 the specific heat of this solution; column 3 its molecular weight, or

more strictly, the weight corresponding with the chemical formula of the solution. It is given in two terms, the first being the molecular weight of the substance in solution, the second the sum of the weights of the molecules of water. Column 4 gives the molecular heat of the solution, i.e. the products of its specific heat and molecular weight; column 5, the difference between this molecular heat and the heat which would be required by the water of the solution alone; column 6 gives the specific gravity of the solutions; column 7, their molecular volume; and lastly, column 8, the difference between this volume and that of the water alone.

The numbers in column 4 of the preceding tables express the *water-value* of the solution, that is the weight of water which requires the same amount of heat as the molecular weight of the solution, and the table shows that this water-value differs in most cases but little from the amount of water present in the solution. In the case of sulphuric acid for example, the solution with 5 molecules of water has a water-value of 92.7, the weight of the molecules of water in the solution being 90, that of the whole molecule 170; in the solution with 50 molecules of water, these values are 900, 900 and 980 respectively. In still more dilute solutions the water-value sinks even below the molecular weight of the water actually present. Similar phenomena are observed in most other solutions. The differences in column 5 are generally positive in concentrated solutions, gradually sink to zero, and become negative in dilute solution. In some few cases, as with hydrochloric acid and potassium hydrate, they are always negative.

Previous researches by other experimenters, as well as those of Thomsen, have shown that when an aqueous solution is mixed with water, contraction takes place, i.e. the volume of the solution is less than the sum of the volumes of the constituent liquids; thus (p. 597) 270.7 volumes of a soda-solution NaHO + 15H²O, mixed with 15 molecules or 270 volumes of water, give, not 540, but only 537.9 volumes; and the foregoing experiments show that when an aqueous solution is mixed with water, the resulting solution has a lower molecular heat than the sum of the molecular heats of the constituents; e.g. the same soda-solution requires 272.2 units of heat to raise its temperature by a certain amount; but when mixed with 270 grams of water it requires for that purpose, not 542.2, but only 533 units. A similar relation is found when acids and alkalis are mixed. When potash or soda is neutralised with hydrochloric, nitric, or sulphuric acid, the molecular heat of the resulting compound is higher than the sum of the molecular heats of the constituents, while on the other hand it is found that these potassium and sodium salts have a molecular volume greater than the sum of the volumes of their constituents; in other words expansion has taken place during combination. In the case of ammonia salts the reverse takes place. Contraction is the result of the combination, and the molecular heat of the compound is less than the sum of the molecular heats of the constituents.

Marignac (*N. Arch. Ph. Nat.* xxxix. 217) has estimated the specific heats of various aqueous solutions, and of the solution of sulphur, phosphorus, iodine, and bromine in carbon sulphide, by determining the relative weights of water and of the liquid under examination, which are heated to the same temperature by equal quantities of heat. The source of heat was a mercurial thermometer with a large bulb, heated to 65-10°. Marignac's results with sulphuric acid, hydrochloric acid, and sodium chloride, agree nearly with those of Thomsen. The following table contains his determinations of the specific heats of other aqueous solutions of the two sodium sulphates and of sugar, and those of the solutions of the bodies above mentioned in carbon sulphide. The numbers in the several columns have the same signification as those in the first four columns of Thomsen's table.

1	0.174	156	27.1

These solutions in carbon-sulphide differ considerably in their behaviour from aqueous solutions of acids and salts. The molecular heat of the mixture of bromine and carbon sulphide is exactly equal to the sum of the molecular heats of the two liquids. In like manner iodine dissolves in carbon sulphide without perceptible diminution of the specific heat which belongs to it in the fused state. When diminution takes place, as in the case of sulphur and phosphorus, it is confined within narrow limits, and the molecular heat of the solution never becomes less than that of the solvent alone.

Respecting the Specific Heats of Mixtures of Ethyl Alcohol and Methyl Alcohol with Water, see *ETHYL ALCOHOL* (p. 475) and *METHYL ALCOHOL*; of Ethyl Alcohol with Carbon Sulphide, Chloroform, and Benzene, see p. 477.

Relations between the Specific Heats of Mixtures and the Heat evolved in their Formation.—These relations have been investigated by A. Dupré (*Proc. Roy. Soc.* xx, 336), chiefly in the case of mixtures of methyl alcohol and water.

1. The difference between the number of heat-units evolved during the mixing of given weights of two substances, at the temperatures t and t' respectively, is equal to the difference between the number of heat-units required to raise the mixture, and that required to raise the two constituents taken separately, from the lower to the higher temperature. Or let U and U' be the units of heat evolved by mixing x and y at the temperatures t and t' respectively; S , S' , and S'' , the specific heat of the mixture z and its constituents x and y respectively; then

$$U - U' = z \cdot S(t - t') - \{x \cdot S'(t - t') + yS''(t - t')\}.$$

2. If more units of heat are evolved at the higher than at the lower temperature, the specific heat of the resulting mixture will be below the calculated mean, and *vice versa*.

3. The absorption of a lesser number of heat-units will of course be equivalent to the evolution of a greater number, while the absorption of a greater number will be equivalent to the evolution of a smaller number of heat-units.

A great many mixtures of various liquids have been found to conform as closely as can be expected with proposition 1. If these propositions prove to be an exposition of a general law, it will be possible to calculate the specific heat of one constituent of a mixture or solution, if the specific heat of the other constituent, the specific heat of the mixture, and the heat evolved or absorbed at two different temperatures between which these specific heats have been estimated, be known. It will also be possible to compare the specific heats of liquid and solid substances when both are placed under similar conditions.

Expansion by Heat. 1. *Of Gases.* Amagat (*N. Arch. Phys. Nat.* xl, 320; xli, 365) has determined the expansions of sulphurous anhydride and carbonic anhydride, as compared with air between the temperatures of 0° and 250° . The following table gives the numbers calculated from the experimental data, the expansion-coefficient of air between the above limits being supposed to be constant and equal to 0.00367:—

	Sulphurous Anhydride	Carbonic Anhydride
At 0°	—	0.003724
Between 0° and 10°	0.004233	—
" 10° and 20°	0.004005	—
At 50°	0.003846	0.003704
" 100°	0.003757	0.003695
" 150°	0.003718	0.003690
" 200°	0.003695	0.003687
" 250°	0.003685	0.003682

The coefficient of expansion of sulphurous anhydride decreases with increasing temperature, at first rapidly, up to a temperature of 50° , and then slowly up to about 250° , above which it apparently remains constant. It appears, therefore, to tend towards a limit different from that of atmospheric air, namely 0.00374. Carbonic anhydride shows a similar result; the coefficient diminishes, though slightly, up to about 200° , above which temperature it appears to remain constant at 0.003696, or also slightly higher than that of atmospheric air.

2. *Of Aqueous Solutions.*—Marignac (*Ann. Chem. Phys.* [4], xxii, 415) has made a series of observations on the density and expansibility of aqueous solutions.

the expansion being measured by means of dilatometers—that is, large-sized thermometers with bulbs of 25 to 28 c.c. capacity. The divisions on the stem allowed variations amounting to no more than $\frac{1}{10000}$ of the total volume to be read off. No perceptible variation could be detected in the volume of a solution, when kept at a constant temperature during several days, the first observation being made as soon as possible after the solution was prepared.

The following tables give the densities, molecular volumes, and coefficient of expansion, at 20°, of various aqueous solutions. Column *n* gives the number of molecules of water present; D, the density of the solution; W, its molecular weight; V, its molecular volume (water = 18); $V - 18n$, the difference between the molecular volume of the solution and that of the water which it contains; E, the coefficient of expansion; all at 20°.

Sulphuric Acid, H²SO⁴ + nAq.

<i>n</i>	D	W	V	$V - 18n$	E
0	1.83211	98	53.40	53.40	0.0005585
5	1.41317	188	132.80	42.80	0.0005660
10	1.26099	278	220.08	40.08	0.0005845
15	1.19033	368	308.60	38.60	0.0005697
25	1.12202	548	487.14	37.14	0.0004975
50	1.06451	998	935.9	35.9	0.0003867
100	1.03251	1898	1835.0	35.0	0.0003107
200	1.01502	3698	3633.6	33.6	0.0002602
400	1.00728	7298	7232.8	32.8	0.0002339
Water	0.99826	18	18	—	—

The continued decrease of the numbers in the last column shows that, whether sulphuric acid itself be mixed with water, or a dilute sulphuric acid be still further diluted, contraction always results.

Sodium Sulphate, Na²SO⁴ + nAq.

<i>n</i>	D	W	V	$V - 18n$	E
25	1.23443	592	478.7	28.7	0.0004102
50	1.12645	1042	923.4	23.4	0.0003608
100	1.06546	1942	1819.5	19.5	0.0003051
200	1.03287	3742	3616.6	16.6	0.0002599
400	1.01586	7342	7214.8	14.8	0.0002344

This table shows that contraction takes place when a solution of sodium sulphate is diluted with water.

Acid Sodium Sulphate, NaHSO⁴ + nAq.

<i>n</i>	D	W	V	$V - 18n$	E
25	1.17053	570	486.1	36.1	0.0005554
50	1.09168	1020	932.7	32.7	0.0004349
100	1.04718	1920	1830.3	30.3	0.0003390
200	1.02367	3720	3628.0	28.0	0.0002776

Comparative Table of the Molecular Volumes of Solutions of Neutral Sodium Sulphate, Acid Sodium Sulphate, and Sulphuric Acid.

<i>n</i>	H ² SO ⁴	NaHSO ⁴	Na ² SO ⁴
25	487.1	486.1	478.7
50	935.9	932.7	923.4
100	1835.0	1830.3	1819.5
200	3633.6	3628.0	3616.6
400	7232.8	—	7214.8

It will be seen that the molecular volume of the acid sulphate is always above that of the mean of the sulphuric acid and neutral sulphate; so that when a solution of neutral sulphate is mixed with sulphuric acid, expansion *always* takes place.

Hydrochloric Acid, HCl + nAq.

n	D	W	V	V-18n	E

These results show that, in a mixture of a solution with water, the coefficient of expansion of the mixture is higher than the mean of the coefficients of expansion of the two constituent liquids. They also confirm the general law that the dilution of a solution is attended with contraction. This contraction, however, diminishes as the temperature at which the mixture is made rises, so that it seems very probable that at temperatures sufficiently elevated the dilution of a solution would no longer be accompanied by contraction of volume.

As a general result of his experiments on the specific heat, density, and expansion of solutions, Marignac concludes that the state of combination of a salt in solution is invariable, and is established immediately and finally at the moment of mixture or dilution. This conclusion is strengthened by the fact already noticed that the volume of a solution remains constant at the same temperature, and that the equilibrium of temperature is established as quickly on the mixing of two solutions as on that of two masses of water at different temperatures.

Fusion and Solidification. *Determination of Melting Points.*—For the exact determination of melting points, E. Kopp (*Deut. Chem. Ges. Ber.* v. 645) recommends the use of a mercury-bath instead of an oil- or water-bath. The substance is placed on the mercury, and covered with a small funnel of thin glass. The melting point and the solidifying point can be observed most readily if the substance is opaque and becomes transparent when fused. Substances which soften before melting are fused and introduced into a little conical capillary tube, which, after cooling, is placed 0.5 to 1.0 centimeter before the surface of the mercury. As soon as the substance becomes soft or begins to melt, it is forced out of the tube and appears above the surface of the mercury.

Influence of a Change of Density upon Melting Point.—In accordance with the mechanical theory of heat, which requires that the melting point be raised or lowered

according as the specific gravity is increased or diminished, F. Mohr (*Ann. Ch. Pharm.* clxii. 61-67) has found by experiment that, in the case of garnets, fusion lowers the melting point at the same time that it diminishes the specific gravity.

Melting and Solidifying Points of Fats.—F. Rüdorff (*Pogg. Ann.* cxlv. 279), after testing all the usual methods for determining the melting points of fats, finds that the most concordant results are obtained by covering a thermometer-bulb with a layer of fat about 3 mm. thick, immersing it in hot water, and observing the temperatures at which the fat begins to separate from the bulb and to ascend through the water.

The solidifying points of some fats were determined by observing the temperatures at which they became solid whilst they were violently agitated; but with the glycerides and some other fats; which exhibit a rise of temperature during solidification, it was found best to take as solidifying point that temperature to which the thermometer rises during solidifying.

The following table exhibits the results :—

	Melts at	Solidifies at	Temperature rises during solidification to
	°C.	°C.	
Yellow bees'-wax . . .	63·4	61·5 62·6 62·3	— — —
White bees'-wax . . .	61·8	61·6	—
Paraffin . . .	49·6 52·5 to 54 53	49·6 53 52·9	— — —
Spermaceti . . .	52·7 to 53·2 43·5 44·1 to 44·3	52·7 43·4 44·2	— — —
Stearic acid . . .	55·3 56·2 to 56·6 56·0 to 54·4	55·2 55·8 55·7	— — —
Japan wax . . .	50·4 to 51·0	—	50·8
Cacao butter . . .	33·5	—	27·4
Nutmeg butter . . .	70 to 80	—	41·7--41·8
Mutton suet . . .	46·5 to 47·4	32 to 36	{ Several degrees
Beef suet . . .	43·5 to 45·0	27 to 35	

The phenomenon of a rise of temperature during solidification was also observed in artificial mixtures of fats; for instance, of spermaceti and stearic acid, and of paraffin and stearic acid, and is probably due to the constantly varying composition of the liquid remaining behind during partial solidification. A change in composition as solidification goes on may possibly also explain the great interval of temperature during which beef and mutton suet pass from the liquid into the solid state.

An apparatus for determining the melting points of organic bodies is described by J. Löwe (*Dingl. polyt. J.* cci. 250; *Chem. Soc. J.* [2], ix. 973).

For De Coppet's experiments on the Solidification of Saline Solutions, see *Ann. Chim. Phys.* [4], xxiii. 366; *Chem. Soc. J.* [2], x. 1062.

Thermic Phenomena accompanying Allotropic and Isomeric Transformation. According to Berthelot (*Compt. rend.* lxx. 941), 1 gram of octohedral sulphur on dissolving in carbon sulphide absorbs 12,800 units of heat (gram-degrees). According to Person, the heat of fusion of octohedral sulphur is 9,400 units for 1 gram. Berthelot finds, moreover, the transformation of amorphous soluble sulphur into octohedral sulphur under the influence of aqueous sulphydric acid is attended with the absorption of 2,600 units of heat for 1 gram, and that of insoluble sulphur from flowers of sulphur into octohedral sulphur, with the development of 2,700 units. Hence it appears that the transformation of insoluble into octohedral sulphur at 185° is not attended either with evolution or with absorption of heat. The conversion of prismatic into octohedral sulphur develops, according to Mitscherlich, 2,300 units of heat: consequently, the transformation of prismatic into amorphous insoluble sulphur at ordinary temperatures develops about 5,000 units. Accordingly the transformation of dissolved octohedral into insoluble sulphur under the influence of direct sunlight at ordinary temperatures is attended with a development of 12,800 units for 1 gram, and that which takes place in ordinary sulphur at about 113° after fusion is likewise at-

tended with development of heat. Light seems to incite the change, but does not effect the actual work of transformation.

Respecting the heat-phenomena attending the transformation of cyanic acid into cyamelide, and of cyamelide into cyanuric acid, see 1st Suppl. (p. 518).

Heat of Chemical Action.

I. Heat developed in the Combination of the Elementary Bodies.

A. *In the Combinations of Hydrogen with the Non-metallic Elements.*
—J. Thomsen (*Deut. Chem. Ges. Ber.* iv. 941; v. 789) has determined the affinity of hydrogen for the non-metallic elements, as measured by the quantities of heat evolved in their several combinations, with the following results:—

1. *Chlorine.*—The affinity between hydrogen and chlorine, estimated by burning chlorine in an atmosphere of dry hydrogen, gave—

$$(H, Cl) = 22,000 \text{ heat-units,}$$

a number differing considerably from that obtained by Favre & Silbermann, viz. 23,783 (iii. 100).

For the absorption of hydrochloric acid gas by water, Thomsen finds—

$$(HCl, Aq) = 17,314 \text{ heat-units,}$$

when 400 mol. water are present to each molecule of hydrogen chloride. Hence for the formation of hydrochloric acid in aqueous solution, we have—

$$(H, Cl, Aq) = 39,315 \text{ heat-units.}$$

2. *Bromine.*—The affinity of bromine for hydrogen was determined from the heat evolved in the decomposition of an aqueous solution of potassium bromide by chlorine, which gives—

$$(KBr, Aq, Cl) = 11,478 \text{ heat-units.}$$

Further it is known that $(Br, Aq) = 539$ h.-u.; $(H, Cl, Aq) = 39,315$ h.-u.; $KHO, Aq, HCl, Aq = 13,740$ h.-u. and $(KHO, Aq, HBr, Aq) = 13,750$ h.-u.: hence, by calculation—

$$(Br, Aq, H) = 27,837 \text{ heat-units,}$$

$$(Br, H, Aq) = 28,376 \text{ „}$$

Further, the absorption of hydrobromic acid gas by water gives

$$(HBr, Aq) = 19,207 \text{ heat-units:}$$

consequently, for the affinity between bromine and hydrogen we have—

$$(H, Br) = 8,440 \text{ heat-units.}$$

3. *Iodine.*—The affinity of hydrogen for iodine was determined in like manner by the decomposition of aqueous potassium iodide with chlorine, which gives—

$$(KI, Aq, Cl) = 26,209 \text{ heat-units,}$$

and the heat of neutralisation of hydriodic acid by potash is $(KAq, HIAq) = 13,657$ h.-u.; hence the affinity in aqueous hydriodic acid is found to be—

$$(H, I, Aq) = 13,171 \text{ heat-units.}$$

Moreover, the heat of absorption of hydriodic acid is found to be—

$$(HI, Aq) = 19,207 \text{ heat-units:}$$

hence, for the affinity of hydrogen for iodine in gaseous hydriodic acid we find—

$$(I, H) = - 6036 \text{ heat-units.}$$

4. *Oxygen.*—Direct combustion of oxygen in an atmosphere of dry hydrogen gave—

$$(H^2, O) = 68,357 \text{ heat-units,}$$

which is intermediate between the number determined by Andrews and that found by Favre & Silbermann (iii. 105).*

5. *Sulphur.*—The affinity of sulphur and hydrogen was determined by the heat evolved on passing gaseous hydrogen sulphide into a solution of iodine in dilute hydriodic acid, in which iodine dissolves more freely than in pure water and without change of temperature. Experiment gave—

$$(I^2, Aq, SH^2) = 21,830 \text{ heat-units;}$$

* The numbers in the table here referred to relate to the combustion of 1 gram (or one atom) of hydrogen; Thomsen's number to the combustion of 2 grams.

and since

$$(I, H, Aq) = 13,171 \text{ heat-units,}$$

we have for the affinity of sulphur to hydrogen—

$$(H^2, S) = 4,512 \text{ heat-units.}$$

Further, Thomsen has found for the heat of absorption of hydrogen sulphide in water—

$$(H^2S, Aq) = 4,754 \text{ heat-units :}$$

hence, the affinity of hydrogen for sulphur in aqueous solution is expressed by—

$$(H^2, S, Aq) = 9,266 \text{ heat-units.}$$

The number for the affinity of hydrogen to sulphur in gaseous hydrogen sulphide applies strictly only to sulphur in the state in which it separates from that combination, viz., as yellow, somewhat elastic sulphur, and would require a small correction to make it applicable to rhombic sulphur.

6. *Nitrogen*.—Every atom of chlorine passed into an aqueous solution of ammonia produces an evolution of heat represented by—

$$(NH^3, Aq, Cl) = 30,871 \text{ heat-units ;}$$

and as the neutralisation of hydrochloric acid by ammonia gives $(HCl, Aq, NH^3, Aq) = 12,270$ heat-units, we obtain for the affinity between nitrogen and hydrogen in aqueous solution :

$$(N, H^3, Aq) = 35,142 \text{ heat-units ;}$$

but the heat of absorption of ammonia in water is—

$$(NH^3, Aq) = 8,435 \text{ heat-units ;}$$

therefore, by subtraction—

$$(N, H^3) = 26,707 \text{ heat-units.}$$

The mode of calculating the total heat of combination of the ammonium-compounds is indicated by the equation—

$$(NH^3, Cl, Aq) = (N, H^3, Aq) + (H, Cl, Aq) + (NH^3, Aq, HCl, Aq).$$

From his former determinations of the reactions on the right-hand side, Thomsen obtains—

$$(N, H^3, Cl, Aq) = 86,730 \text{ heat-units.}$$

$$(N, H^3, Br, Aq) = 75,790 \quad "$$

$$(N, H^3, I, Aq) = 60,580 \quad "$$

$$(N, H^3, S, Aq) = 50,600 \quad "$$

As also the latent heats of solution of the first three of these compounds are known, viz. :—

$$(NH^3, Cl, Aq) = -3,880 \text{ heat-units.}$$

$$(NH^3, Br, Aq) = -4,380 \quad "$$

$$(NH^3, I, Aq) = -3,550 \quad "$$

the heats of combination of the ammonium-compounds in the solid state can be calculated—

$$(N, H^3, Cl) = 90,610 \text{ heat-units.}$$

$$(N, H^3, Br) = 80,170 \quad "$$

$$(N, H^3, I) = 64,130 \quad "$$

7. *Carbon*.—The affinity between hydrogen and carbon is calculated from the heat developed in the combustion of hydrocarbons. For marsh-gas and ethylene this amount of heat has been already several times determined. Thomsen has extended the investigation to acetylene.

a. *Marsh-gas*.—Since the heats of combustion of marsh-gas, as found by Dulong, Andrews, Favre, and Silbermann, do not differ much from each other, Thomsen adopts the mean of these determinations, viz. :—

$$(CH^4, O^4) = 209,900 \text{ heat-units ;}$$

from which the affinity of hydrogen and carbon is deduced by the equation—

$$(CH^4, O^4) = 209,900 \text{ heat-units} = (C, O^2) + 2(H^2, O) - (C, H^4).$$

Now Favre & Silberman found, for the heat of combustion of graphite (which may be regarded as the normal form of carbon) 7,800 heat-units per gram: consequently $(C, O^2) = 12 \cdot 7800 = 93,600$ heat-units; and since, according to Thomsen, $(H^2, O) = 68,357$, it follows that

$$\begin{aligned}(C, H^4) &= (C, O^2) + 2(H^2, O) - (CH^4, O^2) \\ &= 93,600 + 136,714 - 209,900 \\ &= 20,414 \text{ heat-units.}\end{aligned}$$

The affinity of carbon and hydrogen in marsh-gas is therefore positive.

β. Ethylene.—The heat of combustion of this gas is, according to Thomsen's experiments,

$$(C^2H^4, O^2) = 334,800 \text{ heat-units;}$$

from which, by the equation

$$(C^2H^4, O^2) = 2(C, O^2) + 2(H^2, O) - (C^2, H^4),$$

there follows

$$(C^2, H^4) = -10,880 \text{ heat-units.}$$

γ. Acetylene.—The affinity of carbon and hydrogen in acetylene is calculated from its heat of combustion—

$$(C^2H^2, O^2) = 310,570 \text{ heat-units;}$$

from which, by the equation

$$(C^2H^2, O^2) = 2(C, O^2) + (H^2, O) - (C^2, H^2),$$

there follows

$$(C^2, H^2) = -55,010 \text{ heat-units.}$$

The affinity of hydrogen for every first member of the four natural groups of the non-metallic elements is positive, but diminishes for the members with greater atomic weights, and is even negative for some of the highest members, namely, for iodine, and according to Hautefeuille, for selenium (p. 616). Although no satisfactory explanation of this can be given at present, it must, at all events, be remembered that many thermo-chemical equations do not represent the actual physical conditions, inasmuch as they express the reactions of atoms upon each other instead of molecules. Thus, the heat of combustion of hydrogen in chlorine ought to be expressed, not by $ClH = 22,001$ heat-units, but by $(Cl^2, H^2) = 44,002$ heat-units, and the true value of the (Cl, H) can only be calculated from the equation $(Cl^2, H^2) = 2(Cl, H) - (Cl, Cl) - (H, H)$, in which the terms on the right-hand side are at present unknown.

From the reactions

$$\begin{aligned}(C^2, H^2) &= -55,010 \text{ heat-units,} \\ (C^2, H^4) &= -10,880 \text{ " } \\ (C, H^4) &= +20,420 \text{ " }\end{aligned}$$

it might appear that the affinity of carbon for hydrogen is negative. But as the hydrocarbons once formed produce a great amount of heat in their combination with more hydrogen, thus:—

$$\begin{aligned}(C^2, H^4) - (C^2, H^2) &= (C^2H^4, H^2) = +44,130 \text{ " } \\ 2(C, H^4) - (C^2, H^4) &= (C^2H^4, H^2) = +51,720 \text{ " }\end{aligned}$$

it can scarcely be doubted that the affinity of carbon for hydrogen is really positive, as, indeed, appears directly from the formation of marsh-gas.

The fact that the formation of the lower compounds of carbon with hydrogen and oxygen produces less heat than their combination with more hydrogen or oxygen, and that the direct combination of carbon with other elements can only be effected at very high temperatures, may perhaps be explained by the following hypothesis:—

Carbon, as it is known as graphite, diamond, or charcoal, is in a negative or passive condition, out of which it must be brought before it can combine chemically with other elements, a certain amount of force being necessary to effect this transformation from the passive into the chemically active state.

This force cannot at present be estimated, but amounts probably to about 70,000 heat-units for every carbon-atom.

B. In the Combination of Oxygen with other Non-metallic Elements.—*Formation of the Oxygen-acids of Sulphur* (Thomsen, *Dent. Chem. Ges. Ber.* v. 1014).—The following determinations relate to the affinities of sulphur and oxygen in the aqueous solutions of the several acids.

For the heat of absorption of sulphurous anhydride in water:

$$(SO^2, Aq) = 7,698 \text{ heat-units.}$$

For the oxidation of aqueous sulphurous acid by means of chlorine gas :

$$(\text{SO}^2\text{Aq}, \text{Cl}^2) = 73,907 \text{ heat-units.}$$

For the complete oxidation of sodium thiosulphate by hypochlorous acid in aqueous solution :

$$(\text{Na}^2\text{S}^2\text{O}^3\text{Aq}, 4\text{ClOH}, \text{Aq}) = 251,624 \text{ heat-units.}$$

For the action of iodine on a solution of sodium thiosulphate :

$$(2\text{Na}^2\text{S}^2\text{O}^3\text{Aq}, \text{I}^2) = 7,954 \text{ heat-units.}$$

For the decomposition of sodium thiosulphate by hydrochloric acid in aqueous solution :

$$(\text{Na}^2\text{S}^2\text{O}^3\text{Aq}, 2\text{HClAq}) = -2,176 \text{ heat-units.}$$

For the resolution of potassium dithionate in the dry way into potassium sulphate and sulphur dioxide :

$$(\text{K}^2\text{SO}^4, \text{SO}^2) = 0.$$

For the latent heat of sulphate and dithionate of potassium :

$$(\text{K}^2\text{SO}^4, \text{Aq}) = -6,384 \text{ heat-units,}$$

$$(\text{K}^2\text{S}^2\text{O}^6, \text{Aq}) = -12,986 \quad ,,$$

To calculate from these numbers the relations of affinity of the sulphur acids, the following determinations, previously established by Thomsen, are required : relating to the thermic phenomena in the formation of water, of aqueous hydrochloric and hypochlorous acid (p. 606) ; in the neutralisation of sulphuric acid, &c. ; and, finally, in the reaction between 2 mol. hydrochloric acid and 1 mol. sodium dithionate in aqueous solution :

	Heat-units		Heat-units
(H ₂ O)	68,357	(2NaHOAq, SO ² Aq)	28,970
(I, H, Aq)	13,171	(2NaHOAq, S ² O ³ Aq)	27,070
(Cl, H, Aq)	39,315	2(NaHOAq, HClAq)	27,480
(Cl, O, H, Aq)	28,322	2(NaHOAq, HIAq)	27,350
(NaHOAq, SO ² Aq)	14,754	(NaHOSO ² Aq, 2HClAq)	-978

Also, the heat of combustion of sulphur, as determined by Favre and Silbermann :

$$(\text{S}^2, \text{O}^2) = 71,072 \text{ heat-units.}$$

The calculation of the affinities in question is made from these numbers as follows :—

Since sulphurous acid in aqueous solution is converted by chlorine into sulphuric and hydrochloric acid, we have the equation :

$$(\text{SO}^2\text{Aq}, \text{Cl}^2) = (\text{SO}^2\text{Aq}, \text{O}) - (\text{H}^2\text{O}) + (\text{Cl}^2, \text{H}^2, \text{Aq}) ;$$

and therefore, according to the numbers above given,

$$(\text{SO}^2\text{Aq}, \text{O}) = 63,634 \text{ heat-units,}$$

and

$$(\text{SO}^2, \text{O}, \text{Aq}) = (\text{SO}^2\text{Aq}, \text{O}) + (\text{SO}^2, \text{Aq}) = 71,332 \text{ heat-units.}$$

From this follow the total heats of formation of sulphurous and sulphuric acids :

$$(\text{S}, \text{O}^2, \text{Aq}) = (\text{S}, \text{O}^2) + (\text{SO}^2, \text{Aq}) = 78,770 \text{ heat-units,}$$

and

$$(\text{S}, \text{O}^2, \text{Aq}) = (\text{S}, \text{O}^2) + (\text{SO}^2, \text{O}, \text{Aq}) = 142,404 \text{ heat-units.}$$

The decomposition of potassium dithionate in the dry way into sulphur dioxide and potassium sulphate, is not attended either with evolution or with absorption of heat : therefore

$$(\text{K}^2\text{SO}^4, \text{SO}^2) = 0, \text{ and } (\text{K}^2\text{O}^2, \text{SO}^2) = (\text{K}^2\text{O}^2, 2\text{SO}^2).$$

These reactions may be split up into

$$(\text{K}^2\text{O}^2, \text{SO}^2) + (\text{K}^2\text{SO}^4, \text{Aq}) = (\text{K}^2\text{O}, \text{Aq}) + (\text{SO}^2, \text{O}, \text{Aq}) + (2\text{KHOAq}, \text{SO}^2\text{Aq}),$$

and

$$(\text{K}^2\text{O}^2, 2\text{SO}^2) + (\text{K}^2\text{S}^2\text{O}^6, \text{Aq}) = (\text{K}^2\text{O}, \text{Aq}) + (2\text{SO}^2, \text{O}, \text{Aq}) + (2\text{KHOAq}, \text{S}^2\text{O}^6\text{Aq}).$$

On subtracting these two equations from each other, the first and third terms, being equal, disappear ; and all the remaining terms are known, except $(2\text{SO}^2, \text{O}, \text{Aq})$, which can therefore be calculated, viz. :

$$(2\text{SO}^2, \text{O}, \text{Aq}) = 68,950 \text{ heat-units.}$$

R R

We have then, for the total heat of formation of dithionic acid :

$$(S^2, O^4, Aq) = (2SO^2, O, Aq) + 2(S, O^2) = 211,094 \text{ heat-units.}$$

In the reaction of hypochlorous acid on sodium thiosulphate, 2 mol. of sulphuric acid are formed, together with 4 mol. of hydrochloric acid resulting from the deoxidation of the hypochlorous acid :

$$(Na^2S^2O^3Aq, 4ClOHAq) = \begin{cases} (S^2O^2Aq, O^4) \\ 2(NaHOAq, SO^2Aq, 2HClAq) - (2NaHOAq, S^2O^2Aq, \\ 4(Cl, H, Aq) - 4(Cl, O, H, Aq) \end{cases}$$

Now, according to the preceding data, the heat evolved in the reaction between 1 mol. sulphuric acid and 2 mol. hydrochloric acid with 1 mol. sodium hydrate is $14,754 - 978 = 13,776$ units. The heat of neutralisation of thiosulphuric acid cannot be determined directly, on account of the instability of this acid ; but the decomposition of its sodium salt by hydrochloric acid is immediately attended with an absorption of heat amounting to 2,176 units, which indicates that the heat of neutralisation of thiosulphuric acid exceeds that of hydrochloric acid by about this number, and is therefore equal to about 29,656 units. As this number agrees nearly with the heat of neutralisation of sulphurous acid, viz. 28,970 units, it is assumed to be equal to the latter. The decomposition of the thiosulphuric acid into sulphur and sulphurous acid takes place gradually only, and is therefore without perceptible influence on the quantity 2,176. By introducing these values, together with those previously given, into the above equation, we obtain for the heat liberated in the oxidation of thiosulphuric to sulphuric acid,

$$(S^2O^2Aq, O^4) = 209,070 \text{ heat-units ;}$$

and by means of the equations

$$\begin{aligned} 2(S^2, O^2, Aq) &= (S^2, O^2, Aq) + (S^2O^2Aq, O^4) \\ (S^2, O^2, Aq) &= (S, O^2, Aq) + (SO^2, Aq, S) \end{aligned}$$

we obtain further :

$$\begin{aligned} (S^2, O^2Aq) &= 75,738 \text{ heat-units.} \\ (SO^2Aq, S) &= - 3,032 \text{ ,,} \\ (SO^2, S, Aq) &= + 4,666 \text{ ,,} \end{aligned}$$

for the heat-reactions implied in the formation of thiosulphuric acid.

The heat produced in the oxidation of thiosulphuric acid to *tetrathionic* acid can be calculated from the heat liberated in the reaction of iodine upon sodium thiosulphate :

$$2Na^2S^2O^3Aq, I^2 = \begin{cases} (I^2, H^2Aq) + 2(NaAq, HIAq) \\ (2S^2O^2Aq, O) - (O, H^2) \\ (2NaAq, S^4O^3Aq) - 2(2NaAq, S^2O^2Aq). \end{cases}$$

By assigning to these reactions their values, as given above (the neutralisation heat of tetrathionic acid is taken as equal to that of dithionic acid, 27,070 heat-units), we have

$$2(S^2O^2Aq, O) = 53,489 \text{ heat-units ;}$$

from which, by the equations

$$\begin{aligned} (S^4, O^3, Aq) &= 2(S^2, O^2, Aq) + (2S^2O^2Aq, O) \\ (S^4, O^3, Aq) &= 2(S, O^2) + (2SO^2, O, S^2, Aq), \end{aligned}$$

the affinities satisfied in the formation of tetrathionic acid are found :

$$(S^4, O^3, Aq) = 204,965 \text{ heat-units.}$$

If we consider thiosulphuric acid to be formed by the reaction of sulphurous acid, sulphur, and water, we obtain the effect of the second atom of sulphur by the equation :

$$(2SO^2, Aq) - (SO^2, S, Aq) = 7,698 - 4,666 = 3,032 \text{ heat-units,}$$

and considering tetrathionic acid to be formed in an analogous way from dithionic acid, we obtain the effect of the two additional atoms of sulphur from the equation—

$$(2SO^2, O, Aq) - (2SO^2, O, S^2Aq) = 68,950 - 62,821 = 6,129 \text{ heat-units.}$$

As $6,129 = 2 \times 3,064$, while the former difference was $= 3,032$, and as the calculations for thiosulphuric and dithionic acid are quite independent of each other, it follows that, for every additional atom of sulphur, the total heat of formation of the sulphur-acids is diminished by 3,032 to 3,064 heat-units.

It has not therefore been thought necessary to determine experimentally the heats of

formation of trithionic and pentathionic acids, as that of tetrathionic acid may be safely assumed to be about 3,064 units less than that of trithionic acid, and that of pentathionic acid about as much less than that of tetrathionic acid.

The heats of formation of the seven acids of sulphur are collected together in the following tables. Table I. shows the development of heat in the formation of the acids, from sulphur, oxygen, and water. Table II those which are obtained when the acids are derived from sulphurous anhydride.

TABLE I.

	Heat-units
(S, O ² , Aq)	= 78,770
(S ² , O ² , Aq)	= 75,738
(S, O ³ , Aq)	= 142,404
(S ² , O ³ , Aq)	= 211,094
(S ³ , O ³ , Aq)	= 208,030
(S ⁴ , O ³ , Aq)	= 204,965
(S ⁵ , O ³ , Aq)	= 201,901

TABLE II.

	Heat-units
(SO ² , Aq)	= 7,698
(SO ² , S, Aq)	= 4,666
(SO ² , O, Aq)	= 71,332
(2SO ² , O, Aq)	= 68,950
(2SO ² , S, O, Aq)	= 65,886
(2SO ² , S ² , O, Aq)	= 62,821
(2SO ² , S ³ , O, Aq)	= 59,757

If, in calculating the heat of formation of these acids, we take account also of the quantity evolved in the formation of the water contained in the hydrates, we obtain the values in Table III.

TABLE III.

	Heat-units
Sulphurous acid (SO ² , O, H ² , Aq)	= 76,055
Thiosulphuric acid (SO ² , S, O, H ² , Aq)	= 73,023
Sulphuric acid (SO ² , O ² , H ² , Aq)	= 139,869
Dithionic acid (2SO ² , O ² , H ² , Aq)	= 137,307
Trithionic acid (2SO ² , S, O ² , H ² , Aq)	= 134,243
Tetrathionic acid (2SO ² , S ² , O ² , H ² , Aq)	= 131,178
Pentathionic acid (2SO ² , S ³ , O ² , H ² , Aq)	= 128,114

If we suppose the acids to be formed from sulphurous acid and hydroxyl, for which Thomsen has found—

$$(H^2, O^2, Aq) = 45,045 \text{ heat-units,}$$

we obtain for—

Sulphuric acid (SO ² , Aq, H ² , O ² , Aq)	= 86,946 heat-units.
Dithionic acid (2SO ² , Aq, H ² , O ² , Aq)	= 76,886 "

The corresponding values for every other polythionic acid with n sulphur-atoms may be found by subtracting $(n-2)$ 3,064 heat-units from that of dithionic acid.

C. *General Results.*—The results of the preceding investigations on the affinities of the elements, together with others obtained by similar methods, are collected in the following Tables. (*Deut. Chem. Ges. Ber.* vi. 1533.)

Reaction	Heat-units evolved or absorbed	Remarks	
1. Hydrogen.			
Water	(H^2, O) Mol. Heat of volatilisation at 100° Mol. Heat of Fusion	68,360 9,660 1,440	Régault Bunsen

D. *The Common Constant of Affinity.*—A comparison of the quantities of heat evolved in a large number of chemical reactions leads to the conclusion, that these quantities, and therefore also the forces of affinity which they measure, are multiples of a common constant, the value of which is about 18,000 heat-units. The following numbers exhibit this reaction in two series of chemical processes:

$(\text{N}^2\text{O}^2, \text{O}, \text{Aq})$	=	2. 18,170 heat-units
$(\text{N}^2\text{O}^2, \text{O}^2, \text{Aq})$	=	3. 18,214 "
$(\text{N}^2\text{O}^2, \text{O}^2, \text{Aq})$	=	4. 18,235 "
$(\text{Cu}, \text{O}, \text{SO}^2\text{Aq})$	=	3. 18,075 "
$(\text{Pb}, \text{O}, \text{SO}^2\text{Aq})$	=	4. 18,888 "
$(\text{Fe}, \text{O}, \text{SO}^2\text{Aq})$	=	5. 18,772 "
$(\text{Cd}, \text{O}, \text{SO}^2\text{Aq})$	=	3. 18,094 "
$(\text{Zn}, \text{O}, \text{SO}^2\text{Aq})$	=	6. 18,077 "
$(\text{Mg}, \text{O}, \text{SO}^2\text{Aq})$	=	10. 18,092 "

In these two series the character of the chemical reaction is perfectly analogous for the members of each; the former representing the formation of the oxygen-acids of nitrogen from nitrogen dioxide, oxygen and water, the latter that of metallic sulphates from metal, oxygen, and sulphuric acid.

The conversion of aqueous chlorine into hydrochloric acid with decomposition of water, gives the thermic relation:

$$(\text{Cl}^2\text{Aq}, \text{H}^2) - (\text{H}^2, \text{O}) = 5,403 \text{ heat-units};$$

whence, since $(\text{H}^2, \text{O}) = 6,836$ h. u., we find for the conversion of chlorine-water into hydrochloric acid, by direct addition of hydrogen $(\text{Cl}^2\text{Aq}, \text{H}^2) = 73,764$ h. u.; and in like manner may be calculated the quantities of heat which would be evolved in the conversion of aqueous solutions of bromine and hydroxyl into water by direct addition of hydrogen. The result is as follows:—

$(\text{Br}^2\text{Aq}, \text{H}^2)$	=	55,654 = 3. 18,551 heat-units
$(\text{Cl}^2\text{Aq}, \text{H}^2)$	=	73,764 = 4. 18,441 "
$(\text{H}^2\text{O}^2\text{Aq}, \text{H}^2)$	=	91,675 = 5. 18,335 "

A similar group of processes is exhibited by the action of chlorine on solutions of ferrous chloride, stannous chloride, and sulphurous acid also on mercury and cuprous chloride suspended in water:

$(\text{Hg}^2\text{Cl}^2, \text{Aq}, \text{Cl}^2)$	=	37,075 = 2. 18,537 heat-units
$(2\text{FeCl}^2, \text{Aq}, \text{Cl}^2)$	=	54,810 = 3. 18,270 "
$(\text{SnCl}^2, \text{Aq}, \text{Cl}^2)$	=	73,875 = 4. 18,469 "
$(\text{SO}^2\text{Aq}, \text{Cl}^2)$	=	73,907 = 4. 18,477 "

These numbers show that the common constant of affinity has the same value, whether the element which enters into combination be oxygen, hydrogen, or chlorine.

A similar relation is exhibited by the quantities of heat evolved in the following reactions:—

$(2\text{FeSO}^4\text{Aq}, \text{O}, \text{SO}^2\text{Aq})$	=	36,800 = 2. 18,400 heat-units
$(2\text{CrO}^3\text{Aq}, 3\text{SO}^2\text{Aq})$	=	36,884 = 2. 18,442 "
$(\text{Mn}^2\text{O}^4\text{Aq}, 2\text{SO}^2\text{Aq})$	=	72,647 = 4. 18,162 "

The first of these reactions, in which ferrous sulphate is converted into ferric sulphate by oxygen and sulphuric acid, is perfectly analogous to the conversion of ferrous into ferric chloride by the action of chlorine; and the quantities of heat evolved in the two reactions are as 2 : 3. In the two other processes, chromic and permanganic acids

are converted by sulphuric acid into the normal sulphates of chromium and manganese, with evolution of oxygen. The quantities of heat evolved are as 2:4, and the common constant is the same as before.

When hydrogen dioxide and permanganic acid act on one another in presence of a free acid, sulphuric or hydrochloric acid, for example, 5 mol. of oxygen are evolved for each molecule of permanganic acid decomposed, the products of the reaction being water and manganous sulphate or chloride. The thermic effects of the two reactions are:

10 atoms or 5 mol. of oxygen are given off, and the quantity of heat developed amounts to 10 times the value of the common constant.

The mean value of the common factor in the twelve reactions above cited, in which hydrogen, chlorine, sulphuric acid, and hydrogen dioxide are the reagents common to the several groups, is 18,427 heat-units; and the mean value for the nine processes in which oxygen is the common reagent, is 18,361 heat-units. It may therefore be inferred that, allowing for unavoidable errors of observation, the actual value of the constant of affinity is the same in all these cases (Thomson, *Deut. Chem. Ges. Ber.* vi. 239).

E. Development of Heat in the Combination of Hydrogen with the various Modifications of Sulphur and Selenium.—Hautefeuille (*Compt. rend.* lxxviii. 1554) has determined the quantities of heat evolved in the combination of hydrogen with sulphur and selenium in their various molecular states. The mode of experimenting consisted in decomposing hydriodic acid gas with sulphur and selenium at ordinary temperatures within a mercury calorimeter. According to Favre, 1 mol. hydriodic acid, in separating into free hydrogen and solid iodine, evolves 6,840 units of heat. Now Hautefeuille finds that the substitution of 1 atom of octohedral sulphur for iodine ($2\text{HI} + \text{S} = \text{H}^2\text{S} + \text{I}^2$) develops 13,680 heat-units. Consequently, in the combination of 1 atom octohedral sulphur with hydrogen there are evolved $13,680 - 2 \cdot 4,430 = 4,820$ units of heat. Moreover, the heat of combustion of 1 atom of hydrogen is 34,462 units (iii. 105), and that of 1 atom of octohedral sulphur is 71,968 units; therefore the heat of combustion of 34 grams of hydrogen sulphide is:

$$2 \cdot 34,462 + 71,968 - 4,820 = 136,072 \text{ heat-units.}$$

The direct oxidation of hydrogen sulphide by means of hypochlorous acid, gave a somewhat higher number, viz., 136,400; but this reaction is complicated by the formation of sulphur chloride, which oxidises but slowly.

The conversion of 1 atom of insoluble into crystallised sulphur is attended, according to Favre, with the absorption of 6,204 units of heat. Consequently, in the decomposition of hydrogen sulphide into hydrogen and insoluble sulphur, there are absorbed $6,104 - 4,820 = 1,284$ units of heat; and in the combination of hydrogen with insoluble sulphur, effected by means of hydriodic acid, $13,680 - 6,104 = 7,476$ units are evolved. Direct experiment gave a larger number, but still below 8,860; the difference is attributed by Hautefeuille to the difficulty of preparing insoluble sulphur in the pure state.

The development of heat which takes place in the preparation of hydriodic acid by hydrogen sulphide and iodine is due, partly to the solution of the hydrogen sulphide in water, partly to the chemical reaction. Estimating the heat of solution of 1 mol. hydrogen sulphide in water at 6,750 units, it is found that 1 mol. of this dissolved acid, on decomposing in the manner above mentioned, evolves 24,000 heat-units. The hydriodic acid (2 mol.) thereby produced contains, in the dilute state, according to Favre, 28,950 heat-units less than its elements; and the whole of this quantity of heat must have been set free if the dissolved hydrogen sulphide had decomposed without absorption of heat. The 4,950 units thus absorbed represent the quantity of heat which would be developed in the direct combination of hydrogen with the undetermined variety of sulphur which is obtained by precipitating this element from a solution of hydrogen sulphide.

The evolution of heat in the formation of hydriodic acid becomes less as the concentration of the solution is greater. The reaction will go on, attended with evolution of heat, so long as the solution of hydriodic acid has not attained the degree of concentration at which it loses the quantity of heat which is required for the decomposition of the hydrogen sulphide in aqueous solution, that is to say, about 11,650 units. It is a question whether, at a higher degree of concentration, the reverse action would take place. Under pressure this seems to be the case; otherwise concentrated hydriodic acid acts upon sulphur only when gaseous acid is evolved in consequence of elevation of temperature.

The evolution of heat in the combination of selenium with hydrogen may be determined in a similar manner. The decomposition of gaseous hydriodic acid by red selenium and by metallic selenium, is attended with only a very slight evolution of heat. 1 mol. hydrogen selenide, in resolving itself into hydrogen and metallic selenium, would give out 5,400 heat-units; if it were resolved into hydrogen and red selenium, it would evolve 4,280 units. Consequently, the combination of hydrogen with these two modifications of selenium must be attended with absorption of heat. Hydrogen selenide is likewise decomposed by iodine, with separation of red selenium, which then unites with the excess of iodine (Hautefeuille).

A. Naumann (*Deut. Chem. Ges. Ber.* ii. 177) finds that hydrogen sulphide does not act at ordinary temperatures on iodine dissolved in dehydrated carbon sulphide, or on solid or aqueous iodine in the absence of water. A solution of iodine in carbon sulphide saturated with hydrogen sulphide does not lose the odour of that gas by keeping; but when shaken with water it makes the water turbid by separation of sulphur. This behaviour of iodine to hydrogen sulphide is explained by the thermic relations of the two substances. The reaction represented by the equation $\text{H}_2\text{S} + \text{I}_2 = 2\text{HI} + \text{S}$, which is intended merely to exhibit, in their simplest form, the quantitative relations of the bodies present before and after the chemical change, requires an absorption of $5,480 + 2 \cdot 3,600 = 12,620$ units of heat (iii. 115). It cannot, therefore, take place independently at ordinary temperatures. That it takes place in presence of water is due to the fact, that the dissolution of the hydriodic acid produced (2HI) gives rise to the evolution of 37,800 heat-units (iii. 113; $147 \cdot 7 \times 128 \times 2 = 37,811$). The total evolution of heat is therefore $37,800 + x - 12,680 = 25,120 + x$, where x denotes the negative heat of solution of iodine alone, taken with a positive sign. But it is found that the heat developed by the absorption of equal quantities of hydriodic acid gas is less as the quantity of that acid already dissolved in the water is greater. The positive sum of the quantities of heat evolved must therefore diminish as the quantity of hydriodic acid in the liquid increases, until the positive and negative evolutions of heat neutralise one another, and the total evolution is reduced to nothing. The inference thence deducible, that the mutual action of iodine and hydrogen sulphide goes on in presence of water will reach its limit at a certain degree of concentration of the resulting solution of hydriodic acid, at which gaseous hydriodic acid must be dissolved with absorption of heat, is fully verified by experiment. The limit of concentration in question corresponds with a specific gravity of 1.56 at ordinary temperatures referred to water at the same temperature; whereas the acid which distils over at 127° – 128° under the ordinary atmospheric pressure has a specific gravity of 1.67 (*1st Suppl.* 738), and a solution saturated at 0° a specific gravity of 1.99. Aqueous hydriodic acid of specific gravity 1.56 absorbs hydriodic acid gas passed into it, with considerable rise of temperature.

F. Heat of Combination of Iodine with Oxygen.—A. Ditte (*Ann. Chim. Phys.* [4] xxi. 52) has determined the heat of combustion of iodine in oxygen by means of the formation of phosphoric acid resulting from the action of iodine on red phosphorus (see Iodic Acid); also the heat of solution of iodic anhydride and iodic acid, and the heat of contraction of iodic acid from the corresponding densities, expansion-coefficients, and specific heats, whence also the heat of combination of iodic acid with water is deduced:

	Heat-units	
	For 1 gram	For 1 mol.*
Heat of Combination of Iodine (I_2) to Iodic Anhydride	+ 110.00	+ 2792.0
Heat of Solution of Iodic Anhydride I_2O_5	— 5.7	— 1902.4
Heat of Solution of Iodic acid HIO_3	— 12.7	— 2240.6
Heat of Contraction of Iodic acid	+ 0.45	+ 1135.7
Heat of Combination of Iodic Anhydride (I_2O_5) with Water	+ 0.6	+ 307
Specific Heat of Iodic acid	0.1625	

G. Heat of Combination of Boron and Silicon with Chlorine and Oxygen (Troost & Hautefeuille, *Compt. rend.* lxx. 185, 252).—The experiments, made with a mercury calorimeter, gave the following results:—

Amorphous Boron.

	Heat-units	
	For 1 gram	For 1 atom
In Combination with Oxygen	14,420	158,600
In Combination with Chlorine	9,455	104,000
In the action of Boron Chloride on 140 times its weight of Water	7,200	79,200

* This number differs widely from Thomsen's (p. 619).

Amorphous Silicon.

	For 1 gram	For 1 atom	
		Si=28	Si=21
In Combination with Oxygen	7,830	219,240	164,430
In Combination with Chlorine	5,630	157,640	118,230
In the action of Silicon Chloride on 140 times its weight of Water	2,915	81,640	61,220
In the Isomeric Transformation of Amorphous into Crystallised Silicon	290	8,120	6,090

H. *Heat of Oxidation of Magnesium, Cadmium, Indium, and Zinc* (A. Ditte, *Compt. rend.* lxxii. 762, 858; lxxiii. 108).—The determinations were made in the mercury-calorimeter by two methods. In the first, equivalent weights of the metal and of its oxide were dissolved in sulphuric acid, and the quantities of heat thereby evolved were determined. The difference of these two numbers gives the quantity of heat produced when the metal is oxidised at the expense of hydrogen, and by combining this result with the known heat of combustion of hydrogen itself, the heat developed by the direct combustion of the metal can be calculated. In the second method, the heats of solution of the metal and of its oxide in iodic acid were determined. Now 1 eq. of the metal in passing to the state of iodate decomposes $\frac{1}{2}$ eq. iodic acid, whereby 2,792 units of heat are expended, and from this the heat of combustion of the metal may be calculated. For magnesium both methods were used; for zinc and indium, the first; for cadmium, the second. The following are the mean values of the heats of combustion obtained:—

	Equivalent	Heat of Combustion	
		for 1 gram	for 1 eq.*
Magnesium	12	6130.5	73,566 heat-units
Zinc	32.5	1357.6	44,122 "
Indium	37.8	1044.6	39,486 "
Cadmium	56	271.1	15,182 "

The difference between the number found by Ditte for zinc and the number 42,451 determined by Favre & Silbermann arises from the difference in the heat of solution of oxides according to the temperatures to which they have been previously raised. For zinc oxide, Ditte found the following thermic effects on solution in dilute sulphuric acid, according to the temperature to which the zinc hydrate had been previously heated:—

Temperature	for 1 gram	for 1 equiv.
350°	244.2	9,890 heat-units
Dark red heat	272	11,016 "
Bright red heat	299.7	12,138 "

This marked effect of temperature alone on the properties of a body is shown by the experiments with magnesia cited in the following table, where T denotes the temperature of ignition, D_o the density of the ignited oxide, α its expansion-coefficient for 1° between 0° and 100°; Q₁ the heat of solution of 1 eq. magnesia in dilute sulphuric acid; D_h the density of the hydrate reproduced by moistening the calcined magnesia with water; Q₂ the heat of solution, in gram-degrees, of 1 eq. of this hydrate:—

T	D _o	α	Q ₁	D _h	Q ₂
350°	3.1932	0.0003104	16,655	2.3261	14,244
440°	3.2014	0.0002402	18,417	2.3631	14,431
Dull red heat	3.2482	0.0001764	19,234	2.6040	18,340
Bright red heat	3.5699	0.0001634	20,094		

These numbers show that after strong ignition, the rate of expansion diminishes while the density and the development of heat attending combination with sulphuric acid increase. This last result is contradictory to the generally received opinion that the quantity of heat in a body diminishes as its density increases.

Ditte (*Compt. rend.* lxxiii. 272) has also determined the heat of combination of cadmium oxide in two modifications with dilute sulphuric acid (382.5 grams in a litre).

	For 1 gram	For 1 eq.
Black crystallised oxide (obtained by igniting the nitrate)	229.6	14,238
Orange-coloured amorphous oxide (obtained by igniting the carbonate or by combustion of the metal)	234.1	14,513

* To find the quantities of heat evolved in the combustion of an atom of each of these metals, the number for indium must be multiplied by 3, those for the other metals by 2.

Marignac (*Archives des Sciences* [2], xliii. 209) has also determined the heat of solution of magnesia and zinc oxide, after calcination, at different temperatures, in dilute sulphuric acid, and has arrived at conclusions different from those of Ditte. The acid diluted with 25 eq. water and having a sp. gr. of 0.8637 was contained in a cylindrical metallic vessel whose heat-capacity was equivalent to 6 grams of water; this vessel was suspended within an iron cylinder surrounded by water at the temperature of the room. After the temperature of the acid had become constant, a weighed quantity of the oxide was introduced. A thermometer divided into $\frac{1}{10}$ of a degree was used as a stirrer and indicated the rise of temperature, which was in all cases read off four minutes after the introduction of the oxide. The dissolution of the oxides, which were finely divided and added in small quantities (not exceeding 1.2 gram), was complete in two or three minutes. Taking account of the circumstance that magnesium nitrate and magnesium hydrate cannot be completely freed by heating from nitric acid and water respectively, the means of several experiments give the following relative values:—

				Gram-degrees
1 gram of Magnesia heated to 440				874
"	"	"	dull redness	875
"	"	"	bright redness	867
"	Zinc oxide	"	350°	261
"	"	"	dull redness	266
"	"	"	bright redness	264

From the first three values, Marignac does not think himself justified in concluding that the heat of solution of magnesia is diminished by previous strong ignition, since the differences fall within the limits of probable experimental error; but he regards them as showing at least that no increase takes place. The three values for zinc oxide likewise do not exhibit any appreciable alteration in the heat of solution, the somewhat smaller number obtained at 350° being probably due to a residue of 0.5 pc. of water. As the most probable absolute values of the heat of solution of 1 gram of the oxides in dilute sulphuric acid, Marignac gives for magnesia 905, and for zinc oxide 275 gram-degrees. He is of opinion that Ditte's observations are affected by an error arising from the calorimetric method employed.

Thermal Effects of the Combination of Alcohols with Bases.—Borthelot (*Compt. rend.* lxxiii. 663) has examined the thermal effects of the combination of bases with alcohols, phenols, and aldehydes, and with some compounds which, like silicic acid, have a character intermediate between acids and alcohols, with the view of throwing some light upon the chemical character of these bodies. The calorimeters used were of platinum, holding about 600 cubic centimeters up to 1 litre and 2.25 litres of liquid; these were placed within a vessel having several concentric walls, some of which were lined with silver-plate, the rest with tin-plate. The external compartment, which was very large, was filled with water several days before the experiment. The thermometers used indicated differences of temperature within $\frac{1}{100}$ of a degree. When the liquids operated upon contained half an equivalent, which was most frequently the case, they were called normal solutions, but sometimes they contained only one-quarter of an equivalent in 1 litre.

Ethyl Alcohol.—It is well known that the alcoholates of barium, potassium, sodium, are decomposed, gradually at least, by water; and that the presence of an excess of water does not permit their existence is shown by mixing a solution of alcohol (32 grams in 1 litre) with a solution of potash (20.2 grams of K_2O in 1 litre). The rise of temperature observed was .005°, which is so small that it falls within the errors of experiment, and may be neglected. Also, if the water be added after the mixing of the alcohol and the potash (160H²O for C²H⁵O), the formation of the alcoholate is completely stopped, whilst with this degree of dilution the polyatomic alcohols still manifest their affinity for the alkalis.

Glycerin.—The thermal reaction taking place when the normal solutions are mixed is expressed as follows:—

The dilution of the resulting mixture with five times its volume of water produces an absorption of 363 heat-units. The heat evolved on mixing being nearly equal to that absorbed on diluting, it may be concluded that the compound formed in the first reaction is destroyed by the addition of so much water.

Further experiments showed that more heat is evolved on adding more glycerin, as well as on adding more soda to a solution of glycerin containing 100 grams in a litre.

These experiments lead to the following general conclusions:—

1. The reaction of glycerin upon the alkalis produces heat, not excooling, in the case of the normal solutions, the $\frac{1}{30}$ th part of the heat evolved by the combination of an acid with a base.

2. The heat increases with the number of equivalents of glycerin added to 1 equivalent of sodium hydrate, and *vice versa*, without being proportional to the quantities added, either of the one or the other compound.

3. The heat diminishes as the dilution becomes greater, and none at all is evolved in the presence of 1200 H²O. In short the compound formed in a concentrated solution is decomposed, with absorption of heat, on the addition of a sufficient quantity of water.

These phenomena, particularly the continual division of the base between the alcohol on the one and the water on the other side, may be considered as characterising in general, and almost numerically, the combination of bases with alcohols; they differ from the phenomena attending the combination of bases with true acids, inasmuch as the neutral salts of the latter are formed in fixed proportions, and are not destroyed by the addition of any amount of water.

Mannite.—The thermic reaction observed on mixing the normal solutions was—

The heat, although much more considerable than in the case of glycerin, is still only the $\frac{1}{10}$ th part of the heat of combination of the true acids.

On adding the soda successively, the following results were obtained:—

which value agrees with the first determination.

Total .. + 1,209

The evolution of heat does not, therefore, increase proportionately to the weight of sodium hydrate added.

The absorption of 1,430 heat-units observed on diluting the solution obtained in this experiment, proved the decomposition of the compound formed in the concentrated liquid.

The reaction $(C^6H^{14}O^8 + Aq) + \left(\frac{K^2O}{2} + Aq\right)$ produced 1,145 h. u., that is to say, almost the same as when sodium hydrate is taken.

Lime in its reaction with mannite was found to be thermically equivalent to potash or soda.

In general, whether an alcohol combines with an acid to form an ether, or with a base to form an alcoholate, it appears that the amount of combination taking place always depends upon the quantity of water present, which itself exhibits a strong tendency to combine with the acid or base.

Although in the reactions of etherification, equilibrium is obtained after a considerable time only, while the formation and decomposition of the alcoholates in the presence of water seems to be instantaneous, it appears, notwithstanding this difference, that the combination of alcohols with acids, as well as with bases, obeys laws of chemical statics which, though less general but more simple, predominate in the formation of neutral salts.

Gum.—300 c. c. of a solution of 1 part of gum in 100 parts of water were mixed with 134 c. c. of a solution of soda (24.6 per litre).

The heat evolved was	+ 132 units
The addition of 137 c. c. of soda-solution produced	+ 29 „
Finally, the addition of other 39 c. c. produced	+ 6 „
	+ 167 „

The heat absorbed on adding 5 volumes of water to the mixture was -174 units, which, differing very little from the heat of combination, indicates an almost complete decomposition of the compound at first formed.

Phenol.—100 parts of water dissolve 1 part and more of crystallised phenol, 2,075 heat-units being absorbed during the solution of every 94 grams (the molecular weight) of phenol. When a solution of this strength acts upon an equivalent solution of soda occupying a ten times smaller volume, the following reactions are observed:—

These numbers show, 1st, that only *one* phenate of sodium is formed; 2nd, that the evolution of heat is independent of the quantity of water present; and that, for these reasons, phenol, in accordance with other properties already known, seems to act towards the alkalis like one of the true acids, from which it differs by having only half as great a heat of combination.

It was found that—

On adding the potash in successive portions, the heat increased proportionately to the quantity of base added.

With *ammonia* phenol exhibits peculiar thermic phenomena:—

These numbers show that the heat evolved on adding ammonia in successive portions to phenol is not proportional to the quantity added, being greater for the earlier than for the later portions. This result is attributed by Berthelot to the partial decomposition of ammonium phenate by water.

Baryta and lime gave the following results:—

No more heat is produced by an excess of base.

The following reactions show that the heat evolved is in proportion to the weight of base added:—

The phenates of the alkali-metals yield their total heat of combination at the moment of their formation.

The fact that the amount of heat evolved by the combination of the hydrates of potassium, sodium, barium, and calcium with phenol is very nearly the same, and that it is scarcely influenced by the greater or smaller quantity of water present, strengthens the conclusion arrived at before, as to the close relationship of phenol to the true acids.

Trinitrophenol, or *Picric Acid*.—That picric acid possesses the character of a true acid is shown from the following results:—

The addition of a second equivalent of soda produces no more heat. The behaviour of ammonia, on being added by successive thirds, is illustrated by the following table:—

The 1st third of an equivalent of ammonia added evolved	4,240 heat-units
" 2nd " " "	4,200 "
" 3rd " " "	4,270 "
" 4th " " "	— "
	<hr/>
	12,710 "

It appears, then, that neither an acid nor a basic ammonium salt can have been formed.

The heat absorbed during the solution of picric acid was found = 7,000 units.

Aldehyde.—The solution of 1 mol. of aldehyde in water produces 3,620 heat-units, three-fourths of which are evolved almost instantaneously, whilst several minutes are required for the liberation of the remaining fourth. This large evolution of heat seems to indicate the formation of a definite compound, with a constitution perhaps resembling that of the hydrate of chloral.

On mixing equivalent solutions of aldehyde and of sodium hydrate, it was found that

which is about one-third part of the heat of combination of the true acids.

Here, also, a little more than half of the heat is given off at once, whilst the second half requires four or five minutes. Dilution of the mixture obtained with five times its volume of water causes an absorption of 1,510 heat-units, indicating a decomposition, at least partial, of the compound at first formed. It appears, therefore, that aldehyde partakes of the character of an acid as well as of a base; the combination with water, however, and the evolution of the heat of combination in successive unequal quantities, are phenomena peculiar to aldehyde.

Alcoholic acids.—1. *Salicylic.* The first of these compounds behaves as a monobasic acid and as an acid alcohol at the same time. The heat evolved on mixing a solution of salicylic acid with a solution of sodium hydrate is 14,600 units, which number agrees with its first character.

When a second equivalent of soda-solution is added, the liquid becomes too dilute for the exhibition of any sensible increase of heat.

On addition of a second equivalent of soda evolves . . . 2,000 "

Then, on dilution with a five-fold volume of water . . . -2,050 "

whence it appears that the bibasic salicylate is decomposed by a large quantity of water, whereas the monobasic salt is independent of the quantity of water present.

2. *Lactic acid*, $C^3H^5O^3$.—1 equivalent (= 90 grams) was dissolved in 2 litres of water and half an equivalent of soda in 1 litre of water:—

In another experiment . . . 13,440 "

On further addition of 1 eq. soda . . . 210 "

Then, on dilution with 5 vol. water . . . 70 "

3. *Tartaric acid*, $C^4H^4O^6$.—

On dilution with an equal volume of water . . . -35 "

Therefore, in the union of the neutral tartrate with soda . . . +30 "

It appears, then, that the alcoholic acids exhibit their double function by the quantities of heat developed in their combination with bases. Their acid character shows itself in all cases by the evolution of a quantity of heat proportional to the quantity

II. Reciprocal Transformations of the Nitrogen Oxides.

		Heat-units
Monoxide	$\text{N}^2\text{O} = \text{N}^2 + \text{O}$	+ 18,000 (heat or electric spark).
	$2\text{N}^2\text{O} = \text{N}^2 + \text{N}^2\text{O}^2$	- 51,800 (imaginary reaction).
	$4\text{N}^2\text{O} = 3\text{N}^2 + \text{N}^2\text{O}^4$	+ 11,400 (spark).
Dioxide	$\text{N}^2\text{O}^2 = \text{N}^2 + \text{O}^2$	+ 88,800; then + $\text{N}^2\text{O}^2 = \text{N}^2\text{O}^4$, or
	$2\text{N}^2\text{O}^2 = \text{N}^2 + \text{N}^2\text{O}^4$	125,000 (heat or spark).
	$\text{N}^2\text{O}^2 = \text{N}^2\text{O} + \text{O}^2$	68,800; then + $\text{N}^2\text{O}^2 = \text{N}^2\text{O}^3$, or
	$2\text{N}^2\text{O}^2 = \text{N}^2\text{O} + \text{N}^2\text{O}^3$	91,000 (heat or spark).
Trioxide	$\text{N}^2\text{O}^3 = \text{N}^2\text{O}^2 + \text{O}$	- 22,000; then + $\text{N}^2\text{O}^3 = \text{N}^2\text{O}^4$, or
	$2\text{N}^2\text{O}^3 = \text{N}^2\text{O}^2 + \text{N}^2\text{O}^4$	- 5,800

The trioxide dissolves in water without appreciable decomposition when the quantity of water is large and the temperature low; but with insufficient water or an elevated temperature, a double dissociation appears to take place, part of the hydrate being decomposed into water and anhydride, and a portion of the latter into dioxide and oxygen. The oxygen converts a further portion of nitrous acid into nitric acid, and the dioxide is evolved until, by the destruction of the nitrous acid, the solution has become so dilute that the tension of dissociation is balanced by the dioxide which remains dissolved.

Tetroxide	$\text{N}^2\text{O}^4 = \text{N}^2 + \text{O}^4$	+ 48,600 (spark).
	$\text{N}^2\text{O}^4 = \text{N}^2\text{O}^3 + \text{O}$	- 16,200; then + $\text{N}^2\text{O}^4 = \text{N}^2\text{O}^5$, or
	$2\text{N}^2\text{O}^4 = \text{N}^2\text{O}^3 + \text{N}^2\text{O}^5$ (gas)	- 12,800.

The last reaction is, however, imaginary. It is noticeable that the parallel reaction of the dioxide is real, and disengages heat; that of the trioxide, which absorbs a small amount of heat, leads to a dissociated system, and that of the tetroxide, which theoretically absorbs a larger quantity of heat, cannot be effected.

Pentoxide.— N^2O^5 (gas) = $\text{N}^2\text{O}^4 + \text{O}$ 3,400 heat-units.

The inverse reaction does not appear actually to take place. In the case where both N^2O^3 and N^2O^4 are liquid, this reaction would produce no thermic effect whatever.

The different modes of action between nitrogen tetroxide and water may be well illustrated by filling two tubes of different diameters with the vapours of the dry tetroxide, leaving rather more of the liquid in the narrow tube than in the wide one. After cooling, the tubes are opened under water, when the wide one fills entirely, owing to the reaction, $\text{N}^2\text{O}^4 + n\text{H}^2\text{O} = \text{NO}^2\text{H}$ (dilute) + NO^2H (dilute) (which disengages 13,600 heat-units for $\text{N}^2\text{O}^4 = 92$ grams). In the narrow tube, the vapours (and especially the liquid tetroxide), coming in contact with a smaller quantity of water at once, decompose thus:

The tube remains partly filled with the dioxide.

III. Action of Metals on Nitric and Nitrous Acids.

$\text{N}^2\text{O}^3\text{H}^2\text{O}$ (dilute)	= N^2O^4 (gas)	+ $\text{H}^2\text{O} + \text{O}$ (combined)	disengages	- 33,200 + Q*
"	= N^2O^4 (gas)	+ $\text{H}^2\text{O} + 2\text{O}$	"	- 49,400 + 2Q
"	= N^2O^3 (dissolved)	+ $\text{H}^2\text{O} + 2\text{O}$	"	- 36,400 + 2Q
"	= N^2O^3	+ $\text{H}^2\text{O} + 3\text{O}$	"	- 71,400 + 3Q
"	= N^2O	+ $\text{H}^2\text{O} + 4\text{O}$	"	+ 2,600 + 4Q
"	= N^2	+ $\text{H}^2\text{O} + 5\text{O}$	"	- 15,400 + 5Q
N^2O^2 dilute	= $\text{N}^2\text{O}^2 + \text{O}$ (combined)	disengages		- 35,000 + Q
"	= $\text{N}^2 + 3\text{O}$	"	"	- 51,800 + 3Q

The value -41,400 obtained by Favre for the reduction of N^2O^3 to N^2O^2 has been hitherto accepted. The presence of 9 p.c. of N^2O or 6 p.c. of free nitrogen in the gas evolved by the action of copper on nitric acid would account for the discrepancy.

IV. *Formation of Ammonia from Nitric Acid.*—If nitric acid be reduced to ammonia, by the nascent hydrogen evolved by a metal from dilute sulphuric or hydrochloric acid, the reaction NO^2H (dilute) + $3\text{H} = \text{NH}^3$ (dilute) + $3\text{H}^2\text{O}$ evolves + 21,500. With nitrous acid the reaction is:

Q is the quantity of heat produced by the union of 16 grams of oxygen with the metal employed.

The Heat-phenomena accompanying the transformation of Nitrogen Tetroxide into Nitric Acid, and the introduction of these two bodies into Organic Compounds have also been determined by Troost & Hautefeuille (*Compt. rend.* lxxiii. 378), with results agreeing nearly with those of Berthelot.—The heat evolved in the combination of 1 eq. liquid nitrogen tetroxide with oxygen gas to form nitric anhydride, N^2O^5 , was found to be 23,500 units, the experiment being so made that the nitric anhydride was dissolved in 100 parts of water. The reduction of nitric anhydride by hydrogen, with formation of nitrogen tetroxide and water, yields therefore $34,460 - 23,500 = 10,960$ units for 1 equivalent. The reduction of nitric acid to nitrogen tetroxide disengages more heat the greater the concentration; thus acid of the maximum density gives 17,500 heat-units; acid of sp. gr. 1.48 gives 17,100; acid of sp. gr. 1.46 gives 16,900; and acid of sp. gr. 1.43 gives 15,300.

The heat disengaged in the reduction of nitric acid (whatever be its state of concentration) in substitution is always much smaller than the total heat observed in the combustion of the substitution-compounds. The following table gives the principal results. The second column of figures shows the heat disengaged by the reduction of the nitric acid employed, as determined in each case:

Products of substitution	Heat disengaged by an equivalent of the organic body	Heat disengaged in the reduction of the nitric acid	Heat lost in the combination
Nitrobenzene . . .	38,400	16,900	21,500
Dinitrobenzene . . .	76,800	34,400	42,400
Nitrotoluene . . .	38,000	16,900	21,100
Dinitrotoluene . . .	76,000	34,400	41,600
Nitronaphthalene . .	36,500	15,200	21,300
Dinitronaphthalene . .	73,000	32,300	40,100

In the production of nitric ethers the amount of heat disengaged is not so great as with the substitution-compounds. This appears from the following table:—

Nitric ethers	Heat disengaged by an equivalent	Heat disengaged by an equivalent of the nitric acid used
Nitroglycerin	19,000	6,330
Gun-cotton	52,000	10,400
Nitromannite	24,500	4,080

These results confirm Berthelot's conclusion, that, for a given quantity of nitrogen entering into combination, the available mechanical work is greater in the nitric ethers than in the nitro-substitution-products.

Thermochemical Researches on the Ammonia Salts (Berthelot, *Compt. rend.* lxxiii. 745, 864, 957, 1003, 1050).—These researches are divided into three parts, relating: 1. To the formation of ammonium salts of strong acids, such as hydrochloric, nitric, and sulphuric acid. 2. To that of the salts of weak acids, as carbonic, boric, hydrocyanic, phenic, and sulphydric acid. 3. To the reciprocal actions between various ammonium salts and the corresponding salts of the alkali-metals.

Part 1. Ammonium Salts formed by Strong Acids.

The following values relate to liquids containing $\frac{1}{2}$ eq. in a litre, so that their mixture in equal volumes yields a liquid containing $\frac{1}{2}$ eq. of neutral salt in the litre ($1 : 210 H^2O$).

HCl + NH^3	12,630	12,270	mean 12,450	heat-units
HNO^3 + NH^3	12,630	12,620	"	12,570 "
$\frac{1}{2}H^2SO^4$ + NH^3	14,760	14,320	"	14,530 "

These numbers are not sensibly altered by the addition of an excess of water, or acid or ammonia.

These values were determined, in the first place, by the reciprocal action of acids and salts. The difference $K_1 - K$ of the quantities of heat evolved in the two reactions (e.g. decomposition of ammonium chloride by sulphuric acid and of ammonium sul-

phate by hydrochloric acid) is equal to the difference of the heats of neutralisation of ammonia by sulphuric and hydrochloric acid: $K_1 - K = N - N_1$;

Taomsen found 320 and 148.

Another mode of determination is found in the *reciprocal action of bases or salts*. The difference $K_1 - K$ of the two quantities of heat thus evolved is likewise equal to the two heats of neutralisation $N - N_1$:

These calculations of $N - N_1$ depend upon the knowledge of the developments of heat attending upon the action of other bases on the same acids.

	Berthelot	Thomsen
$\frac{1}{2}\text{H}_2\text{SO}_4 + \frac{1}{2}\text{K}_2\text{O}$	15,710	15,645
$\text{HCl} + \frac{1}{2}\text{K}_2\text{O}$	13,590	13,750
$\text{HNO}_3 + \frac{1}{2}\text{K}_2\text{O}$	13,830	13,770
$\frac{1}{2}\text{H}_2\text{SO}_4 + \frac{1}{2}\text{Na}_2\text{O}$	15,870	15,690
$\text{HCl} + \frac{1}{2}\text{Na}_2\text{O}$	13,690	13,740
$\text{HNO}_3 + \frac{1}{2}\text{Na}_2\text{O}$	13,720	13,680
$\frac{1}{2}\text{H}_2\text{SO}_4 + \frac{1}{2}\text{CaO}$	16,020	15,570
$\text{HCl} + \frac{1}{2}\text{CaO}$ (dissolved)	13,850	13,950
$\frac{1}{2}\text{H}_2\text{SO}_4 + \frac{1}{2}\text{BaO}$	18,400	18,450

A third mode of determination adopted by Berthelot consists in causing four salts, formed by two bases and two acids, to act on one another in pairs (*the reciprocal action of salts*). The difference of the two thermal effects $K_1 - K$ is said to be equal to the excess obtained by subtracting the difference of the heat of neutralisation of the two acids by the one base from the same difference for the other base:

$$K_1 - K = (N - N_1) - (N' - N'_1)$$

But the examples adduced do not afford very satisfactory evidence in favour of this conclusion; it is difficult to see, for example, in what sense 146 can be said to be equal to 80.

Part 2. Ammonium Salts formed by Weak Acids

Boric Acid.

	Heat-units
B_2O_3 (1 eq. cryst. acid, i.e. 70 grams of boric anhydride in 4 litres of liquid) + NH_3 (1 eq. in 2 litres)	8,980
+ NH_3 (second eq.)	2,620
+ NH_3 (third eq.)	1,050
	12,650
H_3BO_3 (samoliquid) + NH_3 (1 eq. in 4 lit.)	5,440
$\text{B}_2\text{O}_3 \cdot \frac{1}{2}(\text{NH}_4)_2\text{O}$ (1 eq. in 4 lit.) + 1 vol. water	2,800
+ 5 "	2,170

	Heat-units
B^2O^3 (1 eq. in 4 lit.) + $\frac{1}{2}\text{Na}^2\text{O}$ (1 eq. in 2 lit.)	11,560
+ $\frac{1}{2}\text{Na}^2\text{O}$ (second eq.)	8,260
+ $\frac{1}{2}\text{Na}^2\text{O}$ (third eq.)	170
B^2O^3 (same liquid) + $\frac{1}{2}\text{Na}^2\text{O}$ (1 eq. in 4 lit.)	11,130
$\text{B}^2\text{O}^3 \cdot \frac{1}{2}\text{Na}^2\text{O}$ (1 eq. in 4 lit.) + 1 vol. water	560
+ 5 "	780
Disodic Borate (the above liq.) + 5 "	145
Trisodic Borate " + 5 "	166

Here then there is a progressive decomposition of the ammonium borate by water, deeper and more rapid than that of the sodium borate.

Carbonic Acid.

$$(\frac{1}{2}\text{CO}^2 + \text{Aq}) + (\text{NH}^3 + \text{Aq}) \dots 5,350 \text{ heat-units.}$$

This value relates to a solution of 1.250 grm. carbonic anhydride in the litre or 1 eq. of salt produced in 20 litres.

Moreover, the solution of ammonium bicarbonate in 50 pts. water gave -6,280 heat-units for 1 eq. A solution of 79 gms. in 2 litres gave, on dilution with 9 vol. water -600 heat-units for 1 eq. The decomposition of this salt (1 eq. in 20 lit.) by hydrochloric acid gave 3,320 units; and since dissolved carbonic acid has no appreciable action on a solution of sal-ammonium, we have

$$(\text{CO}^2 + \text{Aq}) + (\text{NH}^3 + \text{Aq}) = 12,450 - 3,320 = 9,130 \text{ for 20 lit. of liquid,}$$

$$\text{or } 9,130 + 600 = 9,730 \text{ " } 2 \text{ "}$$

Indirect determinations:—

$$(\frac{1}{2}\text{CO}^2 + \text{Aq}) + (\frac{1}{2}\text{K}^2\text{O} + \text{Aq}) \text{ 10,100 heat-units}$$

$$\frac{1}{2}\text{CO}^2 + \text{Aq} + (\frac{1}{2}\text{Na}^2\text{O} + \text{Aq}) \text{ 10,200 "}$$

For the formation of the bicarbonates of sodium and potassium Berthelot assumes the values 1,110 and 1,100; greater dilution produced scarcely any alteration in the amount of heat evolved.

(1.) Neutral Carbonate, $\frac{\text{Am}^2\text{CO}^2}{2}$.

			K ₁ - K	N (calc.)
$\frac{1}{2}\text{Am}^2\text{CO}^2$ (1 eq. in 4 lit.)	+ KNO^3 (1 eq. in 4 lit.)	- 120	}	+ 3,110 5,730
$\frac{1}{2}\text{K}^2\text{CO}^2$ "	+ AmNO^3 "	- 3,220		
$\frac{1}{2}\text{Am}^2\text{CO}^2$ "	+ NaCl "	- 20	}	+ 3,040 6,000
$\frac{1}{2}\text{Na}^2\text{CO}^2$ "	+ AmCl "	- 3,060		
$\frac{1}{2}\text{Am}^2\text{CO}^2$ "	+ $\frac{1}{2}\text{K}^2\text{SO}^4$ "	- 100	}	+ 3,080 5,830
$\frac{1}{2}\text{K}^2\text{CO}^2$ "	+ $\frac{1}{2}\text{Am}^2\text{SO}^4$ "	- 3,180		

These values agree nearly enough with the above value, 7,170, for liquid of half this degree of dilution. They were obtained at 22°. N appears to increase slightly with decreasing temperature. The value 6,700 was actually found by the combination of—

$$\frac{1}{2}\text{Am}^2\text{CO}^2 + \frac{1}{2}\text{K}^2\text{O} = 3,400 \text{ and } \frac{1}{2}\text{K}^2\text{CO}^2 + \text{NH}^3 = 0.$$

(2.) Ammonium Bicarbonate, AmHCO^3 .

			K ₁ - K	N (calc.)
AmHCO^3 (1 eq. in 4 lit.)	+ KNO^3 (1 eq. in 4 lit.)	- 40	}	+ 40 0,720
KHCO^3 "	+ AmNO^3 "	- 80		
AmHCO^3 "	+ NaCl "	0	}	+ 260 0,620
NaHCO^3 "	+ AmCl "	- 260		
AmHCO^3 "	+ $\frac{1}{2}\text{K}^2\text{SO}^4$ "	+ 20	}	+ 140 0,700
KHCO^3 "	+ $\frac{1}{2}\text{Am}^2\text{SO}^4$ "	- 120		
AmHCO^3 "	+ $\frac{1}{2}\text{K}^2\text{O}$ "	+ 4,940	}	+ 1,170 0,636
KHCO^3 "	+ NH^3 "	+ 3,770		

These values agree with that previously found, namely 9,730.

Dissolved carbonic acid evolved no sensible heat in its action on solutions of ammonium bicarbonate. In presence of water, on the other hand, the action of ammonia on carbonic acid increases with its quantity, as in the case of boric acid and of phenol. The heat evolved in the action of 1 eq. carbonic acid on varying quantities of ammonia varied from 5,300 to 7,400 units, becoming greater as the concentration increased.

The neutral carbonates of potassium and sodium may be mixed together or with other neutral fixed alkali-salts without perceptible evolution or absorption of heat. The bicarbonates of potassium and sodium exhibit the same behaviour. So likewise

does ammonium bicarbonate; it is but slightly decomposable by water or by stable neutral salts, as potassium nitrate, sodium sulphate, sodium chloride, or ammonium chloride; neither does it act on bicarbonate of potassium.

With neutral ammonium carbonate the case is different:

					Heat-units
$\frac{\text{Am}^2\text{CO}^3}{2}$	(1 eq. in 4. lit.)	+	$\frac{\text{K}^2\text{CO}^3}{2}$	(1 eq. in 2 lit.)	- 360
"	"	+	1	"	- 1,290
"	"	+	1 $\frac{1}{2}$	"	- 1,540
"	"	+	2	"	- 1,660
KHCO^3	(1 eq. in 4 lit.)	+	$\frac{\text{Am}^2\text{CO}^3}{2}$	(1 eq. in 2 lit.)	+ 560
"	"	+	1	"	+ 800
"	"	+	1 $\frac{1}{2}$	"	+ 980
"	"	+	2	"	+ 1,106

On the other hand, ammonium bicarbonate is decomposed by potassium carbonate and sodium carbonate with absorption of heat:

KHCO^3	(1 eq. in 4 lit.)	+	$\frac{1}{2} \text{K}^2\text{CO}^3$	(1 eq. in 2 lit.)	- 940
"	"	+	1	"	- 1,170
"	"	+	1 $\frac{1}{2}$	"	- 2,290
"	"	+	2	"	- 2,690

Ammonium bicarbonate is attacked even by the neutral carbonate—

AmH	(1 eq. in 2 lit.)	+	$\frac{1}{2} \text{Am}^2\text{CO}^3$	(1 eq. in 2 lit.)	+ 620
--------------	-------------------	---	--------------------------------------	-------------------	-------

a result which would be inexplicable if the two carbonates could really mix without alteration.

Lastly, the solution of potassium carbonate is not attacked by ammonia, whilst the solution of neutral ammonium carbonate progressively absorbs heat as ammonia is gradually added to it.

From the preceding observations Berthelot infers that weak acids are characterised by imperfect combination, and by a division of the base of a salt between the acid and the water. The vague notions hitherto entertained respecting the distinction between strong and weak acids and bases may thus be reduced to greater precision. A *strong acid* and a *strong base*, form, by their union, neutral stable salts which are not perceptibly decomposed by water, and are not modified by excess of base; to this class of salts belong the sulphates, chlorides, and nitrates of potassium and sodium. On the other hand, a *weak acid* forms with all strong bases, and especially with ammonia, neutral salts which are partially decomposed by water. Moreover, the energy of weak acids exhibits different degrees, recognisable by the heat-phenomena produced by the action of water on their salts, and by the progressive action of several equivalents of ammonia. These differences of energy are strikingly displayed in the following double decompositions of salts:—

Part 3. Reciprocal Action of the Ammonia Salts and the Salts of the Fixed Alkalis.

1. *Both Salts formed by Strong Acids* (1 equivalent of each salt previously dissolved in such a manner that the volume of the liquid shall be 2 litres):

$\frac{1}{2} \text{Am}^2\text{SO}^4$	+	KNO^3	- 100
$\frac{1}{2} \text{K}^2\text{SO}^4$	+	AmNO^3	40
$\frac{1}{2} \text{Am}^2\text{SO}^4$	+	KCl	0
$\frac{1}{2} \text{K}^2\text{SO}^4$	+	AmCl	- 20
$\frac{1}{2} \text{AmNO}^3$	+	KCl	+ 110
$\frac{1}{2} \text{KNO}^3$	+	AmCl	- 110
$\text{C}^2\text{H}^3\text{AmO}^2$	+	NaCl	+ 120
$\text{C}^2\text{H}^3\text{NaO}^2$	+	AmCl	- 20

The heat-phenomena developed on diluting the same saline solutions with an equal volume of water at the same temperature are as follow:—

$\frac{1}{2} \text{K}^2\text{SO}^4 + \text{Aq}$	- 70	$\frac{1}{2} \text{Na}^2\text{SO}^4 + \text{Aq}$	- 70	$\frac{1}{2} \text{Am}^2\text{SO}^4 + \text{Aq}$	+ 20
$\text{KCl} + \text{Aq}$	+ 90	$\text{NaCl} + \text{Aq}$	- 20	$\text{AmCl} + \text{Aq}$	+ 10
$\text{KNO}^3 + \text{Aq}$	- 160	$\text{NaNO}^3 + \text{Aq}$	- 110	$\text{AmNO}^3 + \text{Aq}$	- 100

From this it appears that the mixing of two neutral stable salts is always attended with slight evolution or absorption of heat, which, however, is not the case of the

actions of water on the two solutions in the separate state. Hence Berthelot concludes that the thermoneutrality of salts asserted by Hesso (*Ann. Chim. Phys.* 1842 [3], iv. 222) does not exist. The true law of the mutual action of salts is represented, according to Berthelot, by the equation (p. 628):

$$K_1 - K = (N - N_1) - (N' - N'_1).$$

2. One Salt formed by a Strong, the other by a Weak Acid.

a. Neutral Carbonates.

	Heat-units
$\frac{1}{2}K^2CO^3 + AmNO^3$	-3,220
$\frac{1}{2}Am^2CO^3 + KNO^3$	-120
$\frac{1}{2}K^2CO^3 + \frac{1}{2}Am^2SO^4$	-3,180
$\frac{1}{2}Am^2CO^3 + \frac{1}{2}K^2SO^4$	-100
$\frac{1}{2}Na^2CO^3 + AmCl$	-3,060
$\frac{1}{2}Am^2CO^3 + NaCl$	-20

These numbers show that stable ammonia salts, in presence of water, are almost completely decomposed by the carbonates of potassium and sodium, with formation of the still more stable nitrates, chlorides, and sulphates of the potassium and sodium, and of the least stable carbonate of ammonium. The latter being immediately decomposed in presence of water gives rise to the observed thermic effect, corresponding with a complete or at least a considerable action.

b. The bicarbonates of potassium, sodium, and ammonium, being stable in water, exhibit but feeble thermal effects in their reaction with neutral stable alkali-salts, inasmuch as the latter also do not give rise to any salt decomposable by water with absorption of heat.

c. Phenates (1 eq. in 11.5 litres).

$C^2H^3NaO + AmCl$	-4,100 heat-units
$C^2H^3AmO + NaCl$	+100 "
$C^2H^3NaO + \frac{1}{2}Am^2SO^4$	-4,300 "

Hence it appears that sodium phenate in presence of stable ammonia salts is completely or almost completely decomposed into sodium chloride, sulphate, &c., and ammonium phenate.

d. Borates (1 eq. in 11.5 litres).

$\frac{Na^2O}{2} B^2O^3 + AmCl$	-2,250	$\frac{Na^2O}{2} B^2O^3 + \frac{1}{2}Am^2SO^4$	-2,250
$\frac{Am^2O}{2} B^2O^3 + NaCl$	-480	$\frac{Am^2O}{2} B^2O^3 + \frac{1}{2}Na^2SO^4$	-460

The chief product of these reactions is ammonium borate. The borates of sodium and ammonium appear, however, to act upon one another:

$$\frac{Na^2O}{2} B^2O^3 + \frac{Am^2O}{2} B^2O^3 \quad . \quad . \quad . \quad -200;$$

while, on dilution with an equal volume of water, sodium borate alone gives -560, and ammonium borate -1,000 heat-units.

e. Cyanides.

KCy (1 eq. in 2 litres) + $AmCl$ (1 eq. in 2 litres)	-600
$AmCy$ + KCl	-40
$KCy + \frac{1}{2}Am^2SO^4$	-590

The entire transformation of potassium cyanide into ammonium cyanide and potassium chloride (or sulphate) would give $1,140 - (2,940 - 1,300) = -500$ heat-units, to which, on account of the dilution, must be added -100, giving the number -600, obtained as above.

According to Thomsen, whose results are confirmed by Berthelot, the sulphides of potassium, sodium, and ammonium, are completely resolved by water into sulphhydrate and free alkali. But the sulphhydrates are stable in presence of water, or if not completely, at least as much so as the bicarbonates:

$$2AmCl + Na^2S \quad . \quad . \quad . \quad +1,260.$$

This quantity of heat answers to the action of 1 eq. free soda on ammonium chloride, both of which come into play in the reaction.

3. Both Salts formed by Weak Acids.

a. Carbonates and Cyanides (each solution containing $\frac{1}{2}$ eq. in the litre).

In the second case the transformation is complete. Potassium hydrate, potassium carbonate, and ammonium cyanide do not act on potassium cyanide; the bicarbonates, on the other hand, produce with the cyanides an evolution of heat, because the excess of acid in the bicarbonate takes up part of the base united with the hydrocyanic acid.

b. Carbonates and Phenates.

In both cases decomposition takes place in consequence of dilution and of the peculiar reaction; the most stable salt, viz. sodium carbonate, is the chief product.

c. Carbonates and Borates.

In the second case the transformation is almost complete; and it probably takes place, to a small extent also in the first, since the first number is smaller than that which answers to the simple dilution of the sodium borate (-560).

In this case ammonium borate and sodium bicarbonate are almost the only products, the latter being the most stable, and not perceptibly decomposable by water. The converse reaction appears, however, to take place to a certain extent, inasmuch as the dilution of ammonium borate absorbs a quantity of heat (-1,000) greater than -490. The latter conclusion is confirmed by the following reaction:

This is exactly the heat of dilution of sodium borate by pure water; there is, therefore, no transformation of any importance.

The foregoing researches on the double decompositions of dissolved salts show that under the conditions of the experiments the most stable compound is formed in largest quantity, and often to the exclusion of all the rest (Berthelot, *Compt. rend.* lxxiii. 1050).

Heat evolved or absorbed in the formation and decomposition of Formic Acid.—Favre & Silberrmann found the heat of combustion of formic acid to amount to 98,000 heat-units per molecule, that is to about as much as that of the carbon contained in it. According to this determination, the production of formic acid from sodium hydrate and carbon monoxide must be attended with an absorption of heat amounting to 21,000 heat-units, instead of a development of heat, as in most other cases. In the formation of formic acid from carbon monoxide and sodium carbonate or bicarbonate, the absorption of heat must amount to 24,500 and 381,000 heat-units respectively. Hence Berthelot infers that formic acid must have a constitution different from that of the other fatty acids, and he seeks to explain the anomaly in several ways. Yet the number given by Favre & Silberrmann rests, according to their own statement, on an imperfect experiment, and its deviation from the theoretical number is regarded by them as due to this circumstance.

Thomsen has therefore made a determination of the heat of combustion of formic acid, based on the fact that potassium formate in dilute aqueous solution is completely oxidised to carbonate by potassium permanganate. He finds that

that is, that 72,912 heat-units are developed in the oxidation of the formate in the above manner (the symbol K stands for KOH).

From this number he calculates the heat of combustion of formic acid, as well as the heat evolved in the formation of the acid from its elements:—

Heat-units		Heat-units
147 =	(CO ² H ² Aq)	
13,200 =	(CO ² HKAq, KAq)	{(CO ² H ² O) = 60,193
72,912 =	(CO ² HKAq, O, KAq)	{(CO ² , 2KAq) = 26,066
86,259		89,259

This calculation gives 60,193 heat-units for the heat developed by the complete oxidation of a molecule of formic acid to water and carbon dioxide, which is about 36,000 less than the amount determined by Favre & Silbermann, and adopted by Berthelot.

In the formation of formic acid from its elements, the development of heat is calculated to amount to 105,124 heat-units:—

(C, H ² , O ²) + (H ² O ² , O) = (C, O ²) + (H ² , O)
105,124 + 60,193 = 96,960 + 68,375
Heat-units Heat-units Heat-units Heat-units

Thomsen further shows that the formation of the acid from carbon monoxide and water would be accompanied by an evolution of 6,607 heat-units; that the formation of sodium formate from carbon monoxide and sodium hydrate is attended with a development of at least 19,954 heat-units; that the formation of the acid from carbon dioxide and hydrogen would likewise be attended with an evolution of heat amounting to 8,164 heat-units; that the heat absorbed in the decomposition of formic acid into carbon monoxide and water by sulphuric acid is compensated by the heat evolved in the union of the sulphuric acid with the water; and that the decomposition at a high temperature of the vapour of formic acid into carbon dioxide and hydrogen, and the rise of temperature which Berthelot has observed to accompany that decomposition, are perfectly normal phenomena. He therefore concludes that formic acid does not present the remarkable anomalies in the heat-phenomena of its formation and decomposition, which Berthelot supposes it to exhibit (*Deut. Chem. Ges. Ber.* v. 957). See further, Berthelot (*Compt. rend.* lxxvi. 1433; *Chem. Soc. J.* 1874, 1099).

Heat evolved in the Combination of Sulphuric Acid and Water.—The quantities of heat evolved in the hydration of sulphuric acid have been determined by different observers, not always with concordant results. The following table exhibits these determinations of the quantities of heat in kilogram-degrees evolved by the mixture of 1 mol. hydrogen sulphate, H²SO⁴, with 1, 2, 3 . . . mol. water; the numbers being reduced, when necessary, to a common unit:—

1 gram H ² SO ⁴	Abria	Hess	Hess	Favre & Silbermann	Thomsen	Favre & Quillard
H ² SO ⁴ with H ² O . .	64.2	63.5	77.7	64.7	65.3	66.4
" 2H ² O . .	94.7	95.3	110.4	94.6	—	99.5
" 3H ² O . .	113.0	—	—	111.9	111.9	118.3
" 4H ² O . .	124.2	—	—	122.2	—	130.1
" 5H ² O . .	131.1	127.1	148.9	130.7	130.3	139.2
" 6H ² O . .	—	—	—	136.2	—	146.9
" 7H ² O . .	—	—	—	141.8	—	152.9
" 8H ² O . .	—	—	—	145.1	—	—
" 9H ² O . .	—	—	—	148.5	—	—
" excess of water . .	—	—	—	148.5	17.6	—

Pfaundler (*Jahresb. f. Chem.* 1869, 122) has measured the quantities of heat evolved by the different hydrates of sulphuric acid when mixed with an excess of water, and has thence calculated the values sought. The hydrate to be examined was enclosed in quantities between 10 and 50 grams in thin narrow-necked glass bulbs, which were weighed before and after filling. One of these bulbs was placed in a small shallow basket suspended in the calorimeter, and moved about in the water—the quantity of which was calculated so as to yield, on mixing, the hydrate SO³ . 120H²O or H²SO⁴ . 116H²O—till the water and acid had attained the same temperature. The thermometer was then read off, and the bulb immediately broken. The acid, on stirring, mixed with the entire liquid in less than a second, and the thermometer rose quickly and soon came to rest, the large quantities of liquid employed and the short duration of the experiment rendering the influence of the surrounding strata of air quite im-

perceptible. From the observed results, the values in the following table were determined:—

Formula	Quantity of heat evolved with an excess of water		Quantities of heat evolved in the formation of several hydrates from 1 gram of monohydrate, H^2SO^4	Quantities of heat evolved on addition of each molecule of water to 1 gram of monohydrate
	Per gram of substance	Per gram of monohydrate, H^2SO^4 , contained in the substance		
$\text{SO}^3 \cdot \text{H}^2\text{O}$	181.16	181.16	0	0
$\text{SO}^3 \cdot 2\text{H}^2\text{O}$	130.66	142.69	38.47	—
$\text{SO}^3 \cdot 3\text{H}^2\text{O}$	94.15	111.44	69.72	69.72
$\text{SO}^3 \cdot 4\text{H}^2\text{O}$	73.06	93.10	87.97	—
$\text{SO}^3 \cdot 5\text{H}^2\text{O}$	56.84	77.72	103.44	33.72
$\text{SO}^3 \cdot 6\text{H}^2\text{O}$	47.05	68.66	112.50	—
$\text{SO}^3 \cdot 7\text{H}^2\text{O}$	40.15	62.31	118.85	15.41
$\text{SO}^3 \cdot 8\text{H}^2\text{O}$	28.50	49.43	131.73	12.88
$\text{SO}^3 \cdot 9\text{H}^2\text{O}$	21.04	40.36	140.80	9.07
$\text{SO}^3 \cdot 10\text{H}^2\text{O}$	15.73	33.07	148.09	7.27
\vdots	\vdots	\vdots	\vdots	\vdots
$\text{SO}^3 \cdot 120\text{H}^2\text{O}$	0	0	181.16	—

The numbers in the last column but one are immediately comparable with those of former observers given in the preceding table. Some of them agree most nearly with those of Favre & Silbermann, others with those of Favre & Quillard.

Heat disengaged in the Reaction between the Haloid Acids and Water, and its relation to the Molecular Volume of the Solutions (Berthelot, *Compt. rend.* lxxvi. 679).

1. *Hydrochloric Acid*.—A molecule of the gas, (36.5 grams) in presence of 100 to 400 times its weight of water disengages 17,480 heat-units (gram-degrees), and when aqueous hydrochloric acid of different degrees of concentration is diluted with water, the heat disengaged varies inversely as the quantity of water already united with the hydracid. The molecular volume of the solution $\text{HCl} + n\text{H}^2\text{O}$ is expressed by the formula:

$$V = 18n + \frac{10}{n}.$$

2. *Hydrobromic Acid*.—The heat evolved in this case by a molecule of the gas is 20,700 heat-units, and the effects of dilution are the same as those produced with hydrochloric acid, except that, at the maximum of concentration, the solutions of hydrobromic acid disengage somewhat more heat, a relation analogous to that obtained with the two gases. The molecular volume of the solution $\text{HBr} + n\text{H}^2\text{O}$ is expressed nearly by the formula:

$$V = 18n + 25.5 + \frac{7}{n}.$$

3. *Hydriodic Acid*.— $\text{HI} + 700 \text{H}^2\text{O}$ disengages 19,570 heat-units, and the heat disengaged on diluting the concentrated solution is nearly the same as that from hydrochloric acid and hydrobromic acid, from which it would appear that the molecular work accomplished in the reaction by these three hydracids on the same number of equivalents of water is the same. The formula representing the molecular volume of the solution $\text{HI} + n\text{H}^2\text{O}$ is

$$V = 18n + 35.5.$$

At 0°C . one volume of water dissolves 500 volumes of hydrochloric acid gas, and at -12° , 560 volumes; of hydrobromic acid at 10° , about 600 volumes; and of hydriodic acid about 425 volumes.

An almost constant difference is observed between the molecular volumes of dilute solutions of hydriodic acid and hydrochloric acid, and also between hydrobromic acid and hydrochloric acid, which in the former case is 17.3 c.c., and in the latter 24 c.c. The same differences are found in dilute solutions of the chlorides, bromides, and iodides of potassium, sodium, and ammonium; also between the solid salts the volume occupied by KI being 17.2 c.c. greater than that of KCl, and KBr 7.3 c.c. greater than KCl. Nearly the same differences in the molecular volumes exist in certain organic compounds, such as the chloride and iodide of acetyl. In numerous cases, however, this does not obtain, as in the comparison of the metallic salts, where the same is found

that the molecular volume of a chloride is less than that of the bromide, and this again less than the corresponding iodide. This agrees with the thermic results obtained in the formation of these compounds, the formation of chlorides disengaging more heat than that of the bromides, which in their turn disengage more than the corresponding iodides. It would seem, moreover, that the formation of compounds which present an almost constant difference between their molecular volumes, corresponds with a nearly constant difference in the amount of heat disengaged.

Thermal Phenomena of Double Decomposition.—*a.* Bertholot and Longuine (*Compt. rend.* lxi. 626) have examined the thermal effects produced in double decompositions which are completed in a short time and at ordinary temperatures, without yielding secondary products. Such reactions are found in the decomposition of the chlorides and anhydrides of acid radicles by water and alkalis. The acid chloride, or dilute acid solution, was introduced into a weighed quantity of water or dilute alkali, contained in a platinum calorimeter, its quantity determined by a final weighing, and verified by alkalimetric determinations. The correction for cooling was always less than $\frac{1}{100}$, and sometimes as little as $\frac{1}{1000}$ of the entire rise of temperature.

Decomposition of Acetyl Chloride by Water.—For 1 eq. = 78.5 grams of acetyl chloride, the mean of three determinations gave 23,300 heat-units. The heat of solution of 1 eq. hydrochloric acid gas is, according to the mean of four experiments, 17,430 heat-units, and that of 1 eq. fused glacial acetic acid about 400 heat-units. Consequently, the heat evolved in the reaction $C^2H^3OCl + H^2O = C^2H^3O^2 + HCl$ is $23,300 - 17,400 - 400 = 5,500$ units, if the several bodies are supposed to be in their ordinary state.

The heat of combination of 1 eq. hydrochloric acid with 1 eq. potash in dilute solutions was found, as the mean of two experiments, in accordance with Favre & Silbermann's determination, to be 15,700 units, which number, taking account of the specific heat of solutions of calcium chloride (p. 600), must be reduced to 14,900. The heat of combination of 1 eq. acetic acid with potash amounted, in the mean of three experiments, to 14,100 units, which, taking account of the specific heat of solutions of potassium acetate, will be reduced to about 13,400.

Decomposition of Acetyl Bromide by Water.—The mean of three determinations gave, for 1 eq. = 123.0 heat-units, the heat of solution of 1 eq. hydrobromic acid gas was found, as the mean of four experiments, to be 21,150. Hence the heat evolved in the reaction $C^2H^3OB^r + H^2O = C^2H^3O^2 + HBr$ is $23,300 - 21,150 - 400 = 1,750$ units, the several bodies being supposed to be in their ordinary state.

Decomposition of Acetyl Iodide by Water.—Three determinations gave, as a mean for 1 eq., 21,400 heat-units. The heat of solution of 1 eq. hydriodic acid was found, as a mean of three experiments, to be 19,570 units. Hence the heat evolved in the reaction $C^2H^3OI + H^2O = C^2H^3O^2 + HI$ is $21,400 - 19,570 - 400 = 1,430$ units.

Decomposition of Butyryl Bromide by Water.—The heat evolved for 1 eq. was 27,000 units. But the experiment lasted nearly an hour, and correction for cooling amounted to nearly $\frac{1}{10}$ th of the total value. The result was therefore checked by the decomposition with dilute potash, which gave 56,100 heat-units. If, from this, we deduct the heat of combination of butyric acid with potash in dilute solutions, which appears, from the mean of two experiments, to be 14,950 units, also the heat of combination of dilute hydrobromic acid with potash, which, according to Favre, is 15,500 units, we find indirectly, for the heat of decomposition of butyryl bromide by water, 25,650 units. The mean of the direct and indirect values is 26,300 units. The heat of solution of 1 eq. butyric acid in water was found to be about 600 units. Hence the heat evolved in the reaction $C^4H^7OBr + H^2O = C^4H^7O^2 + HBr$ is $26,300 - 21,150 - 600 = 4,550$ units, the several bodies being supposed to be in their ordinary state.

Decomposition of Acetic Anhydride by Water.—For 1 eq. = 102 grams the mean of two experiments gave 12,800 heat-units. The duration of the experiment for an hour rendered necessary a correction for cooling amounting to $\frac{1}{10}$ th of the total value. After deduction of heat of solution of acetic acid, the reaction $(C^2H^3O)^2O + H^2O = 2C^2H^3O^2$ gave 12,000 heat-units.

***β.* Thermal Effects accompanying the Dilution of Solutions, and Influence of Water in Double Decompositions.**—Marignac (*N. Arch. Ph. Nat.* xxxvi. 310; *Compt. rend.* lxi. 1180) has examined these phenomena by means of solutions containing 1 gram of substance in the anhydrous state, or (in the case of acids and salts) containing only constitutional water, in 10, 20, 40 . . . c.c.; such solutions are designated as $\frac{1}{10}$, $\frac{1}{20}$, $\frac{1}{40}$. . . solutions. The thermic effect of dilution was determined by mixing each solution with an equal volume of water. The total quantity of the mixed liquid usually amounted to 500–600 c.c. The thermometers used indicated the temperature to $\frac{1}{500}$ th of a degree. The results are as follow:—

1. The addition of water to the solution of a single body produces a positive or negative alteration (rise or fall) of temperature, which, for the most part, does not exceed 0.2° for $\frac{1}{10}$ -solutions, diminishes to $\frac{1}{2}$ for dilution to $\frac{1}{20}$, and to $\frac{1}{8}$ for dilution to $\frac{1}{80}$; and may therefore be neglected below this limit. This rule, however, does not apply to all cases. Thus, in the dilution of sulphuric acid, the rise of temperature increases the more the solutions are diluted, amounting to 92, 135, 185, and 255 heat-units for 1 eq. (= 49), accordingly as the solutions were diluted to $\frac{1}{10}$, $\frac{1}{20}$, $\frac{1}{40}$, or $\frac{1}{80}$.

2. The mixture of the solutions of two salts which do not act on one another, produces in general less alteration of temperature than the simple dilution of these solutions. Development of heat takes place most frequently in cases where the two salts may be supposed not to act on one another, e.g. with two salts of the same base, and absorption of heat when they are capable of forming a double salt. Sometimes, however, the thermic action in these reactions is much more considerable, as in the mixing of sulphates of alkali-metal with sulphuric acid, which is attended with considerable absorption of heat.

3. The dilution of a solution containing two salts which do not act on one another with an equal volume of water, generally produces a very slight thermal effect, which is nearly equal to the sum of the thermal effects produced by diluting the two salts separately, and decreases rapidly as the solutions are more diluted. A remarkable exception to this rule is exhibited by the dilution of the acid sulphates of the alkali-metals, which is attended with a considerable absorption of heat, rapidly increasing with the dilution. In the case of acid sodium sulphate this thermal effect increases for 1 eq. from 58 heat-units for a $\frac{1}{10}$ -solution to 525 units for a $\frac{1}{80}$ -solution. This result affords the explanation and, to a certain extent, the measure of the decomposition of this salt by water.

4. The mixing of two saline solutions, or of a salt and an acid which decompose one another without forming an insoluble product, gives rise to more or less considerable thermal effects, which Marignac has not yet completely studied on account of the difficulty of separating them from the complicated effects resulting from the dilution of the solutions employed. The experiments have therefore been limited to a small number of bodies, merely to ascertain how the results vary according to the degree of dilution. These preliminary experiments show that the thermal effect varies considerably with the degree of dilution, and therefore that the chemical action may also vary therewith. Thus the action of sulphuric acid on a mixture of 55 quantity of sodium sulphate evolves 218 units of heat for $\frac{1}{10}$ -, and 539 units for $\frac{1}{80}$ -solutions. On the other hand, in the action of nitric acid on sodium sulphate, there is an absorption of heat varying from 1,965 to 1,255 units, accordingly as $\frac{1}{10}$ - or $\frac{1}{80}$ -solutions are employed. That different chemical actions really take place in these cases follows also from the thermal effect produced on diluting such a mixture. Equivalent quantities of sulphuric acid and sodium nitrate, mixed in $\frac{1}{10}$ -solutions, yield -90, +45, +169, and +388 heat-units, when diluted to $\frac{1}{20}$, $\frac{1}{40}$, $\frac{1}{60}$, and $\frac{1}{80}$. Similar effects may also take place on mixing the solutions of two neutral salts. The mixing of equivalent quantities of aluminium sulphate and sodium acetate is attended by an absorption of heat varying from 2,454 to 3,047 units for a dilution of $\frac{1}{10}$ to $\frac{1}{80}$. This experiment shows further the incorrectness of the assumed principle of *thermo-neutrality*, according to which double decomposition between two neutral salts should not be accompanied by any change of temperature. Moreover, it does not appear to be a matter of indifference whether two concentrated salt-solutions are first mixed and then diluted, or first diluted and then mixed. Dilution after the mixing of concentrated solutions does not appear to bring about so complete a state of equilibrium, or to produce this effect so quickly, as the mixing of previously diluted solutions.

Decomposition by Heat. Dissociation—Thermolysis (F. Mohr, *Ann. Ch. Pharm.* clxxi. 361).

The term 'dissociation' was originally applied by Deville to signify the separation of a compound into its elements, ultimate or proximate, by the agency of heat alone without the intervention of any other substance capable of breaking up the combination by its superior affinity for one of the elements. It has sometimes been used to denote more especially those decompositions by heat in which only a partial separation of the constituents take place; but the original signification is the most convenient and is most generally adopted. As however, 'Dissociation' might be applied equally well to the separation of a mass into its constituent particles, similar or dissimilar, by mechanical or any other means, Mohr proposes to replace it by the more specific term 'Thermolysis.'

An essential condition of decomposition by heat is that one or both the constituent elements be capable of assuming the gaseous state: compounds like borates and silicates, both whose constituents are fixed in the fire, are never decomposed by heat alone.

Another essential condition of thermolysis is that the constituents of the compound shall, in combining, have given out heat; and the process of thermolysis consists in restoring to the elements the heat which they have lost in combination. When 1 gram of hydrogen gas unites with 8 grams of oxygen to form water, a quantity of heat is evolved capable of raising the temperature of 34,462 grams of water by 1° centigrade, the two gases and the water produced being supposed to be at the temperature of 0° C. Whence is this heat derived? It did not pre-exist in the gases as heat, at least not as sensible or communicable heat; but the gases in combining have lost that peculiar movement of their atoms and molecules, which is the essential condition of the gaseous state, and have been converted into the much less volatile compound, water. Now it is just this quantity of motion which, in the act of combination, is converted into sensible heat, amounting to 34,462 units; and if the water is to be resolved into its constituents, these 34,462 units of heat must be restored to the elements, and reconverted into the kind of motion which is essential to the gaseous state. This may be effected in two ways:—

1. *By Thermolysis*, whereby the heat is restored to the water directly, either by means of Grove's white-hot platinum ball, or Deville's white-hot platinum tube (1st Suppl. 426).

2. *By Electrolysis*. In this mode of decomposition the required quantity of motion is imparted to the elements of water in the form of an electric current, which may be generated by dissolving zinc in acidulated water. Now a given quantity of oxygen develops more heat in combining with zinc than in combining with an equivalent quantity of hydrogen: hence when the zinc decomposes water, with formation of zinc-oxide and liberation of hydrogen, there is an excess of heat available for conversion into other forms of energy; and this excess, by the peculiar arrangement of the voltaic apparatus, is transferred to the conducting wire and thence to the decomposing cell, where it effects the decomposition of the electrolyte. The required amount of energy may of course be supplied in other ways, *e.g.* the application of muscular power or steam-power to drive a magneto-electric machine, &c.

Mercury heated in the air nearly to its boiling point takes up oxygen, forming red mercuric oxide, which at a higher temperature is resolved into its elements. In this combination of the oxygen and mercury is attended with evolution of heat (though, in the peculiar circumstances of the reaction, it is not directly observable), inasmuch as the oxygen has passed from the gaseous and the mercury from the liquid, into the solid state. This quantity of heat is restored by raising the mercuric oxide to a high temperature, and then the compound decomposes.

When 2 volumes of ammonia gas are passed through a red-hot tube, they are resolved into 4 volumes of permanent gases. Now the formation of ammonia (which cannot be effected directly) must have been attended with evolution of heat: 1. because condensation has taken place; 2. because two elements which are permanent gases in the free state, have passed into the less volatile form of ammonia. The heat thus lost in combination is restored by passing the ammonia gas through the red-hot tube.

Marsh-gas, $\text{CH}_4 = 16$, gives out in burning 209,008 heat-units. On the other hand:

1 at. carbon gives out . . .	25,960 heat-units
4 at. hydrogen „ . . .	137,942 „
together	234,808 „
Subtracting the above . . .	209,008 „
there remains . . .	25,800 „

Hence it appears that marsh-gas in burning evolves 25,800 heat-units less than its elements. If, now, 1 volume of marsh-gas be passed through a white-hot tube, it is resolved into 2 vol. hydrogen and a small quantity of carbon. Here, then, is a proof that marsh-gas, in condensing into half the volume which the contained hydrogen would occupy in the free state, has sustained a loss of molecular movement. If the elements are burnt after separation, they again give out the entire amount of 234,808 heat-units; they must, therefore, in separating have regained this amount of molecular movement.

Thermolysis takes place with greater facility in proportion as the elements of a compound differ more widely from one another in their chemical characters; thus, the antimonide of hydrogen is decomposed by heat more easily than the arsenide, and this more readily than the sulphide.

The oxides of the noble metals are very easily resolved into their elements by heat. When such an oxide is reduced by hydrogen, less heat is produced than when the hydrogen combines with free oxygen, because the latter, in its state of combination, as oxide has lost its gaseous form, and the molecular movement belonging thereto.

The peroxides of lead and manganese are resolved by heat into free oxygen and lower oxides; and it is conceivable that at a higher temperature they might be resolved into oxygen and metal.

Carbon bisulphide is resolved, by the heat of an electro-ignited platinum-spiral, into sulphur and carbon, the decomposition being, however, attended, not with absorption, but with emission of heat. This apparent anomaly is explained by the fact that the carbon and sulphur, in combining together at a white heat, pass from the solid to the gaseous state, and absorb heat. A gram of carbon bisulphide in burning in oxygen develops 222 units of heat more than its elements in the free state: it must, therefore, in the act of combination have taken up molecular movement; and it is in consequence of this that the compound is much more volatile than either of its constituents.

Many salts, such as the carbonates, containing volatile acids, are directly resolved by heat into acid and base, and the facility with which they are so resolved is greater as the heat evolved in their formation is less.

The formation of barium carbonate is attended with a greater evolution of heat than that of calcium carbonate, and that of calcium carbonate with a greater evolution of heat than that of magnesium carbonate: on the other hand, magnesium carbonate gives off its carbonic anhydride at a low red heat, calcium carbonate at a cherry-red heat, and barium carbonate only at very high temperatures, so that, indeed, it was long regarded as undecomposable by heat. This example shows clearly that the quantity of heat required for the decomposition of a compound is intimately related to that which has been evolved in its formation.

The same relation is seen in the formation and decomposition of hydrates. Anhydrous potassium oxide, in uniting with water, evolves a very large quantity of heat, the oxide formed when a globule of potassium burns on the surface of water, sinking into the water with explosion; on the other hand, the water in the hydrate is absolutely fixed, and cannot be expelled by any degree of heat, the hydrate volatilising undecomposed at a cherry-red heat. Anhydrous baryta becomes red-hot in combining with water, and the water cannot be expelled from the hydrate by heat. Lime, in combining with water, also evolves a considerable quantity of heat, though less than baryta, and the hydrate gives up its water at a strong red heat. Anhydrous cupric sulphate emits great heat in uniting with 1 mol. of water, less in combining with 4 other molecules; and accordingly these four are given off below the boiling point of water, the fifth only at a red heat.

Sulphuric anhydride unites with 1 mol. of water with passing and explosion, and the hydrate $\text{SO}_3 \cdot \text{H}_2\text{O}$ cannot be decomposed by heat, but distils as a whole. The boiling point of the water has risen by the combination from 100° to 328° , that of the sulphuric anhydride from 52° to 328° . Now when a body becomes less volatile it must have lost molecular motion. Consequently, rise of boiling point and emission of heat are intimately connected, although in the case just cited a solid body (80°) has passed into the liquid state.

The main points in the theory of Thermolysis may be summarised as follows:—

1. Thermolysis or Dissociation is the process opposite to chemical combination: the gaseous constituent of the compound resuming its molecular movement in the form of heat, and transforming it into a new form of movement which it had lost in the act of combination.
2. The quantity of heat taken up by the separated constituents is equal to that which they had lost in combining.
3. Compounds not containing any volatile constituent cannot be decomposed by heat.*

Radiant Heat. Diathermancy.—Only a few substances are known which, in thick as well as in thin layers, transmit more than half of the heat emitted by lamp-black at 100° . Those substances are partly elements, viz., iodine in solution, bromine, and sulphur; partly chlorides, fluorides, and sulphides, viz. rock-salt, fluorspar, carbon sulphide, and sylvin. It appears, however, from the experiments of Schulz-Sellack (*Pogg. Ann.* cxxxix, 182) that not only all chlorides, but likewise the bromides, iodides, and fluorides of the elementary bodies, besides a number of sulphides, transmit a considerable proportion of the heat emitted by lamp-black. The percentage of the total quantity of heat transmitted by the several substances is shown in the following table:—

* Views similar to the above have been developed by Odling in a lecture on *Reverse Chemical Action* delivered before the British Association at Norwich in 1868. See 'A History of Chemical Theory,' by A. Watts, translated by H. Watts, note A, p. 218.

Diathermanous substance	Thickness	Quantity of heat transmitted	
		Lamp-black at 100°	Coal-gas flame
Silver chloride	3 mm.	46 p.c.	30 p.c.
Silver bromide	3	45	42
Potassium bromide	3	16	13
Potassium iodide	3	11	10
Cryolite	10	7	23
Zinc-blende	5	29	23
Arsenious sulphide, As_2S_3	0·8	21	26
	3	8	12
	0·4	50	36
Vitreous Selenium	3	16	5

Most of the substances examined, however, were not perfectly homogeneous, so that part of the heat must have been lost by diffusion and reflection.

A number of liquid compounds and solutions of substances which could not be obtained in the solid form in a fit state for experiment, were examined in a layer 8mm. thick in a glass vessel closed with parallel plates of rock-salt 2mm. thick. The following numbers show the quantities of heat transmitted through the filled vessel in percentages of the quantity passing through the empty vessel; but like those in the preceding table, they do not exhibit the absolute values of the absorption :—

Diathermanous Substance	Transmitted Heat	
	Lamp-black at 100°	Coal-gas flame
Stannic chloride, $SnCl_4$	44 p.c.	80 p.c.
Sulphur chloride, SCl_2	41	95
Carbon bisulphide	50	51
10 parts Phosphorus in 1 part Carbon bisulphide	52	57
1·5 part Stannic iodide, SnI_4 , in 1 part Carbon bisulphide	44	47
1 part Carbon trichloride, CCl_4 , in 4 parts Carbon bisulphide	5	38
Chloroform	2	30
Ethylene chloride, $C_2H_4Cl_2$	0	12
Ethyl iodide, C_2H_5I	0	12

Distribution of Heat in the Solar Spectrum and in the Spectrum of the Lime-light.—

From experiments by S. Lamansky (*Berl. Acad. Ber.* 1871, 632) it appears that the strong heat observed in the bright part of the lime-light spectrum proceeds chiefly from heat-rays which have been bent from their course by diffuse reflection in the rock-salt prisms, as in turbid media. The law established by Melloni's experiments that the ultra-red rays in passing through transparent bodies (as water, glass, mica, quartz, calcspar) suffer a loss which is greater as their refrangibility is less, is shown by Lamansky's observations, made at different hours of the forenoon, to apply also to the absorption of these rays by atmospheric air.

Conduction of Heat. a. *In Gases.*—F. Narr (*Pogg. Ann.* cxlii. 123) has made experiments on heat-conduction and the rate of cooling in hydrogen, nitrogen, air and carbon dioxide, from which the following conclusions are drawn :—(1). The mathematical expression given by Dulong & Petit (v. 53), does not express the true law of the variation of the rate of cooling of a heated body in a gas with the temperature, inasmuch as it gives only the cooling effect of the gas. (2). The cooling effects of different gases differ very considerably, and gases must be ranged, with respect to this effect, not according to their chemical but rather according to their physical character, since hydrogen and carbon dioxide—two gases differing very widely in specific gravity and in capacity for heat—likewise exhibit the greatest difference of cooling power, whereas nitrogen and atmospheric air, which are characterised by almost identical

physical constants, likewise exhibit almost equal rates of cooling. (3). Calculations made to trace the dependence of the observed temperatures on the times of cooling by means of the formula, $\log T - \log T = a_1x + a_2x^2$, showed that in all cases the coefficient a_2 has a very small value, which, with exception of the data of observation relating to hydrogen, was negative. Hence it appears that, for most gases, the deviations from Newton's law of the proportionality of the rate of cooling of a body to the excess of its temperature above surrounding objects (v. 52) are inconsiderable, and that hydrogen exhibits a deviation in the contrary sense. (4). Calculations relating to cooling in a vacuum give also a very small value for the coefficient a_2 , so that the deviations of the rates of cooling calculated from the formula $v = mT$ from the rates actually observed, were but slightly greater than those relating to cooling in hydrogen. For these reasons Nurr regards it as highly probable that Newton's law is the true expression for the cooling effect due to radiation alone.

Stofan (*Wien. Anzeig.*, 1872, 42; *Chem. Soc. J.* [2], x. 177), from experiments with double-walled thermometers of brass or copper-plate, having the space between the metallic envelopes filled with the gas under examination, concludes that the conducting power of air is nearly 20,000 times less than that of copper, and 3,400 times less than that of iron. His experiments confirm the conclusion deduced from the dynamical theory of gases, that the conducting power of any particular gas is independent of its density; also the conclusion deduced by Maxwell from the same theory, that the conducting power of hydrogen is seven times as great as that of air.

For F. Mohr's theoretical views on the heat-conducting power of gases, see *Dent. Chem. Ges. Ber.* iv. 85; *Chem. Soc. J.* [2], ix. 298.

Conduction of Heat in Stratified Liquids.—Experiments relating to this matter by Despretz have been published, since his death, by Saigey (*Compt. rend.* lxxii. 481; *Pogg. Ann.* clxii. 626). A wooden cylindrical vessel 72 centimeters high and 40 cm. in diameter, was half filled with nitrobenzene of sp. gr. 1.20, and water was poured on the top. Ten horizontal thermometers served for the observation of the stationary temperatures, whilst a constant source of heat acted on the surface of the water. In experiment 1, the bulbs of the thermometers were placed in the axis of the cylinder; in experiment 2, they reached only to the middle of its semi-diameter. The following table gives the distances of the thermometers from the surface of separation of the two liquids, and the excesses of the observed temperatures above the temperature of the surrounding atmosphere:—

Thermometers		Experiment No. 1		Experiment No. 2	
Water	A	133.7 mm.	41.26°	137.44 mm.	41.15°
	B	101.8	31.17	110.34	32.01
	C	69.1	23.62	80.25	24.76
	D	41.5	18.66	49.25	19.16
	E	17.5	15.68	15.90	14.83
Nitro-benzene	F	17.5	11.83	15.90	10.68
	G	46.6	7.09	41.90	6.84
	H	75.7	4.48	60.80	4.36
	I	106.2	2.56	101.40	2.43
	K	138.6	1.50	133.00	1.11

On tracing the curves corresponding with these numbers, taking the distances as abscissæ and the excess of temperature as ordinates, it is found that, for equal distances, the ordinates are nearly in geometric proportion. If the distances be taken at 17.5 mm., the mean ratio of the successive ordinates is:

	Experiment 1	Experiment 2
In Water	0.881	0.863
In Nitro-benzene	0.730	0.703

At the boundary of the two liquids, Despretz had unfortunately not placed any thermometers. Here the two curves separate; from the water to the nitro-benzene, which conducts on the average 3.7 times less easily, the calculated temperature rises about 2° or 2.5°.

HELICIN. This body treated with phosphorus oxychloride, is for the most part converted into glucoso-phosphoric acid (p. 561).

HELLEBORE. The constituents of white hellebore-root have been examined by H. Weppen (*Arch. Pharm.* [3], ii. 101, 193), who has obtained from it a bitter substance called *veratramarin*, and an acid called *jervic acid*.

Veratramarin exists in aqueous extracts of the root after the separation of the alkaloids, imparting to them its bitter taste. To obtain it, the sliced root was macerated with cold lime-water, the infusion was freed from lime by means of carbonic acid, and the filtered liquid was mixed with excess of neutral lead acetate and again filtered. The bitter-tasting liquid thus obtained, on standing for some days, deposited on the sides of the vessel a brown crystalline crust (see below). The liquid decanted from this deposit was precipitated with a slight excess of basic lead acetate; the precipitate containing the whole of the bitter substance was decomposed, after thorough washing, by hydrogen sulphide; and the filtered liquid, after boiling to expel excess of the gas, and cooling, was mixed with solution of tannin. The precipitate thereby produced was washed, mixed with lead hydrate, evaporated to dryness over the water-bath, and then exhausted with 40 p.c. alcohol. The pale yellow-body left on distilling off the alcohol, proved to be too small in quantity to admit of full investigation. It appears to be extremely unstable and probably undergoes decomposition during preparation. It reduces alkaline solutions of copper after boiling with acids but not before, and hence appears to be a glucoside. It is soluble in water, but insoluble in ether, benzene, and chloroform, which circumstance makes it difficult to isolate. It is very hygroscopic, deliquescent in the air in a few minutes, and rapidly turning dark brown.

Jervic acid, $C^{14}H^{10}O^{12} + 2H^2O$.—The crystalline body above referred to, which was found to be a lead-salt, was suspended in water and decomposed by hydrogen sulphide; and the acid liquid, filtered hot, was evaporated, leaving a mass of crystals which, after purification, formed a white, light crystalline powder not obtainable in large crystals. This body is *jervic acid*. It is soluble in 10 parts of hot and 100 parts of cold water, sparingly soluble in alcohol and ether, insoluble in benzene, carbon sulphide, chloroform, amyl alcohol, and dilute acids. It gives with neutral and basic lead acetates, precipitates insoluble in acetic but soluble in nitric and hydrochloric acids; with silver nitrate a white precipitate, soluble in ammonia and unaltered by exposure to light; with mercurous nitrate a brilliant white crystalline precipitate, insoluble in water but soluble in nitric acid. With baryta- and lime-water it gives white precipitates which turn yellow after some time.

Jervic acid is quaternary basic. Its potassium and sodium salts are obtained by neutralising an aqueous solution of the acid with the pure carbonates and evaporating over sulphuric acid. They are both very soluble in water, and have an alkaline reaction.

The barium salt is a heavy, glittering crystalline powder, consisting of six-sided tables. The strontium salt is a crystalline powder, rather more soluble than the barium salt.

Calcium *jervate* crystallises more distinctly in four- or six-sided rhombic prisms. There are two silver salts, both obtained by precipitation; also a mercurous salt in the form of a crystalline powder.

The composition of these salts is represented by the following formulae:—

Potassium <i>jervate</i>	.	.	.	$K^4C^{14}H^{10}O^{12} + 2H^2O$
Sodium "	.	.	.	$Na^4C^{14}H^{10}O^{12} + 3H^2O$
Barium "	.	.	.	$Ba^2C^{14}H^{10}O^{12}$
Strontium "	.	.	.	$Sr^2C^{14}H^{10}O^{12} + H^2O$
Calcium "	.	.	.	$Ca^2C^{14}H^{10}O^{12} + 6H^2O$
Acid silver	.	.	.	$Ag^2C^{14}H^{10}O^{12} + 2H^2O$
Neutral silver "	.	.	.	$Ag^4C^{14}H^{10}O^{12}$
Mercurous "	.	.	.	$Hg^4C^{14}H^{10}O^{12} + 4H^2O$

Jervic acid is coloured yellow by alkalis. When boiled with baryta-water, it yields a crystallisable acid, the examination of which is not yet completed.

HELVIN. N. von Kokschnrow (*Jahresb. f. Chem.* 1860, 1228) describes helvin: 1. From Miask in the Ilmen Mountains, in spherical masses, some as big as a man's head; sp. gr. 3.333. 2. From Lupiko in Finland, in crystals, $\frac{202}{2}$, some more than an inch long; sp. gr. = 3.23 to 3.37. Analyses of two specimens from each locality have been made by N. Teich:

	SiO ²	Al ² O ³	GO	FeO	MnO	CaO	MgO	S	H ² O	
1. { 32.67	0.76	18.67	15.03	35.51	—	—	—	—	—	= 97.43.
{ 32.42	0.78	18.46	15.21	35.31	—	—	—	5.77	—	= 102.96.
2. { 30.31	—	10.51	10.37	37.87	4.03	0.60	0.66	5.95	0.22	= 99.25.
{ 33.88	—	10.40	10.37	37.90	4.10	0.66	—	—	0.22	= 94.03.

2nd Sup.

T T

HEPTAMINE-CHROMIUM COMPOUNDS. See CHROMIUM (p. 336).**HEPTANES, C⁷H¹⁶.** *a. Normal Heptane or Heptyl-methane,*

occurs, together with other paraffins, in Pennsylvanian petroleum and in the light oils obtained from cannell- and Boghead-tar. When separated as completely as possible by fractional distillation, it boils at 97.5°-98°, not at 92°-94° as stated by Pelouze & Cahours. When chlorine is passed into its vapour at the boiling heat, two isomeric heptyl chlorides are obtained, which boil at 145°-160°, and are converted, by heating to 200° with potassium acetate and glacial acetic acid, into the corresponding heptyl acetates boiling at 175°-185°. Neither the chlorides nor the acetates can be separated by fractional distillation, but by heating the mixed acetates with potash they are converted into heptyl alcohols, the mixture of which can be separated by fractional distillation into a primary and a secondary heptyl alcohol, each having a nearly constant boiling point, though still not quite pure. The primary heptyl alcohol thus obtained boils at 170°-175°, and is converted by oxidation into *enanthylic acid*, C⁷H¹⁴O², boiling at 219°-222°, and identical with that which is prepared from castor-oil. The secondary heptyl alcohol boils at 160°-162°, and is converted by oxidation into methyl-pentyl ketone, CO { $\begin{smallmatrix} \text{CH}^3 \\ \text{C}^2\text{H}^{11} \end{smallmatrix}$ }, boiling at 150°-152°. The secondary alcohol is there-

fore methyl-pentyl carbinol, { $\begin{smallmatrix} \text{CH}^3 \\ \text{C}^2\text{H}^{11} \end{smallmatrix}$ } CH.OH. The ketone is converted by further oxidation into acetic and normal valeric acid, CH³-(CH²)³-COOH, showing that the heptane from which these derivatives have been obtained is the normal compound CH³-(CH²)⁵-CH³.

B. Ethyl-amyl or Dimethyl-butylmethane, CH { $\begin{smallmatrix} (\text{CH}^3)^2 \\ \text{C}^4\text{H}^9 \end{smallmatrix}$ }, or CH³-CH²-

by the action of sodium on a mixture of the bromides or iodides of ethyl and amyl (1st Suppl. 696). Grimsshaw (*Chem. Soc. J.* [2], xi. 309) prepares it by gradually adding sodium to a mixture of the bromides contained in a flask with reversed condenser, in such proportion as to keep the liquid at 25°-26° by heating it to 100° for some hours, and afterwards distilling off. The mixture of hydrocarbons thus obtained is left standing for some weeks over sodium, then repeatedly rectified over sodium and fractionally distilled, and finally purified by treatment with strong nitric and sulphuric acid, washing with water, leaving it in contact for 48 hours with sticks of potash, again distilling it with sodium, and then leaving it in contact for a week or two with sticks of potash.

The ethyl-amyl thus prepared boiled constantly at 90° and had a specific gravity of 0.6823 at 18.4°. By the action of chlorine on its vapour at the boiling heat, a mixture of chlorides was obtained which did not give any constant boiling point, but yet distilled almost entirely within about 10°. This mixture yielded, by the action of potassium acetate and acetic acid, a liquid which also could not be obtained of constant boiling point, but distilled within about 15°. From this, however, a mixture of alcohols was obtained, of which a more or less complete separation could be effected into a primary alcohol boiling at 165°, and a secondary alcohol boiling at about 147°.

The primary alcohol thus obtained is an iso-heptyl alcohol, as shown by its boiling point, which is about 10° lower than that of normal heptyl alcohol, and by the fact that it is converted by oxidation into an iso-*enanthylic acid*, C⁷H¹⁴O², boiling at 210°-213°, that is to say, 8° or 10° lower than normal *enanthylic acid*.

Now, as ethyl-amyl contains three methyl-groups, two isomeric primary alcohols may be derived from it, namely:

It is for the present impossible to decide which of these two formulæ expresses the true constitution, but the second formula is perhaps the more probable.

The secondary alcohol is methyl-isoamyl-carbinol, CH { $\begin{smallmatrix} \text{CH}^3 \\ \text{CH}^3 \\ \text{CH}^3 \end{smallmatrix}$ } CH²-CH { $\begin{smallmatrix} \text{CH}^3 \\ \text{CH}^3 \end{smallmatrix}$ }, as is proved by the fact of its yielding by oxidation methyl-isoamyl ketone,

$\text{CH}_3\text{--CO--C}^2\text{H}^{11}$, boiling at $143^\circ\text{--}145^\circ$, and identical with that which Popoff obtained (*Zeitschr. f. Chem.* 1865, 577) by the action of zinc-amyl (from ordinary amyl alcohol) on acetyl chloride.

γ . *Dimethyl-diethylmethane*, $\text{C}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{C}^2\text{H}_5 \end{smallmatrix}\right\}_2$.—This modification is contained, together with normal heptane and other hydrocarbons, in Pennsylvanian petroleum. After separation by fractional distillation, it boils at 89.5° to 90° . Like normal heptane and ethyl-amyl, it yields by chlorination, &c., two series of derivatives, the boiling points of which differ in some cases from those obtained from ethyl-amyl:—

	Derivatives of the hydrocarbon from petroleum	Derivatives of ethyl-amyl
Paraffin, C^7H^{16}	$89.5^\circ\text{--}90^\circ$	90°
Olefine, C^7H^{14}	$90^\circ\text{--}92^\circ$	91°
Chloride, $\text{C}^7\text{H}^{13}\text{Cl}$	$144^\circ\text{--}158^\circ$	$140^\circ\text{--}150^\circ$
Acetate, $\left\{\begin{smallmatrix} \text{C}^7\text{H}^{13} \\ \text{C}^7\text{H}^{13}\text{O} \end{smallmatrix}\right\}\text{O}$	$160^\circ\text{--}185^\circ$	$160^\circ\text{--}175^\circ$
Alcohol, $\left\{\begin{smallmatrix} \text{C}^7\text{H}^{15} \\ \text{H} \end{smallmatrix}\right\}\text{O}$	Primary $165^\circ\text{--}170^\circ$ Secondary $148^\circ\text{--}150^\circ$	$163^\circ\text{--}165^\circ$ $146^\circ\text{--}148^\circ$
Ketone, $\text{C}^7\text{H}^{14}\text{O}$	$142^\circ\text{--}146^\circ$	$143^\circ\text{--}145^\circ$
Acid, $\text{C}^7\text{H}^{14}\text{O}_2$	$209^\circ\text{--}213^\circ$	$210^\circ\text{--}213^\circ$

The heptane, C^7H^{14} , was obtained in both cases as a secondary product in the preparation of the acetate from the chloride.

The acid $\text{C}^7\text{H}^{14}\text{O}_2$, derived from the γ heptane, boils at the same temperature as isocananthyllic acid, and has a very similar smell; its salts also resemble the corresponding isocananthylates. The silver salt, $\text{C}^7\text{H}^{13}\text{AgO}_2$, is a flocculent crystalline precipitate. The barium salt does not crystallise, but forms an amorphous mass, like barium isocananthylate. The calcium salt separated, on evaporating its solution by heat, as an amorphous pollicle, but by spontaneous evaporation it was obtained in long, transparent needles or prisms.

The ketone, $\text{C}^7\text{H}^{14}\text{O}$, boils at the same temperature as methyl-isocanmyl ketone, and smells very like the latter compound; but on oxidising it, a marked difference between the two compounds is observed. Methyl-isocanmyl ketone yields, by oxidation, acetic and valeric acids, whereas the ketone derived from γ heptane yields nothing but acetic acid.

Now Popoff has shown that when a ketone is oxidised, the lower, or more stable, of the alcohol-radicles always remains attached to the carbonyl, while the other radicle is oxidised just as its alcohol would be (1st Suppl. 765). According to this law there may exist two ketones, $\text{C}^7\text{H}^{14}\text{O}$, yielding by oxidation only acetic acid, viz:

The first of these two ketones will in the first instance be resolved into acetic acid and methyl-isopropyl ketone, and the latter will yield by further oxidation acetic acid and dimethyl ketone, which will finally be also oxidised to acetic acid.

The second ketone must, according to Popoff's law, yield acetic acid and the oxidation-products of tertiary amyl. But the latter also consist only of acetic acid: for Butlerow has shown that, on oxidising a tertiary alcohol, the most simple radicle always remains combined with the carbon-atom by which the whole group is kept together, whilst the two other radicles are oxidised separately; and experiment has proved that tertiary amyl alcohol, or dimethyl-ethyl carbinol, is oxidised completely to acetic acid.

The first of the ketones is a derivative of *methyl-ethyl-isopropylmethane*, $\text{CH}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{C}^2\text{H}_5 \end{smallmatrix}\right\}_2$, a paraffin which is not yet known; whilst the second ketone is

derived from *dimethyl-diethylmethane* or *carbodimethyldiethyl*, $\text{C}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{C}^2\text{H}_5 \end{smallmatrix}\right\}_2$, which compound Friedel and Ladenburg prepared by the action of zinc-ethyl on dimethyl-dichloromethane $\text{CCl}_2(\text{OH})_2$ (1st Suppl. 826).

At present it is impossible to decide with certainty with which of these two paraffins γ heptane is identical, the quantity of the ketone obtained having been too small to allow of the isolation of the intermediate products of oxidation, which would elucidate

its constitution, and therefore that of the paraffin. The properties of γ heptane agree, however, with those of dimethyl-diethylmethane sufficiently to render their identity not improbable. The latter paraffin boils at 86° – 87° , and has at 20.6° the specific gravity 0.6968, whilst the hydrocarbon from petroleum boils at 89.5° – 90° , and has at 16° the specific gravity 0.709. The higher boiling point of the latter is caused, partly at least, by an admixture of normal heptane boiling at 98° (Schorlemmer, *Chem. Soc. J.* [2], xi. 319).

HEPTENE-CHLORHYDRIN, $C^7H^{13}(OH)Cl$, is formed, together with other products, by treating octene with a 2 to 3 p.c. solution of hypochlorous acid, which, in a solution of this strength, exerts an oxidising as well as a reducing action. By fractional distillation the heptene-compound may be separated, boiling at 206° – 208° . A weaker solution of hypochlorous acid ($\frac{3}{4}$ p.c.) forms chiefly octene-chlorhydrin (P. de Clermont, *Bull. Soc. Chim.* [2], xiii. 404).

HEPTYL ALCOHOL, $C^7H^{14}O$. Normal *Heptyl alcohol*, $CH^3-CH^2-CH^2-CH^2-CH^2-CH^2-CH^2-OH$, may be advantageously prepared from *canthol*, $C^7H^{14}O$, by the action of sodium-amalgam. *Canthol* is shaken with fifty times its weight of water, and a little more than the required quantity of an amalgam containing 1 per cent. of sodium is added, together with an equivalent quantity of dilute sulphuric acid, care being taken to keep the liquid always slightly acid. As soon as the action is over, the liquid is distilled, and the distillate again treated in the same way with the amalgam. The alcohol floating on the top is then removed, and the portion remaining in the aqueous solution is isolated by repeated distillation, the alcohol always coming over with the first portion, from which it may be finally separated by adding potassium carbonate. The product is dried over ignited potassium carbonate, and the alcohol separated from another very high-boiling liquid by fractional distillation. To get rid of some *canthol* and water still present, the liquid is several times distilled over small pieces of sodium, and then left for several weeks in contact with anhydrous baryta.

Normal heptyl alcohol thus prepared is a limpid oily liquid, having an aromatic odour, and boiling under a pressure of 766 mm. at 175.5° – 177.5° , the whole column of mercury being surrounded by the vapour (Grimshaw & Schorlemmer, *Chem. Soc. J.* [2], xi. 1081).

HEPTYLIC ACID and ALDEHYDE. See *Canthol*. **HEPTYLIC ACID and ALDEHYDE.**

HERACLEUM. The volatile oil of *Heracleum giganteum* is a mixture of octyl acetate and the hexylic ether of normal butyric acid. By saponifying the greater portion of the oil which passes over between 200° and 206° with caustic potash, and fractional distillation, the two alcohols may be obtained in the pure state. The octyl alcohol is identical with that which is prepared from the oil of *Heracleum sphondylium* (1st Suppl. 697). The hexyl alcohol will be described further on (Franchimont & Zincke, *Deut. Chem. Ges. Ber.* iv. 822).

HESPERIDENE. The terpene of essential oil of orange-peel. (See TERPENES).

HETEROGENITE. A hydrated cobaltoso-cobaltic oxide occurring, together with calc spar and pharmacolite, in the nickel and cobalt veins of the Wolfgang Maessen mine at Schneeberg in Saxony. It is amorphous, and occurs in botryoidal and kidney-shaped masses, having a dense fracture. Lustre faint. Colour blackish to reddish-brown: the ignited powder is coal-black. Streak dark-brown, with a fatty lustre. Hardness equal to that of calc spar. Sp. gr. 3.44.

Its blowpipe reactions are as follows:—It gives off water when heated in a tube; heated in the forceps it melts with difficulty on the edges, and colours the flame slightly green; appears slightly magnetic after ignition; exhibits cobalt reaction with glass fluxes. It dissolves easily in hydrochloric acid, giving off chlorine and leaving an insoluble residue; the green solution turns red when heated, and gives with ammonia a small precipitate of ferric oxide.

The quantitative analysis of two specimens gave:

	CoO	O	CaO	CoO'	FeO'	AlO'	CaO	MgO	H ² O	Residue	
a	59.03	5.03	0.60	0.35	1.20	1.30	1.60	0.45	14.56	16.00	= 100.12
b	39.94	2.81	0.56	0.32	0.80	—	3.60	2.02	12.25	32.20	= 103.50

Most of these constituents are foreign to the mineral, and on deducting them—namely the insoluble residue, consisting mainly of silica, which remains on dissolving the mineral in acids, as a skeleton made up of large flocks—also the oxides of iron, copper, bismuth, calcium, and magnesium—there remains for the composition of the heterogenite—

CoO	O	H ² O	or	CoO	Co ² O ³	H ² O
75.17	6.41	19.54		14.32	67.26	18.54
68.83	5.51	24.13		16.24	58.13	24.13

agreeing nearly with the formula, $\text{CoO} \cdot 2\text{Co}^2\text{O}^3 + 6\text{H}^2\text{O}$, which requires 14.61 p.c. CoO, 61.61 Co^2O^3 , and 20.78 water.

Hoterogenite was originally mistaken for asbolan or earthy cobalt—a manganese ore—and, in fact, it exhibits a distinct trace of manganese when fused with sodium carbonate and nitro. One specimen was found to contain nickel in the proportion of 1 part nickel to 20 parts cobalt.

Hoterogenite is a product of the decomposition of smaltine or tin-white cobalt (speiss-cobalt); it is interesting as the first mineral in which the amount of cobalt existing as sesquioxide has been actually determined (A. Frenzel, *J. pr. Chem.* [2], v. 404).

HEXAMIDO- and HEXNITRO-ALBUMIN-SULPHONIC ACIDS.

When dried albumin is treated with a mixture of concentrated nitric and sulphuric acids in the cold, and the mixture, after standing for several hours, is thrown into cold water, a precipitate is thrown down, which, when dried, forms three-fourths of the albumin originally taken. It is a bitter, yellow powder, insoluble in water, alcohol, and dilute acids; soluble in dilute alkalis, forming a red solution, from which it may be reprecipitated unchanged. Assuming the formula of albumin to be $\text{C}^{72}\text{H}^{108}\text{N}^{18}\text{SO}^{22}$, the new substance is *hexanitro-albuminsulphonic acid*, $\text{C}^{72}\text{H}^{101}(\text{NO}^2)^6(\text{SO}^2\text{OH})\text{N}^{18}\text{SO}^{22}$. On treating this body with ammonium sulphide, *hexamido-albuminsulphonic acid*, $\text{C}^{72}\text{H}^{101}(\text{NH}^2)^6(\text{SO}^2\text{OH})\text{N}^{18}\text{SO}^{22}$ is formed, as a brownish-yellow powder, having a faint taste, soluble in dilute alkalis, decomposed by strong alkalis, especially on warming, with evolution of ammonia. Nitric acid dissolves it, with evolution of red fumes. It is insoluble in dilute acids, but when freshly precipitated, dissolves readily in concentrated acids (O. Loew, *J. pr. Chem.* [2], iii, 180).

HEXAMINE- (or TRIAMINE-) CHROMIUM-COMPOUNDS. (See p. 336.)

HEXANES, C_6H_{14} . (Schorlemmer, *Phil. Trans.* 1872, 111). *Normal hexane*, $\text{CH}_3 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_3$, occurs, together with other paraffins, in Pennsylvanian petroleum and in the light oils from Boghead and cannol coal. It boils at $60^\circ\text{--}70^\circ$. When chlorine is passed into its vapour at the boiling heat, a mixture of hexyl chlorides is produced, the greater part of which distils constantly at $125^\circ\text{--}126^\circ$. Treated with potassium acetate they yield hexene, C_6H_{12} , boiling at $69^\circ\text{--}70^\circ$, and hexyl acetates distilling between 158° and 160° (not at 145° , as stated by Pelouze and Colours). The secondary alcohol obtained from these mixed acetates is methyl-

butyl carbinol $\frac{\text{CH}_3}{\text{C}_6\text{H}_{13}} \cdot \text{CH}_2\text{OH}$, yielding by oxidation methyl-butyl ketone, boiling at $126^\circ\text{--}128^\circ$, and then acetic and *normal* butyric acid. The primary hexyl alcohol obtained from the same mixture of acetates boils at $150^\circ\text{--}155^\circ$, and is converted by oxidation into caproic acid, which boils at $200^\circ\text{--}205^\circ$, and yields a silver salt crystallising in needles, and a calcium salt in shining scales or ramified needles: its barium salt forms an amorphous mass.

Normal hexane is also produced by the action of zinc and dilute hydrochloric acid on secondary hexyl iodide (methyl-butyl iodide) obtained from mannite. The product contains, besides hexane, small quantities of hexene and dihexyl or dodecane $\text{C}_{12}\text{H}_{26}$. The latter, which boils at 202° , may be removed by distillation, and the hexene by means of bromine. The purer hexane thus prepared boils constantly at 171.5° , and has a specific gravity of 0.6630 at 17° . The chlorides obtained from it boil at $126^\circ\text{--}130^\circ$, and yield a mixture of two hexyl alcohols, viz., methyl-butyl carbinol, boiling at $140^\circ\text{--}141^\circ$, and yielding by oxidation *normal* butyric acid, and a primary alcohol which boils at $150^\circ\text{--}153^\circ$ and is converted by oxidation into a caproic acid boiling at $201^\circ\text{--}204^\circ$ and exhibiting properties similar to the caproic acid derived from petroleum, excepting that the acid from mannite gives a well-crystallised barium salt. The hexane from mannite and some of its derivatives also boil at a few degrees higher than the corresponding petroleum derivatives. These differences are probably due to the presence of small quantities of other paraffins in the hexane from petroleum. The formation of acetic and of *normal* butyric acid from the hexanes from petroleum and from mannite show indeed that both have the constitution of a normal paraffin.

Dipropyl, $\text{C}_3\text{H}_7 \cdot \text{C}_3\text{H}_7$, prepared from normal propyl iodide, $\text{CH}_3 \cdot \text{CH}_2 \cdot \text{CH}_2\text{I}$, (boiling at $102^\circ\text{--}103^\circ$) by heating a mixture of this iodide and anhydrous ether with sodium to $140^\circ\text{--}150^\circ$, is likewise identical in physical properties with the hexane from the two sources above mentioned. The identity is further shown by its mode of formation:

$\text{HC}(\text{CH}_3)_2$
Tetramethyl-ethane, $\begin{array}{c} \text{HC}(\text{CH}_3)_2 \\ | \\ \text{HC}(\text{CH}_3)_2 \end{array}$.—This modification of hexane is derived from

pinacene, $\text{C}^8\text{H}^{10}\text{O}^2$, which is formed by the action of sodium-amalgam on aqueous acetone, and has the constitution of tetramethylated ethene glycol (iv. 647; 1st *Suppl.* 946). Pinacene boiled with iodine and phosphorus in presence of water, or heated in sealed tubes with hydriodic acid, yields a mixture of pinacolin, $\text{C}^6\text{H}^{12}\text{O}$ (anhydride of pinacene), an iodide, $\text{C}^6\text{H}^{11}\text{I}$ (b. p. 142° – 145°), which constitutes three-fourths of the crude product, and small quantities of more condensed derivatives of acetone. The iodide, $\text{C}^6\text{H}^{11}\text{I}$, heated with hydriodic acid, gives, besides a little inflammable gas and several liquid hydrocarbons boiling at about 130° , a liquid hexane boiling at 59° , identical with the so-called hydride of dipropylene which Berthelot obtained by treating diallyl with hydriodic acid (Bouchardat, *Compt. rend.* lxxiv. 800).

HEXHYDRO-ISOXYLENE, C^6H^{16} . See XYLENE.

HEXHYDROPHTEALIC ACID. See PHTHALIC ACID.

HEXETHYL-DISILICIC ETHER. See SILICIC ETHERS.

HEXOKETHYL-DIPHOSPHOPLATINOUS CHLORIDE. See PLATINUM-COMPOUNDS.

HEXOKYDIPHENYL, $\text{C}^{12}\text{H}^{10}\text{O}^4$, is produced, together with methyl chloride, by heating hydrocerulignone with hydrochloric acid in sealed tubes (p. 377).

HEXOKYANTHERAQUINONE, or **TETRA-OKYANTHRAQUINONE**, $\text{C}^{14}\text{H}^8\text{O}^4$. This, according to Jaffé (*Deut. Chem. Ges. Ber.* 1870, 694), is the constitution of rufgallie acid (1st *Suppl.* 999), inasmuch as that acid when distilled with zinc-dust yields anthracene. The formation of rufgallie acid by heating gallie acid with sulphuric acid will accordingly be represented by the equation $2\text{C}^6\text{H}^6\text{O}^2 = 2\text{H}^2\text{O} + \text{C}^{14}\text{H}^8\text{O}^4$.

HEXYL ALCOHOLS. The essential oil of *Heracleum giganteum* yields by fractional distillation a liquid distilling between 201° and 206° , which is a mixture of hexyl butyrate and primary octyl acetate.

The hexyl alcohol thus obtained is a colourless oily liquid with a strong aromatic odour. Its sp. gr. at $23^\circ = 0.819$, and corrected boiling point 156.6° . The corresponding *hexyl iodide*, $\text{C}^6\text{H}^{13}\text{I}$, is a colourless liquid with a faint odour; sp. gr. at $17.5^\circ = 1.4115$; boiling point 179.5° .

The *acetate*, $\text{C}^6\text{H}^{13}\text{C}^2\text{H}_3\text{O}^2$, is a colourless, oily liquid, having at 17.5° the sp. gr. 0.889, and boiling at 168.7° . The *caproate*, $\text{C}^6\text{H}^{13}\text{C}^6\text{H}^{11}\text{O}^2$, is an oily, almost scentless liquid. Sp. gr. at $17.5^\circ = 0.865$; boiling point 245.6° .

On oxidation, this alcohol yields caproic acid, which boils at 204.5° – 205° , and has, therefore, the same boiling point as Lieben's normal caproic acid. As this hexyl alcohol boils at a higher temperature than all other primary hexyl alcohols so far studied, and as the difference between its boiling point and that of normal amyl alcohol is 19° , it is most probably normal hexyl alcohol: $\text{CH}_3\text{—CH}_2\text{—CH}_2\text{—CH}_2\text{—CH}_2\text{—CH}_2\text{—OH}$ (Franchimont a. Zincke, *Deut. Chem. Ges. Ber.* iv. 822).

The cyanide prepared from this alcohol in the usual way yields, by distillation with caustic potash, a heptylic or enanthylic acid which boils at 223 – 224° under a pressure of 762.7 mm., has a sp. gr. of 0.9912 at 24° , and solidifies completely in a mixture of ice and salt, but liquefies entirely again at 8° . It is, in all probability, normal enanthylic acid (Franchimont, *ibid.* v. 786). See ENANTHYLIC ACID.

The hexyl-compounds derived from mannite and from dulcitol have been examined by O. Hocht (*Ann. Ch. Pharm.* clxv. 140), who finds them to be identical both in their physical and in their chemical properties. The alcohols from the two sources, when oxidised by chromic acid, both yield acetic and normal butyric acid: they have, therefore, the constitution of methyl-butyl carbinol $\begin{array}{c} \text{CH}_3 \\ | \\ \text{C}^4\text{H}_9 \end{array} \text{CH}_2\text{OH}$.

HIBISCUS. The *Hibiscus esculentus*, called in Egypt *Bammg*, is there cultivated as a garden vegetable, the unripe green fruits being cooked like French beans. The fruit dried at 100° contains 2 to 2.4 p.c. nitrogen. Like those of other malvaceous plants, it is rich in pectin, starch, and mucilage. The ash contains abundance of potash, soda, magnesia, phosphoric acid, sulphuric acid, and chlorine. The ripe seeds contain 2.4 to 2.5 p.c. nitrogen. The ash of the seed is constituted as follows:—

K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	SiO ²	Cl	CO ²
38.84	4.58	7.81	12.02	0.86	24.69	0.56	0.75	1.64	8.25 = 99.90

(O. Popp, *Arch. Pharm.* [2]. cxlv. 140).

HIPPURIC ACID. Experiments on the influence of various kinds of fodder on the secretion of hippuric acid in the urine of herbivora have been made by Hofmeister (*Landw. Versuchs-Stationen*, xiv. 458).

Sheep fed on clover-hay secreted as an average 5.3 grams only of hippuric acid in 24 hours, but when fed on meadow-hay they secreted an almost constant quantity of 30 grams. The addition of benzoic acid to the clover-hay gave rise to an increase in hippuric acid of rather more than the calculated weight, showing that clover does not in itself prevent the formation. The distillate and watery extract obtained on distilling meadow-hay with water, dried and given to sheep, produced no increase in hippuric acid, but the dried residue caused its secretion in almost the same proportion as the original hay.

Meadow-hay was then exhausted consecutively with water, alcohol, and 3 p.c. soda-ley. The alcoholic extract produced a slight increase in hippuric acid; the watery and alkaline extracts and the residue had no appreciable effect. The non-formation of hippuric acid from this residue is in opposition to the observations of Meissner, who, from experiments on rabbits, arrived at the conclusion that the formation of this acid was due to the digestion of some substance contained in the crude fibre, probably the cuticular membrane. That the nitrogenous constituents of the food do not wholly regulate the secretion of the acid is proved by the facts that the addition of rape-cake to the food has no action on its quantity, but only increases the urea, and that a much smaller quantity is formed by feeding with clover than with graminaceous plants.

Neither do the apomatic substances of the food seem to have much influence: for the alcoholic extract of meadow-hay, containing the greater part of the aromatic bodies, produced but a small quantity of hippuric acid, and Henneberg and Stolman found as much in the urine of oxen fed on oat-straw as in that of oxen eating meadow-hay.

By gradually increasing the quantity of oat-straw given in combination with clover-hay, the hippuric acid secretion in the urine of sheep was gradually increased; in a similar experiment with barley-straw no such increase took place.

Notwithstanding contradictory appearances, Hofmeister is of opinion that the secretion of hippuric acid is influenced by the protein matters and the fibre of the food, though the necessary conditions can be found only by a closer examination of these substances.

E. Wildt (*Deut. Chem. Ges. Ber.* vi. 1494), fed rabbits with pure grass, and found only a trifling production of hippuric acid; with clover rather more was formed; with meadow grass containing a variety of herbage the production was greatly increased; with *Leontodon Taraxacum* (one of the meadow-plants) the yield was equally large. He concludes that some ingredients of the meadow herbage other than grass or clover are the cause of the formation of hippuric acid.

HISINGERITE. A brown amorphous mineral from Lostwithiel in Cornwall has been provisionally described by Church (*Chem. Soc. J.* [2], viii. 3) as hisingerite. Hardness = 2.75. Sp. gr. = 1.74. According to the mean of three analyses, it consists of 52.94 Fe²⁺O³, 36.14 SiO², and 10.49 H²O (= 99.57), together with 0.82 P²O⁵ and traces of magnesia. The formula of the mineral is perhaps Fe²⁺O³. 2SiO² + 2H²O, which requires 50.63 p.c. Fe²⁺O³, 37.98 SiO² and 11.39 H²O, the excess of ferric oxide in the analysis being probably due to the difficulty of separating the mineral from the hematitic matrix in which it is imbedded.

HELMITE. See TANTALATES.

HOMOLOGOUS SERIES. On the Boiling Points of Homologous Organic Compounds, see page 203.

HOPHITE. See PHOSPHATES.

HOPS. Experiments have been made by A. Muntz (*Compt. rend.* lxxiv. 1044), with the object of ascertaining (1), the nature and quantity of the elements which are removed from the soil by a crop of hops; (2), the proportion in which the various elements are assimilated by the hop-plant during the different phases of its growth.

The following analyses, in which special attention has been bestowed upon the separation of the alkalis, were made with hop-plants gathered on September 17 from a hop-garden at Woerth, at the base of the Liebfrauenberg in Elsass.

HORNBLLENDE—HUMIC ACID.

Materials removed from the Soil by a Crop of Hops.

	2,400 plants grown on 28 acres contain	6,316 plants grown on 1 hectare contain
	kilograms	kilograms
Water	4282.560	11270.270
Carbon	997.224	2624.861
Hydrogen	119.904	315.547
Oxygen	764.304	2011.393
Nitrogen	34.633	91.141
Phosphoric acid	8.625	22.699
Magnesia	9.254	24.352
Potash	15.888	41.812
Soda	0.173	0.455
Mineral matter not determined	50.635	133.278
	6283.200	16535.308

HORNBLLENDE, and AUGITE. See AUGITE, p. 117.

HORTONOLITE. This name is given by G. J. Brush (*Sill. Am. J.*, [2], xlviii. 17), to a chrysolite containing iron, manganese and magnesium, occurring at Monroe, Orange County, New York, imbedded in calcespar, or in cavities of the same, together with magnetic iron ore. The mineral is yellow to dark yellowish-green, and in the larger masses almost black. The crystals appear black from a coating of another substance. Hardness = 6.5. Sp. gr. = 3.91. Before the blowpipe it becomes black and magnetic, and gives with fluxes the reactions of iron, manganese, and silica. Hydrochloric acid decomposes it completely, with gelatinisation. The mass is always intimately mixed with magnetic iron ore, sometimes also with graphite. The former was removed by the magnet previous to analysis. Two analyses made by W. G. Mixer, gave:

SiO ₂	FeO	MnO	MgO	CaO	K ₂ O	Loss by ignition
33.52	44.28	4.72	16.79	trace	0.30	0.26 = 99.87
33.66	44.46	3.98	16.56	trace	0.47	0.26 = 99.39

This composition shows that the mineral is a chrysolite, and the crystallographical and optical examination made by J. M. Blake lead to the same conclusion. The angles are very nearly those of chrysolite, and the occurring faces are $0P$, $\infty P\infty$, $\infty P2$, $P\infty$, $P\infty$, $P2$, $P4$. The crystals cleave parallel to the faces of a prism, also parallel to $0P$, and perhaps also parallel to $\infty P\infty$.

HUMIC ACID. HUMUS. W. Detmer (*Landw. Versuchs-Stationen*, xiv. 248) prepares humic acid by exhausting peat and various kinds of peaty soil with solution of potassium carbonate, precipitating the solution with hydrochloric acid, and subjecting the precipitate to a great number of purifying processes. The humic acid was finally precipitated from its solution in boiling water by the addition of hydrochloric acid; it then contained only 0.179 p.c. of nitrogen. The nitrogen present in the earlier stages of purification did not exist as ammonia. The purified humic acid, dried at 120°, gave a mean percentage of 59.75 C., 4.61 H., agreeing with the formula $C^{50}H^{10}O^{27}$; the composition of the salts shows, however, that the true formula is $C^{50}H^{10}O^{27}$.

Humic acid is amorphous. It begins to decompose at 145°. When undried, it dissolves in 8,333 parts of water at 6°, and in 625 parts at 100°; after drying it requires 13,784 parts of boiling water for solution. The presence of salts diminishes its solubility. It is more soluble in phosphoric acid than in other acids. Humic acid reddens litmus; it expels carbonic acid from metallic carbonates, forming insoluble compounds, except with the alkalis. Its solution in ammonia leaves, when dried, a substance having the formula $C^{50}H^{10}(NH^4)^{10}O^{27}$, which is soluble in 2.2 parts of water. Metallic salts form precipitates with ammonium humate. The precipitate formed by calcium chloride has the formula $C^{50}H^{10}Ca^2(NH^4)^2O^{27}$; that by ferric chloride has the formula $C^{50}H^{10}(Fe^3)^4(NH^4)^2O^{27}$; the precipitate by silver nitrate is $C^{50}H^{10}Ag^5O^{27}$. All these compounds are amorphous.

The acid prepared from brown peat (called ulmic acid by Mulder) is identical in composition and properties with that obtained from black peat. Humic, the insoluble humus-substance, is difficult to obtain free from undecomposed vegetable fibre. Cranic and apocrenic acids appear to be products of the oxidation of humic acid.

The changes which peat undergoes during its formation are shown by the following analyses of samples from the Nienwalder Moor. The samples were dried at 120°:—

Description of Peat	Ash per cent.	Composition of Organic Substance per cent.			
		N	C	H	O
Brown peat, from surface	2.719	0.80	57.75	5.43	36.02
Nearly black peat, at 7 feet	7.423	2.10	62.02	5.21	30.67
Black peat, at 14 feet	9.164	4.05	61.07	5.01	26.87

The amount of humus in a soil is best ascertained by oxidation with potassium bichromate, and estimation of the carbonic acid evolved. A moderate quantity of humus improves soil in many ways. From its dark colour humus is a good absorbent of heat; its specific heat is much above that of soil; it is hygroscopic, and greatly increases the water-holding power of sandy soils; it has the power of absorbing ammonia; by its decomposition it is a source of carbonic acid; and the mechanical condition of most soils is improved by its presence. When, however, humus is present in excessive quantity, it acts injuriously, by deoxidising ferric salts, and in other ways.

Humic acid is a strictly colloïd body, and cannot, therefore, directly serve for the nourishment of plants. This result is confirmed by experiments with the spores of an alga, *Euglena viridis*, which show that neither humic acid nor neutral ammonium humate is absorbed by this plant from its solutions. Crenic acid is capable of diffusion through membranes; in an experiment with recently germinated peas it was found, by microscopical observation, that crenic acid had passed into the plant from its solution. The oxidation products of humic acid appear, therefore, to be taken up by plants (Dotner, *Landw. Versuchs-Stationen*, xv. 284).

From experiments by Bretschneider (*Chem. Ackersmann*, 1871, p. 287), it appears that the presence of humic acid in the soil greatly promotes the absorption of nitrogen from the air. The humic acid contained, when dried at 110°: carbon 60.397, hydrogen 4.502, oxygen 35.034, nitrogen .025, ash .042. The experiments were made in four metal dishes, each 6 inches deep, and exposing a surface of 1 square foot. Each vessel contained 15 kilograms of quartz-sand moistened with 3.55 kilograms of water. One vessel was without humic acid; the others contained respectively 1, 3, and 5 p.c. of the weight of the sand. The vessels were exposed freely to the open air for one year, but sheltered from rain and insects, the evaporated water being from time to time replaced. At the end of the experiment the increase of nitrogen with 1 p.c. humic acid was 0.069 gram, with 3 p.c. humic acid 0.239 gram, and with 5 p.c. humic acid 0.454 gram; or, calculating the results for an acre of surface, the increase was respectively 6.24, 21.72, and 41.14 pounds of nitrogen. It is to be observed that the absorption of nitrogen rises more rapidly than the proportion of humic acid present. The experiments do not show that the nitrogen was absorbed as ammonia.

According to Déhéraïn (*Compt. rend.* lxxiii. 1352) humic acid mixed with solution of potash absorbs from the air 7.2 p.c. nitrogen, and humus from old wood mixed with potash absorbs 3.6 p.c.

A peculiar occurrence of humic acid has been observed by T. Lettenmayer (*Deut. Chem. Ges. Ber.* vii. 408). A piece of rotten beech-wood, which had fallen into a cleft of the tree and thus become protected from moisture, was found to be partially covered with a black, glistening, brittle layer of 1 to 2 millimeters in thickness. This was readily soluble, even in cold water, yielding a brown alkaline solution. Acids produced a precipitate consisting of an organic acid of a brownish-red colour. It was found to contain 53.6 p.c. carbon, 4.9 of hydrogen, and but mere traces of nitrogen. After being dried, the acid was insoluble in water, alcohol, and ether, and dissolved with difficulty in alkalis. The original substance was a mixture of the potassium, sodium, and ammonium salts of the acid.

HUMITE. *Chondrodite*.—Elaborate investigations of the crystalline form and chemical composition of this mineral have been made by G. vom Rath.

Crystalline Form (Pogg. *Ann. Ergänzungsband*, v. 320-413; *Jahrbuch für Mineralogie*, 1871, 634).—Vom Rath's observations confirm the discovery of Scacchi, that the crystals of this mineral are referrible to a three-fold type (i. 930). The

numerous combination-faces might indeed be all referred to one primary form; and if we select for this form a pyramid of any one of the three groups or types, then all faces occurring on the same crystal, or on crystals of the same group, may be represented by simple indices; but if the same pyramid be chosen as the primary form of the crystals of the other two groups, the numerous combination-forms of these crystals will be represented by very complicated indices, although they stand to one another in very simple relations, as above observed, with respect to the forms belonging to one and the same group. Nevertheless, the difference between the three primary forms to which the crystals of the three groups must be referred, in order that their combinations may be represented by simple numbers, relate to only one axis, that is to say, to the ratio of this axis to the other two, whereas the lengths of these latter bear the same ratios to one another in all the three groups.

Type I. Calling the macrodiagonal a , the brachydiagonal b , and the principal axis c , the ratios of the axes are:

$$a : b : c = 1.08028 : 1 : 4.40131.$$

The observed forms are:

Pyramids of the principal series	$P, \frac{1}{2}P, \frac{1}{3}P$
Macropyramids	$\frac{1}{2}P_2, \frac{1}{3}P_2, \frac{1}{4}P_2, \frac{1}{5}P_2, \frac{1}{6}P_2$
Prisms	$\infty P, \infty \frac{1}{2}P, \infty \frac{1}{3}P$
Brachydomes	$\frac{1}{2}P_\infty, \frac{1}{3}P_\infty, \frac{1}{4}P_\infty, \frac{1}{5}P_\infty, \frac{1}{6}P_\infty$
Macrodomes	$\frac{1}{2}P_\infty, \frac{1}{3}P_\infty, \frac{1}{4}P_\infty$
Pinacoids	$OP, \infty \frac{1}{2}P_\infty, \infty \frac{1}{3}P_\infty$

Twins occur: (1) with $\frac{1}{2}P_\infty$ as contact-plane; (2) with $\frac{1}{3}P_\infty$. The crystals of the first type are mostly simple; but there are also very regular twins, and, on the other hand, very irregular triple crystals. Cleavage distinctly basal. Colour white, yellowish-white, honey-yellow, chestnut-brown, brown. With the dichroscope, differences of colour are scarcely perceptible; the same also is the case in the other two types.

Type II. $a : b : c = 1.08028 : 1 : 3.14379$.—Whilst the crystalline forms of the first type are invariably holohedral, those of the second exhibit a peculiar and remarkable hemihedry, which converts a portion of the pyramids into hemipyramids. In consequence of this, the crystals of the second type acquire an apparent monoclinic development, whilst the axial elements remain rhombic. The observed forms of this type are:

Pyramids of the principal series	$P, \frac{1}{2}P$
Macropyramids	$2P_2, \frac{3}{2}P_2, \frac{5}{2}P_2, \frac{7}{2}P_2$
Brachypyramids	$3P_2, \frac{5}{2}P_2, \frac{7}{2}P_2$
Brachydomes	$\frac{1}{2}P_\infty, \frac{3}{2}P_\infty, \frac{5}{2}P_\infty$
Macrodomes	$\frac{1}{2}P_\infty, \frac{3}{2}P_\infty$
Pinacoids	$OP, \infty \frac{1}{2}P_\infty$

Twins: (1) with $\frac{1}{2}P_\infty$ as contact-plane; (2) with $\frac{3}{2}P_\infty$. Colour light to dark yellow. The crystals of this type are more interesting than those of the other two, on account of the great variety of their forms; but a searching investigation is often required, not only for the determination of their type, but even of their relation to humite in general.

Type III. $a : b : c = 1.08028 : 1 : 5.65883$.—These numbers, compared with the preceding, show that, with equal secondary axes, the principal axes of the first, second, and third types are to one another as 7 : 5 : 9. This third type includes by far the greatest number of humite crystals; and these crystals are not only the most complicated of the humite species, but likewise the most numerously faced of all known minerals. Hemihedry prevails in this as in the second type; but whereas in the latter the pyramid of the principal series is hemihedrally developed, the corresponding pyramids of the third type are holohedral, and the hemihedry occurs in the macro- and brachy-pyramids. The observed forms are:

Pyramids of the principal series	$P, \frac{1}{2}P, \frac{1}{3}P, \frac{1}{4}P$
Macropyramids	$2P_2, \frac{3}{2}P_2, \frac{5}{2}P_2, \frac{7}{2}P_2, \frac{9}{2}P_2, \frac{11}{2}P_2, \frac{13}{2}P_2, \frac{15}{2}P_2, \frac{17}{2}P_2, \frac{19}{2}P_2$
Brachypyramids	$3P_2, \frac{5}{2}P_2, \frac{7}{2}P_2, \frac{9}{2}P_2, \frac{11}{2}P_2, \frac{13}{2}P_2, \frac{15}{2}P_2, \frac{17}{2}P_2, \frac{19}{2}P_2$
Brachydomes	$\frac{1}{2}P_\infty, \frac{3}{2}P_\infty, \frac{5}{2}P_\infty, \frac{7}{2}P_\infty, \frac{9}{2}P_\infty, \frac{11}{2}P_\infty, \frac{13}{2}P_\infty, \frac{15}{2}P_\infty, \frac{17}{2}P_\infty, \frac{19}{2}P_\infty$
Macrodomes	$\frac{1}{2}P_\infty, \frac{3}{2}P_\infty, \frac{5}{2}P_\infty$
Pinacoids	$OP, \infty \frac{1}{2}P_\infty, \infty \frac{3}{2}P_\infty$

Twins occur with $\frac{1}{2}\bar{P}\infty$ as contact-plane. The colour is mostly brown of various shades, but also yellow, yellowish-white, and white. The colour appears to afford no criterion for the determination of the type. Humite of the third type has hitherto been seldom found together with the first, and never with the second. Its crystals occur especially in two rock-formations, viz., in granular limestone, or in an aggregate of green augite with mica and subordinate separations of lime.

The number of faces observed in humite, including the three pinacoids, and counting the faces common to two types only once, amounts to 135.

Chemical Composition (Vom Rath, *Pogg. Ann.* cxlvii. 246-263).—Rammelsberg (*ibid.* lxxxvi. 404-417), from analyses of chondrodrite from North America and from Pargas, and of the three types of humite, concluded that these three types and chondrodrite are similar compounds of one and the same silicate, $8\text{MgO} \cdot 3\text{SiO}_2$, with varying quantities of a fluoride, $8\text{MgF}^2 \cdot 3\text{SiF}^4$, which may be regarded as isomorphous with the silicate; further, that an increase in the proportion of fluorine is accompanied by a shortening of one of the axes of the crystal, the other two remaining the same. To the proportion 2 : 3 : 4 of fluorine-atoms in the three types III., I., II., correspond primary forms, in which, with equal bases, the vertical axes are as the numbers 1 : $\frac{7}{9}$: $\frac{5}{9}$ or 9 : 7 : 5 (p. 650).

These results seem to show that the atoms of fluorine possess power of essentially modifying the crystalline form. v. Kokscharow has, however, shown that chondrodrite—which was referred by Rammelsberg to the same series, but contains the highest proportion of fluorine, and should, therefore, have a primary form still more obtuse than type II.—really belongs to that type. If, however, two varieties of humite, containing respectively 9 and 5 p.c. of fluorine, can exhibit the same crystalline form, it follows that the morphotropic power supposed to belong to fluorine cannot be exerted in all cases. To throw further light on this point, and determine whether the chemical composition of each of the three types of humite is constant or not, the following analyses were made:—

A pure specimen of each type having been obtained by very careful selection with the aid of the microscope, it was finely pulverised, dried at 100° – 120° , then fused with four times its weight of dry sodium carbonate, and the fused mass continuously boiled in a platinum dish, first with pure water, then with water containing a little ammonium carbonate. The whole of the sodium fluoride was thereby dissolved, the filtrate moreover containing a large quantity of silica and a not inconsiderable quantity of magnesium fluoride. The filtrate was evaporated with repeated addition of ammonium carbonate, and the bulky precipitate, after being well washed with hot water, was united with the residuo of the fused mass. The filtrate, on further addition of ammonium carbonate, deposited a second quantity of silica, which was united with the first, and the small quantity of silica still remaining in solution was separated, as recommended by H. Rose, by means of a solution of zinc oxide in ammonia, the zinc silicate being afterwards decomposed by nitric acid, the liquid evaporated down, and the small quantity of silica contained in it estimated in the usual way. The fluorine was precipitated from the alkaline solution by calcium chloride, and the precipitate containing calcium fluoride and a large excess of carbonate was dried, ignited, and treated with acetic acid, which dissolved the carbonate (mixed with caustic lime) leaving the fluoride as a pasty mass. This was dried on the water-bath in a platinum dish, then treated with hot water, collected on a filter, dried, and ignited, whereby the calcium fluoride was obtained as a white powder. The portion of the original fused mass which was insoluble in water, together with the subsequently separated portions of magnesia and silica, was treated by known methods for the estimation of silica, magnesia, ferrous oxide, lime, and alumina.

Four specimens were examined, three from Vesuvius and one from Sweden.

Type I., from Vesuvius.—Light brownish humite mixed with light green mica, the humite predominating. The mass exhibits cavities (druses), some filled with large thin laminae of mica; some with pure or nearly pure crystals of humite; some also contain very small quantities of calc spar. Sp. gr. 3.208 (at 15°).

Type IIa., from Vesuvius.—Light yellow crystalline granules intergrown with light greenish mica, almost silver-white in thin laminae. A small quantity of admixed calc spar, not mechanically separable, was removed by digestion in acetic acid. Sp. gr. 3.125 (at 13°).

Type IIb., from Sweden.—Crystals, often very impure in the interior, and consisting, to as much as one-half, of grains of galena, laminae of green mica, &c. Sp. gr. 3.057.

Type III., from Vesuvius.—A block, as large as the first, consisting of predominant

humite having an unusual orange-yellow colour, white calcspar, small quantities of greenish and reddish mica, a little white olivine, and isolated slender needles of apatite. Sp. gr. 3.191 (at 17°).

Two analyses were made of each type. The numbers given in the following table are the higher of the two values obtained in each case, as the mode of analysis is adapted to give results in defect rather than in excess.

	I.	IIa.	IIb.	III.
Silica	35.63	34.02	33.96	36.82
Magnesia	54.45	59.23	53.51	54.92
Ferrous oxide	5.12	1.78	6.83	6.48
Lime	0.23	—	—	—
Alumina	0.82	0.99	0.72	0.24
Fluorine	2.43	2.74	4.24	2.40
	98.68	98.76	99.26	100.86

Deducting from the several totals the quantities of oxygen corresponding with the fluorine, we find the following losses:—Anal. I. = 2.34; IIa. = 2.40; IIb. = 2.52; III. = 1.11; whereas an excess might rather have been expected in each case, corresponding with the weight of oxygen replaced by fluorine. These losses appear to be due to water not driven off at 100°–120°, the temperature at which the specimens were dried previous to analysis. Humite dried at 120° gave off 0.34 p.c. water between 120° and 200°.

The following table gives the elementary composition of the several types, after deduction of the oxygen equivalent to the fluorine:—

	I.	IIa.	IIb.	III.
Silicon	16.63	15.88	15.85	17.18
Magnesium	32.67	35.54	32.11	32.95
Iron	3.98	1.38	5.31	3.07
Calcium	0.16	—	—	—
Aluminium	0.44	0.53	0.38	0.13
Fluorine	2.43	2.74	4.24	2.40
Oxygen	41.35	41.54	39.58	43.12
	97.66	97.61	97.47	98.85

If now the iron, calcium, and aluminium be replaced in each case by equivalent quantities of magnesium ($\text{Al}^2 = \text{Mg}^2$), the quantities of magnesium in the three types of humite become:

I.	IIa.	IIb.	III.
35.04	36.82	34.39	34.43;

and dividing these numbers and the quantities of silicon, fluorine, and oxygen by the atomic weights of the respective elements, we find for the relative numbers of atoms of these elements—

	I.	IIa.	IIb.	III.
Silicon	0.594	0.567	0.566	0.613
Magnesium	1.460	1.534	1.453	1.435
Fluorine	0.128	0.144	0.223	0.126
Oxygen	2.584	2.596	2.474	2.695

or, making the number of silicon-atoms = 2, the numbers of the magnesium atoms are:

I.	IIa.	IIb.	III.
5.91	5.41	5.13	4.68

Mean = 5.03.

Hence, neglecting the fluorine, the composition of all humites may be represented by the formula

This formula, which is simpler than the one formerly given by Rammelsberg, viz. $8\text{MgO}.3\text{SiO}^2$, may also be deduced from Rammelsberg's own analyses, if they are calculated with the atomic weight of silicon now adopted.

The relative numbers of molecules of the silicate and of the fluoride, $\text{Mg}^2\text{Si}^2\text{F}^2$, mixed with it are easily calculated from the relative numbers of atoms of the fluorine and oxygen. For 1 atom of fluorine the preceding values give for the numbers of oxygen-atoms:

I.	IIa.	IIb.	III.
20.1	18.0	11.1	21.4

Hence, since each molecule of a fluoride contains twice as many atoms of fluorine as there are atoms of oxygen in the corresponding silicate, it follows that for each molecule of fluoride the numbers of silicate-molecules in the several types are:

$$40\cdot2 \qquad 36 \qquad 22\cdot2 \text{ and } 42\cdot8;$$

and as the differences of fluorine in the three Vesuvian humites scarcely exceed the ordinary errors of analysis, these three humites may be represented by the same formula, viz.:

whereas the Swedish humite contains for the same quantity of fluoride only half that amount of silicate, viz.:

The formula $\text{Mg}^2\text{Si}^2\text{O}^3$ (two-fifths silicate) may be resolved into that of a hemisilicate (or orthosilicate) Mg^2SiO^4 or $2\text{MgO}\cdot\text{SiO}^2$, and that of a tritosilicate $\text{Mg}^2\text{Si}^3\text{O}^5$ or $3\text{MgO}\cdot\text{SiO}^2$; and the fluoride, in like manner, may be regarded as a mixture or combination of Mg^2SiF^8 and $\text{Mg}^2\text{SiF}^{10}$. The hemisilicate is identical with olivine; the tritosilicate is not known in the separate state. Olivine occurs not unfrequently in very small, nearly colourless crystals, accompanying and intergrown with the humite crystals of Vesuvius.

The general conclusions deducible from the preceding analyses are: (1.) All humites are essentially similar in constitution, and the varying replacement of isomorphous constituents has no decided influence on the types. The variation of colour from the lightest yellow to reddish brown, which is observed in each of the types, shows that the replacement of magnesia by ferrous oxide does not affect the type. Moreover, as the quantities of fluorine in the two varieties of type II. are to one another nearly as 1:2, a similar variation in the amount of fluorine may be predicted in the other two types. (2.) Humites contain a small, but perhaps never altogether failing quantity of alumina, comparable perhaps with the small quantity of that substance occurring in augitic minerals and in the enstatite of the meteorite of Ibbenbürgen. (3.) The variation in the amount of silica (which appears also from Rammelsberg's analyses) shows that the composition of the several types of humite is not absolutely constant.

No other silicate occurring on Vesuvius has hitherto been found to contain fluorine. Fluor-spar, which is of extremely rare occurrence in Vesuvian out-casts, has not been found in association with humite.

With regard to the occurrence of humite in Vesuvian out-casts, it may be observed that, whereas some Vesuvian minerals occur chiefly or almost exclusively in blocks of one and the same kind, *e.g.*, mejonite chiefly in limestone blocks, sarcolite exclusively in blocks of green augite, humite is found both in limestone and silicate blocks, the two types of mineral aggregates occurring on Vesuvius. Humites are most frequently associated with mica, light green or reddish-yellow, also with green augite, white olivine, black spinel (ceilanite), and calcespar; more rarely with vesuvian and garnet; still more rarely with sanidin, mejonite, and nephelin.

Of the three types of humite, I. appears to be the rarest, and III. the most abundant.

HYACINTH. See ZIRCON.

HYDANTOIC ACID. See ALLANTOIC ACID, p. 44.

HYDRACIDS. 1. *Constitution in Solution and Inverse Reactions.*—Berthelot (*Bull. Soc. Chim.* [2], xix. 386) has investigated the constitution of the liquids resulting from the union of the hydracids with water, by the indications afforded by the heat produced on dilution, the progressive increase of which with the proportion of water shows the existence of a group of definite hydrates represented by the formulæ—

A second method was to observe when a current of carbonic anhydride passed through the solutions ceased to carry off sufficient acid to give any precipitate with silver nitrate. The limit at 12° corresponds with acids of the composition—

agreeing closely with the results of Bineau, and with those obtained by Roscoe (*Chem. Soc. J.* xiii. 166), and by Roscoe & Dittmar (*ibid.* xii. 128). These hydrates, however, do not seem to be definite combinations, as small quantities of acid are carried off by the current of gas even when much more largely diluted. As it appears, from the experiments of Roscoe & Dittmar, that the difference in composition of the hydrated acids boiling at constant temperatures under pressures varying from 0·60 to 2·50 met. does not vary greatly, being from $\text{HCl} + 6\cdot7\text{H}^2\text{O}$ to $\text{HCl} + 9\cdot3\text{H}^2\text{O}$; $\text{HBr} + 4\cdot2\text{H}^2\text{O}$ to

$5\text{H}^2\text{O}$; $\text{HI} + 4\cdot7\text{H}^2\text{O}$ to $5\cdot5\text{H}^2\text{O}$, Berthelot concludes that they are mixtures of at least two definite hydrates, one of which is stable, whilst the other, the least hydrated, is in a state of partial dissociation varying with the temperature. It is, moreover, the anhydrous acid, and not a definite hydrate, which volatilises below the limit of stability, for hydrobromic acid gas, saturated with the vapour of water, gives the same calorific results on solution as perfectly dry gas.

It would seem, therefore, that concentrated solutions contain a certain amount of anhydrous acid, whose proportion at a given temperature can be calculated, the solutions being mixtures of the hydrates with the anhydrous acid simply dissolved, that is to say, liquefied in them. The precipitation of saturated solutions of the alkaline chlorides by hydrochloric acid also serves to verify the state of hydration of these liquids, the acid taking from the solution of the salt the water necessary to convert it into a stable hydrate. The limit when it ceases to precipitate the salt is $\text{HCl} + 7\cdot5\text{H}^2\text{O}$ with potassium chloride; $\text{HCl} + 6\text{H}^2\text{O}$ with sodium chloride, $\text{HCl} + 9\text{H}^2\text{O}$ with ammonium chloride, and $\text{HCl} + 9\text{H}^2\text{O}$ with barium chloride, the difference in these results being due principally to the greater or lesser solubility of the salt in hydrochloric acid. The results of these determinations are regarded by Berthelot as sufficient to establish the existence of a certain amount of anhydrous acid in concentrated solutions of the hydracids.

The constitution of the hydracids in solution has an important bearing on chemical reactions, especially those in which the action varies with the concentration of the solution, as for example, in the evolution of sulphuretted hydrogen on treating native antimony sulphide with concentrated hydrochloric acid, and the inverse reaction of the precipitation of sulphide of antimony by sulphuretted hydrogen from a solution of antimony chloride in dilute hydrochloric acid; the neutral point here corresponds, at the ordinary temperature, with an acid of the strength $\text{HCl} + 6\text{H}^2\text{O}$. An acid somewhat more concentrated than this attacks native antimony sulphide with disengagement of sulphuretted hydrogen, but on adding a small quantity of water to the liquid, which now contains both antimony chloride and sulphuretted hydrogen in solution, an orange-coloured precipitate of the sulphide immediately makes its appearance. The action of concentrated hydrochloric acid on the antimony sulphide is accompanied by a sensible absorption of heat, due to the formation of the gaseous sulphuretted hydrogen, this absorption being less than the heat of solution of the gas.

In the energetic reducing action exerted by concentrated hydriodic acid, it is really the anhydrous hydracid dissolved which produces the effect 'by virtue of the excess of energy it possesses compared with its definite hydrates,' that is to say the heat corresponding with the transformation of the anhydrous acid contained in the solution into certain stable hydrates. A similar explanation may be given of the inverse action of concentrated hydriodic acid on sulphur, producing sulphuretted hydrogen, and of sulphuretted hydrogen on iodine in presence of a large amount of water, forming hydriodic acid, the neutral point appearing to correspond with an acid of the strength indicated by the formula $\text{HI} + 7\text{H}^2\text{O}$, which is the same as for the inverse actions of concentrated sulphuric acid on concentrated hydriodic acid, and of sulphurous anhydride on iodine in presence of water.

Berthelot concludes, therefore, that dilute solutions of the hydracids contain only definite and stable hydrates, whilst concentrated solutions contain at the same time hydrates in a state of dissociation, and also a certain proportion of anhydrous acid. In the phenomena of inverse chemical reactions produced by these two kinds of solutions, it is the anhydrous acid which effects certain reactions, whilst the hydrates are either indifferent or even produce an inverse action.

2. *Reciprocal Displacement of the Hydracids.*—It is well known that the reciprocal displacements of the hydracids are very often the reverse of those exhibited by the corresponding halogen elements. Thus, on the one hand, chlorine displaces bromine, and both expel iodine from its compounds with silver and the alkali-metals, while, on the other hand, hydriodic acid decomposes bromides and chlorides. Berthelot explained these facts some time ago (*Compt. rend.* lxiv. 414), by showing that the reaction which occurs by preference is always the one which evolves most heat. But the calculations having been founded on determinations which more recent experience has rendered doubtful, he has reinvestigated the thermic relations of the halogens and their hydrogen-acids with the metals potassium, silver, and mercury. The result confirms in every way his previous views, with the exception that the heat developed by the reaction of potassium hydrate with the three hydracids is practically the same for each, when the salts produced are the same in solution. But even in this case the heat of formation of the solid salts is in accordance with the general law.

No constant difference appears to exist between the thermic effects either of the halogens or of the hydracids. Thus, whilst with potassium hydrate the three acids evolve identical quantities of heat, the formation of mercuric iodide from the base and

acid disengages 19·2 heat-units more than the formation of the chloride: with silver oxide and hydriodic acid the heat exceeds by 11·2 units that of the corresponding reaction with hydrochloric acid. Similarly the substitution of chlorine for iodine in the mercury salt disengages less heat than in the salt of any other metal. In the case of the alkali-metals, however, and also with certain non-metallic chlorides, &c., an approximation to a constant difference is observed.

Although the heat of formation of the three potassium salts is the same, the acid with a higher equivalent will nevertheless replace one with a lower. This fact may be demonstrated by mixing each of the three hydracids with the potassium salt of the two others in dilute solution, and then evaporating the mixture. An excess of hydriodic acid (2 equivalents) displaces the other two acids, almost completely, and a similar excess of hydrobromic acid as perfectly expels hydrochloric acid; but with single equivalents of the acid and salt, the substitution is incomplete, the residue always containing salts of both acids, that with the higher equivalent, however, preponderating. The numbers furnished by reciprocal reactions are generally nearly the same; and further, although hydrochloric acid is able to expel a small proportion of the other acids, it does so very imperfectly even when in large excess.

These facts admit of the following explanation:—The two hydracids divide the base between them when the solution is dilute, but when during evaporation the point is reached at which a definite hydrate (or rather a system in which the hydrate, the anhydrous acid, and the vapour of water are in a state of equilibrium) begins to pass off, the hydrochloric acid escapes with greatest facility, because in such a system this acid possesses a higher tension of dissociation than the two others at the same temperature (*Compt. rend.* lxxvi. 742); and though the stability of the hydrates of the two latter is very nearly the same, yet the greater volatility of the bromhydric hydrate is the cause of its passing off in preference to the less volatile iodhydric hydrate. Nevertheless, since the anhydrous acid in both the latter hydrates possesses a certain tension of dissociation, it follows that when the two acids are present in equivalent proportions, or when the more volatile preponderates, a portion of the less volatile will in all cases be lost.

That a division of the base between the two acids actually takes place, may also be demonstrated by adding concentrated hydrochloric acid to a saturated solution of potassium iodide, when a precipitate is obtained consisting of almost pure potassium chloride.

HYDRACRYLIC ACID, $C^3H^3O^3$. An isomeric of lactic acid obtained by the action of moist silver oxide on β -iodopropionic acid (see LACTIC ACID).

HYDRARGILLITE. This mineral occurs (a) in Chester Co., Pennsylvania, as a stalactitic deposit on brown hematite; hardness = 3; sp. gr. = 2·35; (b) at Villarica in Brazil, in spherical lumps of the size of a hazel-nut, cemented together by brown hematite, sometimes radio-fibrous; hardness = 3; sp. gr. = 2·39.

	Al^2O^3	Fe^2O^3	H^2O	SiO^2	P^2O^3	MgO	FeO
a. 63·84	—	33·45	1·50	0·91	trace	trace	90·70
b. 63·60	2·00	34·40	—	—	—	—	100

The formula $Al^2O^3 \cdot 3H^2O$ requires 65·54 p. c. Al^2O^3 and 34·46 H^2O (R. Hermann, *J. pr. Chem.* cvi. 70).

HYDRASTINE. An alkaloid occurring, together with berberine, in the rhizome of *Hydrastis Canadensis* or Golden Seal. It crystallises in white shining four-sided prisms, which lose their transparency when dried. It is very bitter and pungent, and provokes in the mouth a feeling of numbness, which causes it to be employed in America as a local anæsthetic. It is nearly insoluble in water, freely soluble in alcohol, ether, chloroform, and benzene. As the last three do not dissolve berberine, the hydrastine may be easily extracted by treating the powdered root in a displacement apparatus with either of these solvents. The proportion so obtained is about 1½ per cent. (*Pharm. J. Trans.* [3], iii. 604).

HYDRAZOTOLUENE. See TOLUENE DERIVATIVES.

HYDRAZULMOXIN, $C^8N^3H^8O$. A compound formed by the action of water on azulmin, $C^8N^3H^8$, which is formed by the combination of cyanogen with ammonia (p. 416).

HYDRISALIZARIN. See ALIZARIN, p. 40.

HYDROACRIDINE, $C^{21}H^{20}N^2$. See ACRIDINE, p. 26.

HYDRO-AMIDO-TETRAZO-RESORUFIN. See RESORCIN, AZO-DERIVATIVES OF.

HYDROBENZÖIN. See BENZOÏN, p. 171.

HYDROBILIRUBIN. See BILE-PIGMENTS, p. 100

HYDROBORO-CALCITE, more properly called **BORONATRO-CALCITE**. In a commercial sample of this mineral from South America, Graeger (*N. Jahrb. Pharm.* xxxi. 201; *Chem. News*, xx. 119) found—together with 3.76 p.c. NaCl, 1.06 Na₂SO₄, and 4.23 residuo, which must be regarded as impurities—the following quantities of the essential constituents:—

CaO	Na ₂ O	B ₂ O ₃	H ₂ O
17.03	4.26	52.73	25.98 = 100.00

These proportions may be nearly represented by the formula 6(CaO.2B₂O₃) + Na₂O.2B₂O₃ + 18H₂O, which requires 17.85 CaO, 3.29 Na₂O, 52.07 B₂O₃ and 26.70 H₂O.

The composition of the mineral is doubtless variable. Rammelsberg, from his own analyses, deduced the formula 2(CaO.2B₂O₃) + Na₂O.2B₂O₃ + 18H₂O (1st Suppl. p. 366). Graeger also describes a method of utilising the mineral for the preparation of borax.

HYDROCARBONS. *Formation* (F. Pfankuch, *J. pr. Chem.* [2], iv. 35; vii. 97).—Potassium phenate and potassium benzoate yield, when heated together, potassium carbonate and diphenyl. Potassium phenate distilled with potassium acetate yields methylbenzene (toluene); and potassium ethylate distilled with potassium benzoate furnishes ethylbenzene, the yield in both cases being small, in consequence of carbonisation. The addition of pumice or fine sand, and the use of an excess of the acid, increases the product.

The dry distillation of a mixture of potassium phenate and valerate yields isobutylbenzene, boiling at 160°. A mixture of potassium phenate and chlorobenzoate gives monochlorodiphenyl C⁶H⁴Cl melting at 89°. Similarly a mixture of potassium acetate and tribromophenate gives tribromotoluene, C⁶H³Br₃, which crystallises from alcohol in small white needles melting at 150°.

On distilling a mixture of potassium phenate and succinate, a distillate is obtained, yielding, on addition of soda, an oil separable by rectification into toluene and a portion which exhibits a tendency to crystallise and has a very unpleasant smell; its nature has not yet been determined. Potassium phenate and oxalate yield diphenyl, readily obtained pure by washing with soda, then dissolving in alcohol, and precipitating with water. Mononitrodiphenyl is the product of the distillation of a mixture of potassium phenate and nitrobenzoate.

Hydrocarbons are also formed by the action of sulphur on the salts (chiefly barium salts) of organic acids. On heating barium benzoate with sulphur, there is obtained, besides benzene, a crystalline product in considerable quantity, which, under the microscope, is seen to consist principally of two different bodies. The greater portion is toluene, C⁶H⁵, mixed with sulphotoluene. To obtain the toluene pure, the mixed product is either distilled over finely divided lead, obtained from lead acetate by precipitation with zinc, &c., or it is heated in ethereal solution in sealed tubes with lead or copper, and then fractionally distilled. Reaction takes place in the main according to the equation:—

By distilling a mixture of barium acetate and sulphur, and removing the sulphur from the product by means of copper or lead, a liquid hydrocarbon C⁶H⁸ (divinyl) is obtained. It is a light oil boiling at about 20°, and having an extremely sharp persistent, but not unpleasant, odour.

Action of Phosphonium Iodide on Aromatic Hydrocarbons.—The reducing action of phosphonium iodide, PH₄I, or phosphine hydriodide PH₃.HI, is not so powerful as that of hydrogen iodide (1st Suppl. 740). It carries the reduction of hydrocarbons only to the same point as sodium-amalgam does when acting on the acids: consequently, it does not give rise to any compound of the methane series. The stronger reducing power of hydrogen iodide appears to be due to the presence of free iodine, which unites temporarily with the hydrocarbon, and may thus to a certain extent make way for the hydrogen. Now phosphonium iodide is resolved by heat into phosphine and hydrogen iodide, and all the iodine set free by the reducing action is immediately taken up by the phosphine, which is thereby reconverted into phosphonium iodide, with formation of phosphorus iodide.

Benzene is not attacked by phosphonium iodide even at 350°. *Toluene* repeatedly and continuously treated with it, finally at 350°, takes up 2 at. hydrogen and is for the most part converted into C⁶H¹⁰, which boils at 105°–108°. *Xylene* (commercial) is reduced to a hydrocarbon C⁶H¹² which boils at 122°–126°. *Mesitylene* is more easily

reduced than the preceding hydrocarbons; when treated four times with phosphonium iodide, finally at 280° , it is almost wholly converted into hexhydromesitylene C^6H^{12} boiling at 135° – 138° . *Naphthalene* yields an oil boiling at 170° – 190° , and another $C^{10}H^{12}$ boiling at 201° . *Turpentine oil* boiling at 160° gives a hydrocarbon $C^{10}H^{20}$ which likewise boils at 160° and is very stable. These results show that the assumption of hydrogen by aromatic hydrocarbons under the influence of phosphonium iodide is related to the number of methyl groups contained in their molecule, 2 at. hydrogen being taken up for each atom of methyl present (A. Baeyer, *Ann. Ch. Pharm.* civ. 266).

Action of Platinum and Palladium on Hydrocarbons.—The action of platinum made red-hot and plunged into the vapours of alcohols and ethers, which then keep up the incandescence, appears to extend to all hydrocarbons, volatile oils, bodies similar to aniline, &c., but not to the fixed oils, or sulphuretted essential oils. The products of the imperfect combustion, in every case yet examined, are the aldehyde or acid, or both, analogous to the substance experimented upon. The apparatus employed was modified in different cases, but it consisted essentially of a tube containing the incandescent platinum wire, through which was passed a mixture of air and the vapour, the products being collected in a condenser connected with an aspirator. Toluene treated in this manner yielded bitter almond-oil, which, on exposure to air, was converted into benzoic acid. Marsh-gas did not maintain the incandescence unless the wire was heated by the pile till the action had fairly commenced. Davy found, it is true, that the wire suspended above the flame of his safety-lamp remained red-hot after an explosion of marsh-gas, but this was probably due to the presence of other hydrocarbons. The product of the reaction started by the pile is formic acid; no aldehyde could be obtained. Ethylene-vapour, if allowed to pass very slowly over the platinum, keeps the latter red-hot without an explosion taking place, acetic acid being formed. Many other metals act in the same way as platinum, but on account of their melting when heated in a flame, the experiment is difficult to make. Palladium is a better agent in partial oxidation than even platinum. Marsh-gas keeps it red-hot without the aid of the pile. It is also safer than platinum; no instance occurred of its causing ethylene to explode. Other peculiarities of this metal are that it becomes wrinkled on the surface, is rendered brittle, and diminishes in weight after a few days' use in these experiments (J. A. Coquillon, *Compt. rend.* lxxvii. 444).

HYDROCOUMARIC ACID. This term is used in the *First Supplement* (p. 715) as synonymous with melilotic acid, $C^9H^{10}O^4$, the acid which exists combined with coumarin in the yellow melilot, and is produced artificially by the action of nascent hydrogen on coumarin. But from more recent experiments by Zwonger (*Ann. Ch. Pharm. Suppl.* viii. 23) it appears that this synthetic process yields two distinct acids, according to the proportion between the nascent hydrogen and the coumarin, viz., monobasic melilotic acid, $C^9H^{10}O^4$, when the solution contains only a small quantity of coumarin and the nascent hydrogen is in excess; and bibasic hydrocoumaric acid, $C^{10}H^{10}O^4$, when the coumarin is in excess.

To prepare hydrocoumaric acid, a concentrated solution of coumarin in strong alcohol is repeatedly treated on the water-bath with thick pasty sodium-amalgam; sodium-hydrocoumarate then separates out, and may be freed from coumarate and melilotate of sodium by boiling with absolute alcohol. The portion of the acid still remaining in the alkaline mother-liquor may be obtained by evaporating off the alcohol, acidulating with acetic acid and precipitating with lead acetate. The precipitate, after repeated boiling with water, is decomposed by hydrogen sulphide, the acid liquid evaporated to the crystallising point, and the acid which separates, purified by conversion into the sodium salt, &c.

Hydrocoumaric acid, $C^{10}H^{10}O^4$, is slightly soluble in cold, easily in boiling water, and separates therefrom in needles or granular crystals. In ether and in alcohol it is easily soluble. When heated it gives off water at 100° , and is converted into its anhydride, hydrocoumarin. It is not altered by sodium-amalgam.

Hydrocoumaric acid is bibasic. Its ammonium salt does not crystallise. The sodium salt, $C^{10}H^8Na^2O^4 + 10H^2O$, dissolves easily in warm water, and crystallises therefrom in shining colourless tabular prisms: it is dehydrated by alcohol. The lead salt $C^{10}H^8PbO^4$, silver salt $C^{10}H^8Ag^2O^4$, and copper salt $C^{10}H^8CuO^4$, are bulky precipitates, the first two becoming crystalline when left in the liquid.

Hydrocoumarin, $C^{10}H^{10}O^2$, which is best prepared by fusion of hydrocoumaric acid, washing the fused mass with alcohol, and recrystallising from chloroform, is likewise formed, together with melilotic and hydrocoumaric acids, by the action of sodium-amalgam on the aqueous solution of coumarin containing a little alcohol. It forms colourless shining laminae, melts at 222° , is decomposed by prolonged fusion.

It is nearly insoluble in water, alcohol and ether. By boiling with dilute nitric acid, it is converted into a nitro-compound; ammonia and dilute aqueous potash do not act upon it; alcoholic potash converts it into hydrocoumaric acid. It is not converted into mellilotic acid by sodium-amalgam. When fused with potash it yields acetate and salicylate of potassium: $C^{10}H^{10}O^4 + 6H^2O = 2C^2H^3O^2 + 2C^2H^3O^2 + 3H^2$.

HYDROCERULIGNONE, $C^{14}H^{18}O^6$. See CERULIGNONE (p. 376).

HYDROCOTARNINE. See OPIUM-BASES.

HYDRODIBROMAZOBENZENE, $C^{12}H^{10}Br^2N^2$. See BENZENE, AZO-DERIVATIVES OF (p. 148).

HYDRODICHLORAZOXYBENZENE, $C^{12}H^{10}Cl^2N^2O$. See BENZENE, AZO-DERIVATIVES OF (p. 151).

HYDRODINITRAZOBYBENZENE, $C^{12}H^{10}(NO^2)^2N^2$, is formed by the action of cold ammonium sulphide on dinitrazobenzene, just as hydrazobenzene is formed from azobenzene. It is insoluble in water, and crystallises from boiling alcohol in long yellow needles melting at 220° . Oxidising agents reconvert it into dinitrazobenzene. Heated to 220° – 250° , it splits up into dinitrazobenzene and nitraniline, just as hydrazobenzene is decomposed by distillation into azobenzene and aniline (1st Suppl. 272).

The nitraniline thus obtained melts at 110° and is identical with that which is prepared from dinitrobenzene.

By the action of hot ammonium sulphide, hydro-dinitrazobenzene is easily converted into diphenine or hydro-diamido-azobenzene, $C^{14}H^{10}(NH^2)^2N^2$, which indeed is formed directly from dinitrazobenzene by the action of hot ammonium sulphide (p. 436) (Lermontoff, *Deut. Chem. Ges. Ber.* v. 236).

HYDROGEN. On the Evolution of Hydrogen in Alcoholic Fermentation, see FERMENTATION (p. 517).

Preparation of Pure Hydrogen Gas.—Kolbe (*Dingl. polyt. J.* cciv. 160) draws attention to the necessity of using dilute sulphuric acid in the preparation of hydrogen when required in the pure state. He finds indeed that sulphuric, as well as sulphurous, acid can be reduced to hydrogen sulphide by the action of nascent hydrogen, and consequently that hydrogen gas evolved by the action of zinc, even on perfectly pure sulphuric acid, often smells strongly of hydrogen sulphide and blackens lead-paper. The hydrogen sulphide is more abundant, the hotter the acid liquid, and the more concentrated the sulphuric acid which comes in contact with the zinc. If the acid be previously diluted with twice its volume of water, the evolved gas is perfectly free from hydrogen sulphide. Attention to this point is especially necessary in the detection of small quantities of arsenic by Marsh's process, as if the hydrogen contains sulphur, the arsenic may be converted into sulphide and so escape detection.

C. Violette finds that hydrogen, after passing through lead nitrate, silver nitrate, silver sulphate, caustic potash, and oil of vitriol, is perfectly free from hydrocarbons, inasmuch as on passing it over pure copper oxide at red heat, condensing the water in a U-tube, and passing the gaseous products into baryta-water, no opacity is produced in the latter, and the condensed water is quite free from acid reaction.

On the Estimation of Typical Hydrogen in Ammonia-bases, see AMINES (p. 56).

Combination of Hydrogen with Chlorine in the Absence of Light.—When charcoal absorbs dry chlorine, the temperature rises, and if dry hydrogen be brought in contact with the charcoal saturated with chlorine, hydrochloric acid is formed in considerable quantity, while at the same time chlorine is given off and the temperature falls (Melsens, *Compt. rend.* lxxvi. 92).

Absorption of Hydrogen by Palladium.—Roberts a. Wright (*Chem. Soc. J.* [2]. xi. 112) have endeavoured to determine the state of the hydrogen absorbed by palladium by a comparison between the specific heat of the charged palladium, and that of the palladium in its original state. If the hydrogen, as Graham supposed, enters into the combination as a metal, and the resulting compound is an alloy, then, according to what is known of alloys in general, the specific heat of the charged palladium should be a mean between the specific heats of palladium and of hydrogen in the free state. The experiments show that this is not the case; and that the charged palladium is neither an alloy, nor a mixture of palladium hydride with excess of palladium, but that each several charge must be regarded as giving rise to a distinct compound; and therefore that hydrogen and palladium are capable of combining together in proportions which are not expressible by simple multiples of the combining elements.

Favre, on the other hand (*Compt. rend.* lxxvii. 649), considers palladium charged with hydrogen as a true alloy, because the heat developed by the combination (9,000 gram-degrees) is the same for the last as for the first portion of hydrogen added; whereas the absorption of hydrogen by platinum, and that of other gases by charcoal, are merely cases of capillary affinity, in which the gas may be supposed to form a layer whose density diminishes with increased distance from the surface of the solid; this is indicated by the fact that the later portions of gas absorbed evolve less heat than the earlier. The complete saturation of platinum-black with hydrogen (244 volumes) disengages about 20,700 heat-units for one gram of hydrogen absorbed.

Troost & Hautefeuille (*Compt. rend.* lxxviii. 988) likewise find that palladium forms with hydrogen, a definite compound, Pd^2H , which is further capable of absorbing hydrogen in considerable quantity. The density of the pure compound is 11.06, and that of the melted metal from which it was prepared was 12.0. Supposing, therefore, that the elements unite without condensation, that is to say that the hydrogen in combination with the palladium has the same density that it would have if solidified in the free state, the density of this solidified hydrogen will be 0.62. The same value has been obtained by Dewar (*Phil. Mag.* [4], xlvii. 324), from calculations based upon his own experiments. Graham estimated it at 0.733 (*1st Suppl.* 718), but his calculations appear to have been based on the supposition that the compound of palladium and hydrogen was not of definite constitution.

Troost & Hautefeuille (*Compt. rend.* lxxviii. 807) have also examined the compounds of hydrogen with potassium and sodium. They find that both are definite compounds possessing the metallic lustre, and represented by the formulæ K^2H and Na^2H .

To prepare the potassium-compound, the potassium was placed in a small iron vessel at the bottom of a glass tube; the latter communicated with a manometer, and by means of a three-way tap, with a Sprengel pump, and with a supply of dry hydrogen. No gas was absorbed at temperatures below 200° , but on heating the metal to 350° or 400° absorption proceeded more rapidly. It required, however, 250 hours to saturate 2.5 grams of potassium at a temperature of 200° .

The hydrogenised potassium (potassium hydride) is very brittle at the ordinary temperature, and resembles an amalgam of silver in outward appearance, lustre, and crystalline structure. It can be melted in hydrogen or in a vacuum without undergoing alteration, but if brought into contact with air it takes fire immediately. In a vacuum at about 200° , it begins to decompose, and at 411° the tension of the hydrogen is 760 mm.; in order therefore to saturate potassium at this temperature, it is necessary to heat the metal in an atmosphere of hydrogen the pressure of which is a little above that of the atmosphere. The definite compound absorbs hydrogen in quantities varying with the temperature and pressure; thus at 300° and 760 mm. it dissolves 40 vols. of gas; it is necessary, therefore, in order to obtain the definite combination alone, to expel the gas until the pressure of the hydrogen is no higher than the tension of dissociation for the particular temperature at which the experiment is made.

By extracting the gas with the mercurial pump, it was found that one vol. of potassium was combined with 126 vols. of hydrogen; the formula K^2H requires 124.6 vols.

The sodium-compound is prepared in a manner precisely analogous to that already described. Unlike potassium hydride, it is as soft as sodium at the ordinary temperature, but becomes brittle and easily pulverisable a little before fusion. It is silver-white, and less alterable in the air than the corresponding potassium-compound. The density, taken in naphtha, was 0.959, that of the sodium employed being 0.970; consequently, if the elements are united without condensation, the density of the hydrogen in the compound is 0.63, which is a little higher than that of lithium 0.59. The compound dissolves only small quantities of hydrogen; at 400° , under the atmospheric pressure, it takes up only 3 or 4 times its volume.

Lithium, heated to 500° , under a pressure of 760 mm., absorbs 17 times its volume of hydrogen. Thallium, under similar conditions, dissolves only 3 times its volume.

The hydrogen absorbed by palladium is an active reducing agent. A thin palladium plate covered with palladium black on both sides by means of a battery, and charged with hydrogen, may be kept for weeks in alcohol or ether without losing the hydrogen, excepting that a few bubbles come off at first; but if quickly removed, dried, and wrapped in gun-cotton, it glows in a few seconds, the gun-cotton explodes, and the hydrogen burns for a few seconds with a pale flame. In ether, the gas-bubbles which come off seem to consist partly of ethylene formed by deoxidation. Potassium nitrate is soon reduced to nitrite by the charged palladium (Böttger, *Deut. Chem. Ges. Ber.* vi. 1396).

Seytzeff (*J. pr. Chem.* [2], iv. 418), by passing a mixture of the vapour of benzoyl chloride and hydrogen over heated palladium-black, obtained hydrochloric acid and an

oil apparently consisting of benzoic aldehyde mixed with benzyl alcohol. In a similar manner nitrobenzene may be reduced to aniline.

Reduction of Silver Nitrate by Hydrogen.—The precipitation of small quantities of silver by pure hydrogen from solutions of the sulphate, nitrate, and acetate, has been known for some time (1st Suppl. 718), and recently this reaction has been more particularly studied by W. J. Russell (*Chem. Soc. J.* [2], xii. 3). The precipitation takes place with perfectly pure hydrogen, and more readily in a saturated than in a dilute solution. Even from a saturated solution, however, the precipitation occurs only after some time, and the amount precipitated, as compared with that in solution, is always very small. When a saturated solution is used, hydrogen must be bubbled through it for nearly half an hour before precipitation takes place; if the current be continued, a dull greyish substance separates out at first, but afterwards the precipitate is perfectly crystalline and bright, exhibiting a beautiful appearance. At first the amount of silver precipitated is nearly proportional to the time for which it has been exposed to the action of the hydrogen, but after the first 48 hours the amount of silver precipitated increases at a slower and slower rate, and after a certain time the amount of silver present will often begin to diminish. This precipitation of silver by hydrogen is independent of the action of light, but is very much expedited by heat.

On passing hydrogen through the silver nitrate solution only for a minute, and then heating it, a very visible, although not very heavy precipitation immediately appears; it is amorphous, and of a brownish colour. Through a cold solution hydrogen may be passed for about 25 minutes without producing the slightest alteration in appearance. If the solution be then exposed to the air, so that the gas above the liquid diffuses away, silver begins to precipitate after a short time, and a considerable amount will in this way separate out.

The precipitated silver, when examined by the microscope, sometimes exhibits arborescent forms, sometimes appears as a close network of very fine filaments, so intertwined that the whole of the metal can be lifted out of the solution in a connected mass; sometimes it is seen to be in distinct and separate triangular plates of brilliant metal.

The silver prepared by this means is remarkably pure; any gold in the solution would be precipitated with the first portions of silver, and the other metals likely to be present would not be separated out by the hydrogen.

The precipitation may also be effected by merely keeping an atmosphere of the gas above the solution, instead of bubbling it through. If a saturated solution of the silver nitrate be put into a tolerably capacious bottle, and it be then filled with hydrogen, the action will commence rather sooner than if the gas were bubbled through it, and in 18 to 24 hours a somewhat larger amount of silver will be precipitated than by the other process.

The precipitation of the silver, however, cannot be continued indefinitely; indeed, if the solution be left for some time in contact with the atmosphere of hydrogen, the quantity of metallic silver is found to diminish, and, after a few days, yellow crystals of silver nitrite separate out. This result appears to be due in the first instance to the formation of a trace of nitrous acid by the action of the hydrogen on the nitric acid present, this nitrous acid attacking the precipitated silver and combining with it. At the same time nitrogen dioxide is given off, which, by acting on more nitric acid, forms more nitrous acid, thus accelerating the solution of the silver. If much nitric acid be present, the silver nitrite naturally passes back again to nitrate, and this may again be acted upon by the hydrogen. The silver nitrite, on the contrary, is unacted on by hydrogen, and will therefore be the end-product formed by this reaction.

With regard to other metals, *platinum*, *palladium*, and *gold* are completely precipitated from solution by hydrogen in the metallic state, and at ordinary temperatures and pressures. A solution of *copper nitrate*, by long standing in contact with hydrogen, becomes, apparently from the change of colour, converted into nitrite. *Mercuric nitrate* seems to be acted on, and a basic nitrate thrown down, while *bismuth nitrate* seems not to be at all attacked.

Hydrogen Dioxide, H^2O^2 . Houszeau (*Compt. rend.* lxx. 519) has demonstrated the existence of this body in snow fallen at Rouen at various times.

The simultaneous formation of *hydrogen dioxide*, *ozone*, and *ammonium nitrite* in the combustion of hydrogen in the air may be shown by burning a small hydrogen flame under a funnel having its neck drawn out to a long tube. The gases issuing from the tube smell strongly of ozone, which may be further identified by means of *china-paper*, &c. The water which condenses is perfectly neutral, and the presence of hydrogen dioxide and ammonium nitrite in it may be demonstrated by the reactions of these compounds with potassium iodide. The formation of these bodies in the combustion

of hydrogen-compounds in the atmosphere may account for their presence in atmospheric deposits (H. Struve, *N. Peters. Acad. Bull.* xv. 325; *Jahresb.* 1870, 199, 209).

Reactions.—According to Schönn (*Zeitschr. anal. Chem.* ix. 41, 330) the transient colorations exhibited by certain compounds at high temperatures may be permanently produced by means of hydrogen dioxide. When solid *molybdic acid* or *sodium molybdate* is saturated with hydrated barium dioxide, the mass assumes a faint yellow colour even during the trituration, but on adding an acid, e.g. a few drops of concentrated sulphuric or silicofluoric acid, a deep yellow mass is obtained. *Titanic acid* precipitated by boiling immediately acquires a deep reddish-yellow colour when similarly treated. Solutions of titanic acid are also instantly coloured deep reddish-yellow by a solution of hydrogen dioxide in presence of acids. A solution of molybdic acid or sodium molybdate is turned yellow by an acid solution of hydrogen dioxide, without evolution of gas in either case. On brisk agitation, however, the molybdic acid solution often gives off gas and becomes decolorised. Blue molybdic molybdate is first oxidised and decolorised by hydrogen dioxide, with evolution of gas, but afterwards turns yellow. A solution of titanic acid, which has been turned violet by reducing agents, is coloured deep reddish-yellow by hydrogen dioxide without perceptible previous decoloration. Sodium peroxide reacts with the substances above mentioned in the same manner as barium peroxide. On this account a deep red solution is often obtained in decomposing titanium compounds with sodium. Zinc oxide and stannic oxide do not exhibit any coloration.

Molybdic and titanic acid solutions coloured by hydrogen dioxide become colourless again under the influence of reducing agents such as stannous chloride, zinc-dust, and ferrous oxide. These effects may be explained by supposing either that the coloured substances are merely modifications of the colourless bodies, or, which is perhaps more probable, that the colourless acids take up oxygen from the hydrogen dioxide, and this oxygen, being but loosely combined with them, is easily given up again. A concentrated solution of titanic acid may be used as a test for hydrogen dioxide; it is as delicate as other tests used for the purpose, e.g. reagents containing iodine, and the colour which it gives can only be produced by hydrogen dioxide, not by nitrous acid or other oxidising agents (Schönn).

Hydrogen Sulphide, H^2S . **Formation.**—According to Boillot (*Compt. rend.* lxx. 97) sulphur unites directly with hydrogen under the influence of the electric spark.

Preparation.—W. Skay (*Chem. News*, xxvii. 161) proposes to supersede the ordinary laboratory process for the preparation of hydrogen sulphide by the following. The generating flask is charged with fragments of galena and granulated zinc in about equal proportions, and the mixture is covered with dilute hydrochloric acid (1 to 20). An energetic and regular current of sulphuretted hydrogen is then evolved. The gas, accompanied by a little free hydrogen, and requires washing to remove traces of hydrochloric acid.

The apparatus may also be arranged as a simple galvanic couple, in which a piece of massive galena occupies the position of the negative element; the connecting wires are passed through the cork of the apparatus, and are brought into contact with each other by means of binding screws. The evolution of gas commences on making the connection, and ceases instantly when the current is interrupted. This latter arrangement, though somewhat more troublesome to prepare, is nevertheless to be preferred, inasmuch as it avoids the necessity of removing the exciting liquid when the evolution of gas is no longer required.

Decomposition of the Aqueous Solution.—Experiments by L. Raab (*N. Rep. Pharm.* xix. 10) show that the decomposition of aqueous hydrogen sulphide is retarded by keeping it in the dark and in a corked bottle, and still more by inverting the bottle and plunging its neck into water.

reasons, especially on account of the totally different behaviour of the benzhydroxamates and dibenzhydroxamates: the benzhydroxamates therefore are probably represented by the formula $C^6H^5O.NH.OM$.

HYDROZINCITE. This mineral, originally found at Bleiberg in Carinthia, and analysed by Smithson in 1803 (called *zinc-bloom* by Rammelsberg, and *zinconise* by Boudant), occurs as a white earthy coating on the deposits of calamine associated with galena in the Argentiera Mine situated in the Commune of Auronzo, in the extreme northern limit of the Cadore. This earthy deposit contains 14.55 p.c. CO_2 , 73.21 ZnO and 11.83 H^2O , answering to the formula:

and not differing greatly in composition from the hydrozincites hitherto examined (i. 798).*

For the understanding of the formation and decomposition of minerals, it is important to ascertain the intensity of the solvent action exerted upon them by water saturated with carbonic acid. In this respect the carbonates of zinc, native and artificial, exhibit considerable diversities, as the following table will show:—

	Quantity of material dissolved by 1,000 parts by weight of water saturated with CO_2 .	Temp.	Pressure
Hydrozincite of Auronzo . . .	0.355	18°	758 mm.
Basic zinc carbonate precipitated in the cold	0.742	17°	759 „
Smithsonite ($ZnCO_3$) from Tarnowitz, in well-defined crystals	0.367	18°	753 „
Smithsonite from Moresnet, perfectly crystallised	0.435	14°	757 „
Stalactitic calamine from Domojovos (Iglesias)	0.850	15°	749 „

Basic zinc carbonate obtained by precipitation, perfectly washed and dried at 100° was found to contain 14.18 p.c. CO_2 , 64.89 ZnO, and 20.15 water. The Smithsonites of Tarnowitz and Moresnet consist of very pure normal zinc carbonate. The calamine of Iglesias gave by analysis—

H^2O and CO_2	SiO_2	ZnO	FeO	CuO	PbO
12.20	23.07	58.64	3.88	0.45	trace = 98.24.

The solution of this mineral in carbonic acid water contained—besides zinc carbonate-silicic, ferrous oxide, and a trace of copper oxide.

The carbonic solution of the hydrozincite of Auronzo, yielded by spontaneous evaporation a crystalline powder containing 12.98 p.c. CO_2 , 71.25 ZnO, and 15.16 H^2O , which may be represented by the formula $4ZnO.3CO_2 + 4aq$, identical with that of the hydrozincite from Bleiberg, analysed by Smithson.

HYOSCINE, $C^6H^{12}N$ (Höhn n. Reichardt, *Ann. Ch. Pharm.* cxlvii. 98). An alkaloid formed, together with hyoscinic acid, $C^6H^{10}O^2$, by boiling hyoscyamine with baryta-water:

The boiling must be continued for several hours, the excess of baryta precipitated by carbonic acid, and the liquid evaporated to dryness, mixed with a little water and hydrochloric acid, and exhausted with ether, which dissolves out the hyoscinic acid, leaving the hyoscinic in the acid liquid; and on freeing this liquid from hydrochloric acid by means of silver oxide, evaporating to dryness, dissolving the residue in alcohol, removing traces of baryta by carbonic acid, and again evaporating, the hyoscinic remains as an oily strongly alkaline liquid, having a narcotic odour, and solidifying to a crystalline mass on cooling. The *hydrochloride*, $C^6H^{12}N.HCl$, is deliquescent. The *platinchloride* crystallises in beautiful rhombic plates; when boiled with strong potash- or soda-ley, it gives off vapours having a strong alkaline odour.

A small quantity of hyoscinic distils over with the aqueous vapour, together with traces of ammonia, when hyoscyamine is boiled with baryta-water.

HYOSCINIC ACID, $C^6H^{10}O^2$. This acid, isomeric with phloretic acid, remains on evaporating the ethereal solution obtained in the manner above-described, as a

* These, according to the analyses given in Rammelsberg's *Mineralchemie* (p. 239), contain from 12.1 to 15.0 p.c. CO_2 , 71.4 to 78.2 ZnO, and 11.2 to 15.1 water. They appear to be mixtures of zinc carbonate and zinc hydrate in various proportions.

strongly acid syrup having a powerful odour like that of benzoic acid, and solidifying over oil of vitriol to long highly lustrous needles. It melts at 104° – 105° , and when cautiously heated sublimates undecomposed, giving off an odour like that of crude benzoic acid. It dissolves very easily in alcohol and ether, also in hot water, but is much less soluble in cold water. The *barium salt*, $\text{Ba}(\text{C}^{\text{H}}\text{NO}^{\text{H}})^2 + 2\text{H}_2\text{O}$, is neutral, and crystallises in nodular tufts of small spicular crystals. A solution of the acid neutralised with ammonia leaves on evaporation an acid mass very much like hyoscinic acid. Lead acetate forms with hyoscinic acid a white precipitate slowly soluble in acetic acid; silver nitrate forms a white flocculent precipitate (Höhn a. Reichardt).

HYOSCYAMINE, $\text{C}^{\text{H}}\text{H}^{\text{H}}\text{NO}^{\text{H}}$. This alkaloid has been further examined by Höhn a. Reichardt (*Ann. Ch. Pharm.* cxlvii. 98). To prepare it, 20 pounds of Hungarian henbane-seeds were freed from oil by ether, then exhausted with alcohol of 80 p.c. slightly acidulated with sulphuric acid; the alcohol was distilled off; the resinous masses which separated were collected on a filter; and the aqueous solution, nearly neutralised with soda, was precipitated with tannic acid. The precipitate, dried on earthenware plates, was triturated while moist with slaked lime and exhausted with alcohol; the extract was acidulated with sulphuric acid; the alcohol evaporated, the acid liquid agitated with ether, then made alkaline; and the alkaloid taken up with ether. On evaporating the ether, the hyoscyamine remained as an oily liquid which solidified on standing over sulphuric acid (yield 2.8 grams). The liquid containing the tannic acid still retained a portion of the alkaloid (1.5 grams): it was evaporated, supersaturated with alkali, and exhausted with ether. Lastly an additional 0.3 gram was obtained from the fat oil by agitation with acid, water, &c. Höhn a. Reichardt, however, consider it preferable to neutralise the sulphuric acid extract with lime or potash, evaporate nearly to dryness, supersaturate with lime, and extract with alcohol or ether.

Hyoscyamine forms a thick oily liquid, or in the solid state warty crystalline groups of the colour of white wax; it dilates the pupils very strongly, melts at 90° , dissolves easily in alcohol, ether, chloroform, and benzene, and very easily in water. The aqueous solution has a strong alkaline reaction; and in the concentrated state gives precipitates with *alkalis*. With *iodine-water* it forms a crimson-brown, with tannic acid even in very dilute solutions, a white flocculent precipitate; with mercuric chloride a white; with auric chloride a yellowish brown precipitate soluble in excess; with *platonic chloride* a precipitate which cakes together.

Hyoscyamine is resolved by boiling with baryta-water into hyoscinic and hyoscinic acid. The gold-precipitate above-mentioned is decomposed on standing with formation of hyoscinic acid.

Syrupy hyoscyamine appears to form a hydrate, for benzene leaves a portion of it undissolved, and the dissolved portion crystallises more quickly when the benzene is evaporated. On heating the alkaloid, it first emits the characteristic, extremely narcotic odour, then a distinct smell of benzoyl- or salicyl-compounds.

Hyoscyamine Sulphate, $2\text{C}^{\text{H}}\text{H}^{\text{H}}\text{NO}^{\text{H}} \cdot \text{H}_2\text{SO}^4 + 4\text{H}_2\text{O}$, crystallises over sulphuric acid, in radiate groups of white shining needles. The *hydrochloride*, $\text{C}^{\text{H}}\text{H}^{\text{H}}\text{NO}^{\text{H}} \cdot \text{HCl} + 2\text{H}_2\text{O}$, crystallises less easily. The *platinochloride* $2(\text{C}^{\text{H}}\text{H}^{\text{H}}\text{NO}^{\text{H}} \cdot \text{HCl}) \cdot \text{PtCl}_4$, forms a resinous precipitate soluble in alcohol.

HYPOCHLORITE (A. Frenzel, *Jahrbuch f. Mineralogie*, 1871, 355). The name hypochlorite has been applied to certain varieties of green iron-ore occurring massive or earthy at Schneeberg, Johanngeorgenstadt, and Bräunsdorff, in Saxony. The massive hypochlorite of Schneeberg has a crystallo-granular texture, siskin-green or yellowish-green colour, hardness 6, sp. gr. 2.93–3.0, and even to flat conchoidal fracture. The Bräunsdorff mineral has a siskin-green colour, hardness 6, sp. gr. 2.81. Both have the aspect of hornstone, and pass into the earthy condition, which transformation may sometimes be observed in a lump of the massive mineral. Thin sections of both minerals, when examined by the microscope, exhibit, in the midst of a greenish opaque substance, which forms the principal part, brightly polarising portions (quartz), together with brownish needles arranged in spherical groups. Their composition, according to Frenzel's analyses, is also analogous:—

	SiO^2	Fe^2O^3	Sn^2O^3	B^2O^3	P^2O^5
Schneeberg *	88.45	6.00	—	4.76	—
Bräunsdorff	86.00	7.8	5.0	—	trace

These numbers seem to indicate that the hypochlorites in question are mixtures of

* Schüller analysed the Schneeberg mineral with very different results, viz., 80.24 SiO^2 , 14.98 FeO , 13.08 B^2O^3 , 10.84 FeO , and 9.82 P^2O^5 (dl. 237).

silicate of bismuth or antimony, with quartz, ferric oxide, and very small quantities of ferric phosphate.

The earthy variety of antimony hypochlorite is similar in constitution to the massive variety. An earthy crust scraped from a lump of the latter, and quite free from foreign admixtures, gave by analysis 78.0 p.c. silica, 11.4 ferric oxide, 7.3 antimonious oxide, and 1.0 water. The earthy bismuth hypochlorite, on the other hand, differs considerably in constitution from the massive. Pure lumps of it, of hardness 1-2, gave 23.08 p.c. silica, 33.33 ferric oxide, and 43.26 bismuth-oxide, agreeing nearly with the formula, $\text{Bi}^2\text{O}^3 \cdot 2\text{Fe}^2\text{O}^3 \cdot 4\text{SiO}^2$, or perhaps $\text{Bi}^2\text{O}^3 \cdot \text{SiO}^2 + 2\text{Fe}^2\text{O}^3 \cdot 3\text{SiO}^2$, which requires 23.44 p.c. silica, 31.25 ferric oxide, and 45.31 bismuth oxide.

The lump from which this analysis was made exhibited a crystalline structure when broken, and cavities in it were found to be lined with small, indistinct, apparently monoclinic crystals rather harder than the surrounding parts. As this compound differs entirely from Schüler's hypochlorite, Frenzel designates it by a distinct name, bismutho-ferrite. The hornstone-like mixtures may be provisionally distinguished as bismuth and antimony hypochlorite.

HYPOPHOSPHITES. See PHOSPHORUS, OXYGEN-ACIDS OF.

HYPOSULPHITES. See SULPHUR, OXYGEN-ACIDS OF.

HYPOXANTHINE. Salkowski found hypoxanthine in the bone-marrow of leukaemic patients, but did not decide whether it also occurred normally in that substance. P. Heymann (*Pflüger's Archiv. f. Physiologie*, vi. 194) finds that, on adding silver nitrate to the watery extract of the bone-marrow both of man and of the calf, after removal of other substances, a precipitate is formed which has all the characters of argento-hypoxanthine, and on separation of the silver leaves a substance which, in its chemical and microscopical characters, agrees with hypoxanthine.

Peculiar behaviour of Argento-hypoxanthine.—E. Salkowski (*ibid.* 91) finds that when a solution of hypoxanthine to which gelatin has been added, is decomposed by silver nitrate, no precipitate, but only an opalescence of the liquid ensues. The opalescent liquid forms no deposit, even after standing at rest for days or on the application of heat. This property of gelatin is a point to be noticed in testing organic liquids and extracts for hypoxanthine. Neither albumin nor glycogen prevents its precipitation by silver nitrate. Gelatin appears, therefore, to act in some way independent of the mere viscosity of the liquid.

I.

ICE. According to a recent determination by Bunsen (*Pogg. Ann.* cxli. 1) the specific gravity of ice is 0.9164.

IDOCRASE. Dumour (*Compt. rend.* lxxiii. 1040) has analysed idocrase (vesuvian) from Norway, occurring in rounded, translucent, yellowish grains distributed through a calcareous matrix. Sp. gr. = 3.44. Harder than feldspar; fusible in the blowpipe flame; readily acted on by acids. It contained in 100 parts—

SiO^2	Al^2O^3	CaO	FeO	MnO	MgO	H^2O
36.32	16.70	34.86	6.20	1.40	0.73	2.58 = 98.79

agreeing with the formula $18(\text{CaO} ; \text{FeO} ; \text{MnO}) \cdot 4\text{Al}^2\text{O}^3 \cdot 15\text{SiO}^2$ (v. 098).

IGASURIC ACID. According to H. Ludwig (*Arch. Pharm.* [3], ii. 137) this acid (iii. 242) belongs to the class of iron-greening tannins. It was prepared by precipitating an aqueous solution of the alcoholic extract of St. Ignatius' beans with neutral acetate of lead, decomposing the precipitate with hydrogen sulphide, and concentrating the filtrate. It formed a yellowish-brown amorphous mass, the solution of which had a strong acid reaction and a sour astringent taste, and could not be made to crystallise.

The acid did not affect ferrous salts, but caused a dark-green coloration in ferric salts. It rapidly reduced ammoniacal silver-solution, and gave a yellow precipitate with neutral acetate of lead. When neutralised with lime-water, it formed an amorphous greenish-brown lime-salt, which was coloured deep brown by caustic soda, and gave with ferric chloride a green coloration, changing to violet-brown on addition of sodium carbonate.

IGASURINE. This name has been given to an alkaloid, said to exist in *Nux vomica*, and to be obtained from the mother-liquors from which strychnine and brucine have separated; but its separate identity has never been satisfactorily established (iii. 243). To throw further light on the question, Jørgensen (*J. pr. Chem.* [2], iii. 175) endeavoured to prepare a periodide from a preparation said to be igasurine. It was dissolved in dilute hydrochloric acid, and fractionally precipitated by a solution of iodine in potassium iodide. The two precipitates thus obtained were washed with cold water and crystallised from alcohol. In both cases violet-blue crystals were obtained, which had the optical properties and crystalline form of brucine tri-iodide. They gave by analysis 49.1 and 49.05 p.c. iodine, the formula of brucine tri-iodide, $C^{22}H^{22}N^2O^4.HI^3$, requiring 49.1 p.c. These results tend to show that the so-called igasurine is nothing but brucine.

ELSEMANITE. Native molybdic molybdate, $MoO^3.4MoO^3$ from Bleiberg, in Carinthia (see MOLYBDATES).

INDICAN. Jaffé finds that, after the subcutaneous injection of indol, very considerable quantities of indican constantly appear in the urine. The elimination of the latter body begins a few hours after injection, and generally ceases within 24 hours. Kuhne has shown that indol is one of the products of the pancreatic digestion, so that Jaffé's previous conjecture that the indican of urine is, partially at least, derived from this source, appears to be verified. The indol of the intestinal canal is, for the most part, ejected with the faeces, imparting thereto its peculiar odour; a small portion is absorbed and reappears in the form of a conjugated compound, indican, in the urine.

INDIGO. *Artificial Formation.*—From experiments by Emmerling a. Engler (*Deutsch. Chem. Ges. Ber.* iii. 593), it appears that indigo-blue may be obtained artificially from acetophenone or methyl-phenyl ketone $C^6H^5.CO.CH^3$. This ketone treated with nitric acid yields two nitro-derivatives, $C^6H^5(NO^2)O$, one solid the other liquid. The solid modification is produced by adding acetophenone to cooled red fuming nitric acid, and separates, on mixing the acid liquid with water, as an oil which solidifies to a crystalline mass on cooling.

The liquid modification, from which indigo is obtained, is produced by the action of nitric acid aided by heat. 70–80 grams of red fuming nitric acid are heated to 46°–50°, and 5–7 grams of acetophenone are then quickly added; and the liquid, which becomes hot, is poured into water as soon as red vapours issue from the flask, whereupon the nitro-compound is obtained as a reddish-yellow syrupy mass. At lower temperatures, the solid modification is formed at the same time, and at higher temperatures, or when the action is too much prolonged, more highly nitrated derivatives are obtained.

To convert the liquid nitro-acetophenone into indigo-blue, it is cautiously heated, in quantities of 5 to 10 grams, till it begins to decompose; the cooled viscid mass is dissolved in chloroform; 40 to 50 times its weight of a reducing agent consisting of 1 pt. soda-lime to 9 pts. zinc-dust is added; and the dried mass is quickly heated in small narrow test-tubes. A dark-coloured sublimate is then formed, which may be driven from one part of the tube to the other, and gives off violet vapours like those of iodine. Emmerling a. Engler did not, however, obtain it in quantity sufficient for analysis, although they repeated the reduction 300 times. They observed, however, that when the sublimate was treated with lime and ferrous sulphate and the clear liquid was exposed to the air, a purple film formed on its surface. From these results they conclude that indigo-blue is the azo-compound of a peculiar ketone, and indigo-white the corresponding hydrazo-compound. They give the following formulae for these and certain allied compounds:

Indigo-blue

Indigo-white

Isatin

Dioxindol

Oxindol

Indol

Formation of Indigo-blue from Isatin.—Finely pulverised isatin is heated in a sealed glass tube to 75°–80° for several hours with 50 times its weight of a mixture of

parts of phosphorus trichloride and acetyl chloride, with a little free phosphorus. The dark green liquid is then poured into water, and the solution, after filtration, is left for 24 hours in an open dish. The light green liquid gradually turns blue and deposits a dark blue granular powder. This powder is separated by filtration from the clear yellow mother-liquor, and washed with alcohol to remove a red colouring matter soluble therein.

The blue powder thus obtained is insoluble in cold alcohol, dissolves with blue colour in hot alcohol, and in strong sulphuric acid with yellow-green colour, changing to blue on heating; on addition of water a pure blue solution is obtained. The powder volatilises in purple vapours which condense to large needles having a blackish, metallic lustre; it makes a deep blue streak or pure streak on paper, and, in short, it is indigo-blue. The quantity obtained by the process above described is about 10-20 p.c. of the isatin employed. Very small deviations in the mode of operating produce, however, considerable differences in the yield, and sometimes scarcely anything is obtained but a red colouring matter called indigo-purpurin. This substance sublimes more readily than indigo-blue, and condenses to a woolly mass of slender roddish needles; it dissolves in sulphuric acid and the solution diluted with water forms a pure red liquid. It is insoluble in water, slightly soluble in alcohol with deep red colour, dyes silk like fuchsin (Baeyer & Emmerling, *Deut. Chem. Ges. Ber.* iii. 688).

Pure indigo-blue or indigotin, may be obtained in the crystalline state by boiling commercial indigo with *aniline*, whereupon it dissolves, yielding a deep blue solution which, if filtered hot and set aside for some hours, deposits almost the whole of the indigotin in the crystalline state. When required very pure the indigotin should be again crystallised from aniline and the crystals washed with alcohol and dried. As thus obtained it has a fine coppery lustre, equal to that of sublimed indigo. *Benzene*, *chloroform*, boiling *creosote*, and *phenol*, dissolve indigo in small quantity and deposit it, on cooling, in a flocculent state; *alcohol* and *ether*, at their respective boiling points, also dissolve small quantities of indigo (A. de Aguiar and A. Bayer, *Ann. Ch. Pharm.* clvii. 366). Wartha (*Deut. Chem. Ges. Ber.* iv. 334) finds that indigo may also be crystallised from *Venice turpentine*, which, when heated nearly to boiling, dissolves indigo with a fine blue colour, and deposits it on cooling in blue tables; from boiling *paraffin*, which dissolves it with the fine red colour of indigo-vapour, it separates in prisms like those of sublimed indigo. In *petroleum* indigo dissolves with a carmine-red colour; in melted *spermacetic* with a violet, and in *stearic acid* with a blue colour. According to Jacobson (*Diagl. polyt. J.* ccii. 307) indigo likewise dissolves in *nitrobenzene*, *castor oil*, *acetone*, *chloral hydrate*, *camphor*, *oil of turpentine*, *balsam of copaiba*, *cedar oil*, *anilyc alcohol*, *oil of lavender*, *white bees-wax*, *Japanese vegetable wax*, and *Caruba wax*, the last depositing it in small flaky crystals. A solution of indigo in white wax, heated for some time to its boiling point, passes through several shades of colour, and finally becomes brown, owing to the reduction of the indigo. When powdered indigo is added to melting *picric acid*, deflagration takes place.

Estimation of Indigo.—F. Springmühl (*Chem. Cent.* 1870, 703) compares the different methods adopted for the valuation of indigo: 1. The quantity of indigotin may be directly estimated by successive extraction with potash-ley, acetic acid, and alcohol, which dissolve out the indigo-brown, indigo-glutin, and indigo-red, leaving pure indigo-blue. 2. The indigo-blue may be separated from foreign substances by solution in Nordhausen sulphuric acid. The sample is to be dissolved in 20 times its weight of sulphuric acid, the solution diluted with 2,000 parts of water and filtered, and the residue weighed. The sulphuric acid, however, likewise dissolves small quantities of indigo-brown and indigo-red, so that this very simple method gives the amount of indigo-blue rather too high. According to Meyer (*infra*) the sulphuric acid used for dissolving the indigo should have a specific gravity of not less than 1.89.

3. The valuation may be effected by comparing the depth of colour of a solution of the sample with that of a normal solution of indigo. As, however, the normal solution alters by keeping, the results obtained by this method are not very exact. 4. By titration, best with potassium permanganate. A normal solution is prepared by dissolving a known quantity of indigo in sulphuric acid, and the quantity of permanganate required to decolorise it is determined. The sample to be valued is then treated in the same manner and the results compared. Springmühl also recommends titration with acid potassium chromate (iii. 256). According to Meyer, on the other hand, the colour of the resulting isatin-sulphuric acid is so strong that the end of the reaction cannot be distinctly seen, and the results may in consequence be wrong to the amount of $\frac{1}{4}$ to 1 p.c.

According to Löwenthal (*Zeitschr. anal. Chem.* xi. 45) the method of testing indigo based on the oxidation of the sulphuric acid solution, are not so trustworthy as the estimation of the amount of ash present in the sample; this he finds to vary from 4.5 p.c. in a good sample to 29 p.c.

The quality of indigo is sometimes judged of by its specific gravity. G. Leuchs (*J. pr. Chem.* [2], iv. 349), from the examination of a large number of samples, finds that good indigo, containing 56 to 56.5 p.c. indigotin, has a comparatively low specific gravity (1.34), whilst that of the poorer sorts increases as the proportion of colouring matter becomes smaller, that of a specimen of 27 p.c. being 1.675.

R. E. Meyer (*Dingl. polyt. J.* cxvii. 172) has examined an example of Cochin China indigo and compared its amount of indigotin with that in several kinds of indigo in general use. The following are the results:—

Cochin China Indigo	{52.2 51.5}	mean	51.85 p.c. Indigotin.
Bengal Indigo: (1.) Ordinary, heavy, dark-blue			55.00 "
" " (2.) Gras, (reddish, dark blue).			63.60 "
" " (3.)			68.25 "
" " (4.)			69.50 "
Guatemala Indigo: (1.) Brownish-blue, ordinary			55.25 "
" " (2.) Light blue, ordinary			57.75 "

From this it appears that the Cochin China indigo possesses but a very small colouring power. Its colour is, however, a very fine blue, and it leaves, when dissolved in sulphuric acid, only small quantities of foreign organic matters. The determination of the ash shows that this kind of indigo is richer in inorganic matters than other kinds. Bengal indigo (1.) left 6.63 p.c. ash; Guatemala indigo (1.) left 11.34 p.c., Guatemala (2.) left 2.73 p.c.; whereas Cochin China indigo left 22.36 p.c. ash, consisting chiefly of calcium phosphate with small quantities of calcium carbonate, ferric oxide, alumina, magnesia and soda. By exhausting Cochin China indigo with hydrochloric acid, an excellent product is obtained yielding 74.7 p.c. indigotin, and only 3.74 p.c. ash.

INDIUM. *Symbol, In.*—Atomic Weight 113.4 (see 1st Suppl. p. 1137).

Occurrence.—Indium has been detected by the spectroscopy in zinc-blendes from West Ossipee and Eaton, New Hampshire (U.S.) (H. B. Cornwall, *Chem. News*, xxviii. 28).

Preparation.—F. Stolba (*Dingl. polyt. J.* cxviii. 223) prepares indium from indiferous zinc-blende by roasting, as follows: The blende, reduced to a moderately fine powder, is intimately mixed with 10 p.c. of burnt gypsum; the mixture is quickly stirred up with a quantity of water sufficient to make it into a thick paste; this paste is moulded on a paper surface into cakes $\frac{1}{2}$ to $\frac{3}{4}$ inch thick, and 4 or 5 inches in diameter; and these cakes, before they have completely hardened, are pierced through their entire thickness with holes 2 lines in diameter at distances of 1 to $\frac{1}{2}$ inch. The dried cakes are roasted for 4 to 6 hours at a red heat with free access of air, pulverised when cold, treated with hydrochloric or sulphuric acid, and from the resulting solution, kept at the boiling heat in a copper vessel, the indium is precipitated by zinc. From the metallic pulp thus obtained the indium is separated by Böttger's method (1st Suppl. 730).

For the complete and rapid purification of indium from other metals, K. J. Bayer (*Ann. Ch. Pharm.* clviii. 372) employs a method based on the fact that soluble indium compounds are completely precipitated by boiling with acid sodium sulphide, whereas the metals accompanying indium are precipitated by that reagent only partially, and not at all if the solution contains much ammonia-salt. The mode of procedure is as follows:—

Freiberg zinc is dissolved in crude hydrochloric acid, with the exception of a small quantity; the solution is allowed to digest in the cold with this undissolved zinc for 24 to 36 hours, whereby all the indium present is precipitated on the zinc; the clear solution of zinc chloride is then poured off, and the metallic deposit removed from the unattacked zinc. The metallic mud is treated with a few drops of dilute sulphuric acid, to dissolve any basic chloride of zinc, and then washed with hot water until it has no longer an acid reaction. The mixture of metals is then treated with nitric acid; sulphuric acid is added in excess; and the liquid evaporated until all the nitric acid is driven off. By these operations tin is separated as stannic oxide, and lead as sulphate. Water is then added, in which the sulphates of indium, zinc, copper, cadmium, iron, and lead in small quantity, dissolve. The precipitate is removed by filtration, and well washed, and ammonia in great excess is added to the filtrate, whereby the copper, zinc, and cadmium are dissolved, while all the indium and iron remain behind, accompanied by a little zinc, cadmium, lead, and copper. The well-washed precipitate is dissolved in the smallest possible quantity of hydrochloric acid, mixed with acid sodium sulphite in excess, and boiled till the smell of sulphurous acid has almost disappeared. The whole of the indium now separates as a white, fine, crystalline powder, probably

free from copper, zinc, cadmium, and iron. The precipitate is filtered off at once, and washed with hot, de-aerated water. If much iron is present, the precipitate must be filtered in an atmosphere of carbon dioxide; or better, the iron is completely removed by repeated precipitation with sodium bisulphite.

The precipitate may still contain lead or sodium sulphite; it may be obtained pure by dissolving in aqueous sulphurous acid, filtering from any lead sulphite, and boiling the filtrate.

The crystalline indium compound, dried in vacuo over sulphuric acid, has the composition $2\text{In}^{\text{O}} \cdot 3\text{SO}^2 + 8\text{H}^2\text{O}$. The insolubility in water of this sulphite renders it suitable for the quantitative estimation of indium. From the sulphite, the various indium salts can be prepared, as it dissolves easily in dilute acids, with evolution of sulphurous oxide.

From a solution of the chloride, the indium can be completely precipitated by boiling with potassium nitrite. The precipitate contains neither nitrous acid nor potassium; it consists of the hydrated oxide $\text{In}^{\text{O}} \cdot 3\text{H}^2\text{O}$.

A similar mode of preparing indium from Freiberg zinc is described by Rössler & Wolff (*Dingl. polyt. J.* xciii. 487; *Jahresb.* 1869, 277).

Indium-ammonium alum, $\text{In}^{\text{III}}(\text{NH}_4)(\text{SO}_4)^2 + 12\text{H}^2\text{O}$, or $\text{In}^{\text{O}} \cdot (\text{NH}_4)^{\text{O}} \cdot 4\text{SO}_4 + 24\text{H}^2\text{O}$, is obtained by evaporating over the water-bath solutions of indium and ammonium sulphates, mixed in the proportion of their molecular weights. The concentrated solutions, on standing in the cold, deposit the salt in transparent octohedral crystals.

Indium-ammonium alum crystallises easily in large octohedrons, always exhibiting the cube-faces. It appears to melt at 36° , but really breaks up into a solution of the alum and a salt containing less water (see below). The liquefied mass, when examined with the microscope, is seen to contain monoclinic prisms of the latter salt, whilst octohedral crystals of the alum are again formed as it cools. This breaking up takes place even on triturating crystals of the alum with a pestle, the result being, not a dry powder but a moist pasty mass. The alum is very soluble in water, 1 part of water dissolving 2 parts of alum at 16° , and about 4 parts at 30° . It is insoluble in alcohol. The strongly acid aqueous solution deposits on boiling a white powder, corresponding in composition with alum-stone, and having similar properties.

The formation of the ammonio-indic sulphate with a smaller proportion of water, takes place, as it evidently must do, when a solution of the alum is made to crystallise at 36° . Thus formed, it was found to have the composition represented by the formula $\text{In}^{\text{III}}(\text{NH}_4)(\text{SO}_4)^2 + 4\text{H}^2\text{O}$. Corresponding salts were obtained with potassium and sodium sulphates, but it was not found possible to obtain the potassio- and sodio-indic sulphates crystallised with 12 mol. water.

The constitution of the ammonium salt affords additional evidence of the triatomicity of indium (Rössler, *J. pr. Chem.* [2], vii. 14).

INDOL. For the constitutional formulæ of this compound, see p. 666.

INOSITE. Jacobsen (*Ann. Ch. Pharm.* clvii. 227) has found 0.08 p.c. of this substance in the flesh of a young porpoise, and 0.30 in horse-flesh. According to Hilger (*ibid.* clx. 333) inosite exists abundantly in the juice of the grape. He finds, also, that it ferments in contact with putrid cheese, yielding paralactic acid.

INDOPHANE. A blue substance resembling indigo, produced, together with naphthyl-purpuric acid, by the action of potassium cyanide on dinitronaphthol (Hlasiwetz).

According to E. v. Sommaruga (*Chem. Centr.* 1871, 617) the best mode of obtaining it pure is the following:—30 grams of dinitronaphthol with about 2 litres of water are heated to boiling, and sufficient ammonia is added to ensure complete solution. Into this liquid a hot concentrated solution of 45 grams potassium cyanide is dropped. In ten minutes the reaction is completed. The whole is now washed on the filter with boiling water till the filtrate ceases to become coloured. A violet-coloured mass is thus obtained having a beautiful green metallic lustre, and consisting of a mixture of free indophane and a potassium-compound of that body. Washed for a long time with boiling water, the latter becomes coloured, from the solution of a trace of the compound; addition of potassium carbonate prevents this solution, and precipitates from the washings a brown impurity. The mass on the filter is now heated with very dilute hydrochloric acid, filtered, and washed till the filtrate is free from hydrochloric acid.

Pure dry indophane is of a violet colour, and has a beautiful green metallic lustre.

It is insoluble in water, alcohol, ether, benzene, and carbon sulphide, but moderately soluble in sulphuric acid and warm acetic acid, slightly in melted naphthalene. The solutions are purple-red; from these indophane cannot be obtained in the

crystalline state; it may however be sublimed like indigo. Nitric acid appears to oxidise it, forming a brown-red body, soluble in alkaline solutions. Indophane is not reducible by lime and ferrous sulphate, as indigo is.

With aqueous potash or soda indophane yields potassium- and sodium-derivatives which may be obtained pure by filtering and washing till all free alkali is removed; both these compounds greatly resemble indigo. On warming indophane with alcoholic potash-solution, a dark green body is formed at first, and by further action, a humus-like substance is precipitated. Fused potassium hydrate gives the same products with indophane as with naphthyl-purpuric acid.

INULIN, $C^{12}H^{20}O^{10}$. Schützenberger (*Ann. Ch. Phys.* [4], xxi. 234) has made experiments on the products obtained by the action of acetic anhydride at the boiling heat on dahlia-inulin and elecampane inulin, the results of which agree exactly with those of Ferrouillat a. Savigny (*1st Suppl.* 737) with regard to the composition and the optical rotatory powers of the products. He finds also that dahlia-inulin heated to 160° in a sealed tube with 2-3 parts of acetic anhydride is partly dehydrated, and forms two acetyl derivatives; one is soluble in water, and has the rotatory power $[\alpha] = +55^{\circ}$, the other is insoluble in water, and has the value $[\alpha] = +35^{\circ}$; both, however, give numbers agreeing with a tetra-acetyl derivative. Saponified with soda, the soluble body gives a resinous mass $C^{12}H^{16}O^8$, or inulin mass $2H^2O$.

Elecampane-inulin treated in the same manner gave only a black humous mass, together with a trace of dextrorotatory syrup.

INULOID (O. Popp, *Ann. Ch. Pharm.* clvi. 190). This is a soluble modification of inulin contained in the bulbs of the Jerusalem artichoke (*Helianthus tuberosus*) and of the dahlia, gathered before they are ripe, or rather at the time when the deposition of inulin in the cells first commences. The expressed juice, after treatment with lead acetate, gives on standing a precipitate resembling starch, and having the composition and most of the properties of inulin, but a lower specific gravity, and a higher degree of solubility. Dried over sulphuric acid it has the composition $C^{12}H^{20}O^{10} \cdot 2H^2O$. It gives off its water at 105° ; melts at 130° - 135° , passing into an easily soluble state, and decomposes above this point. Its specific rotatory power is $[\alpha] = -30^{\circ}5'$; hence for anhydrous inuloid, $C^{12}H^{20}O^{10}$, dried at 110° it would be $-34^{\circ}5'$, which is very nearly the same in magnitude as that of ordinary inulin. After inversion by acids, the specific rotatory power is -79° . 100 pts. water at 18° - 20° dissolve 1.895 pt. inuloid, and 0.985 pt. inulin. Inuloid dissolves in an ammoniacal solution of copper sulphate, and on boiling is precipitated as a bluish-green substance, $C^8H^{14}O^4 \cdot CuO$, which by protracted boiling is resolved into inuloid and copper oxide. It does not reduce alkaline cupric tartrate. After boiling for some time in water, it passes into a soluble gummy mass; by very long heating with water, or more easily with dilute acids at 110° - 120° , it is converted into lævulose; with cold concentrated sulphuric acid it forms a conjugate acid, which is decomposed on dilution; it precipitates the metal from hot ammoniacal copper or silver solutions; is not coloured by aqueous solutions of iodine or bromine; is not precipitated by aqueous solutions of lead acetate or barium hydrate; but on adding to baryta water on the one hand, and to an aqueous solution of inuloid on the other, a quantity of alcohol not sufficient to cause precipitation, and mixing the two alcoholic liquids, a compound of inuloid with baryta is thrown down, which, after moderate washing with water and drying in a vacuum over sulphuric acid, has the composition $C^8H^{14}O^4 \cdot BaO$.

Inuloid appears to exist in the plant-juice in the form of a soluble combination with synanthrose. By treatment with lead acetate, a compound of lead and synanthrose is formed, and the inuloid is liberated; or this latter may be set free by causing the juice to ferment at 10° - 12° , by which means the synanthrose is decomposed.

IODINE. Sources.—Iodine occurs in considerable abundance in some of the mineral springs of Java. The Genock Watse spring contains in 100 grams, 0.0138 gram of sodium iodide (E. Reichardt, *Arch. Pharm.* [3], ii. 130). The calcium phosphate from the beds in the Departments of Lot and Tarn-et-Garonne contains sufficient iodine to give off violet vapours when treated with sulphuric acid (Kuhlmann, *Compt. rend.* lxxv. 1678). The sodium nitrate of Tarapaca in Peru also contains a considerable quantity of iodine, the mother-liquors of the salt yielding from 2.3 to 4.6 gramm in a litre (E. Wagner, *Dingl. pol. J.* ccv. 76).

Iodine in Sea-Water.—According to Sonstadt (*Chem. News*, xxv. 196, 351, 241) iodine exists in sea-water in the form of calcium iodate. That it is not present in the form of an iodide, is shown by the fact that pure sea-water, collected at some distance from land, gives no iodine coloration when acidified and shaken with carbon disulphide but if a very small quantity of solution of sulphurous acid or ferrous sulphate be first added to reduce the iodic acid, and the liquid be subsequently acidified with dilute

sulphuric acid and agitated with carbon sulphide, a recognisable iodine coloration is obtained, even when only 100 c.c. of water are taken. A more exact method of detection is the following:—

200 c.c. of the water are first mixed with a few drops of a slightly alkaline solution of sodium sulphite; 2 or 3 c.c. of a saturated solution of silver acetate are then added; and lastly about one-fourth of the volume of the liquid of strong hydrochloric acid free from chlorine. The liquid is left at rest for a short time, then filtered, and the precipitate washed with dilute hydrochloric acid and distilled water. The filter and precipitate are moistened with a strong solution of caustic soda, and heated in a covered crucible to low redness for a few minutes. After cooling, water is added, the solution filtered, and the filtrate, strongly acidified with dilute sulphuric acid, is shaken up with carbon sulphide and sufficient very dilute chlorine-water to develop the iodine reaction. The presence of iodine is then immediately indicated by the coloration of the carbon sulphide.

Near the shore, however, where sea-water is exposed to the decomposing action of putrifying organic matters, and, in some places, of sewage, the calcium iodate may be reduced to iodide, or it may even contain free iodine. One or two samples taken near the shore were found to give no colour with carbon sulphide when fresh, but after keeping for a few days, the water was found to contain free iodine, and to retain scarcely a trace of the original iodate.

For the quantitative estimation of iodine in sea-water, Sonstadt proceeds as follows: 500 c.c. of the water are treated with a small quantity of arsenious anhydride dissolved in hydrochloric acid; a few milligrams of cupric sulphate are added; the whole is evaporated to dryness; the residue, after gentle heating, is dissolved in the smallest possible quantity of water; and the insoluble cuprous iodide is collected on a filter and washed. The quantity of iodine in it is then determined by igniting the filter with sodium hydrate, and subsequently titrating the acidulated solution of sodium iodide with very dilute chlorine-water and carbon sulphide. Analyses made in this way showed that 250,000 parts of sea-water contain 1 part of calcium iodate, whence it is calculated that a cubic mile of sea-water contains 17,000 tons of calcium iodate or 11,072 tons of iodine.

Preparation from Residues.—F. Beilstein (*Zeitschr. f. Chem.* 1870, 528) recovers iodine from residues containing also bromine or chlorine, by means of the well-known reaction of nitrous acid with a solution of potassium iodide acidulated with sulphuric acid. The residues are evaporated and ignited; the solution obtained by lixiviation is mixed with dilute sulphuric acid, and the iodine precipitated by passing nitrous acid (prepared from 1 pt. of crude starch with 6 pts. of crude nitric acid) into the liquid separated by filtration, washed with cold water, and dried over sulphuric acid. From the filtrate, after warming, to expel the iodine still remaining in solution, the bromine may be separated by means of manganese peroxide. As the nitrogen dioxide formed from the nitrous acid in the precipitation of the iodine is reconverted into nitrous acid on coming in contact with the air, it might be used over again in operating on the large scale. The nitrous acid obtained in the preparation of arsenic acid from arsenious acid (for the manufacture of fuchsine) might also be advantageously used in the process above described.

Impurities in Commercial Iodine.—The chlorine may be estimated by quickly transferring the iodine, weighed in a stoppered tube, to a large beaker containing 40 c.c. of a freshly prepared concentrated aqueous solution of sulphurous acid, and as soon as the iodine is dissolved (the solution being filtered if necessary) adding half a litre of boiling water, then ammonia in excess, and silver nitrate. The precipitate is treated in the usual manner. To the filtrate from this precipitate nitric acid is added, and the silver chloride estimated.

The ash is also to be estimated by igniting 5 grams of the sample.

The water may be approximately estimated by bringing 1 gram of the sample into a narrow glass tube graduated into tenths of a cubic centimeter, and adding 20 c.c. carbon sulphide, which dissolves the iodine; the solution now occupies 200 divisions of the tube. The tube being well corked is set aside for 2–3 hours, when the water separates out, floating on the surface of the carbon sulphide. Suppose this layer occupies $\frac{1}{10}$ c.c.; its weight will be 0.1 gram, and the sample will contain 10 per cent. water. (Wanklyn, *Chem. Soc. J.* [2], x. 1115).

Commercial iodine sometimes contains iodine cyanide distributed through its mass in fine needles. This impurity cannot be removed by sublimation, as too much iodine sublimes with it; but by treating the impure iodine with iron and water, a solution is obtained containing both iodide and cyanide of iron; and when this solution is treated with potassium carbonate, the whole of the cyanogen is precipitated,

and the potassium iodide obtained is free from cyanide (Wittstein, *Dingl. pol. J.* cc. 310).

Optical Properties.—Iodine in thin layers, as obtained by spreading and pressing it in the fused state between plates of glass, appears brown-red by transmitted light; a very thin layer transmits only the extreme red of the spectrum. Melted iodine appears to have the same colour. Some of its solutions, e.g. in water, alcohol, and acetic acid, exhibit exactly the colour of solid iodine, whilst other solutions, e.g. in carbon sulphide, stannic chloride, phosphorous chloride, &c., exhibit the colour of iodine-vapour (Schulz-Sellack, *Pogg. Ann.* cxl. 334).

The absorption-spectrum of iodine-vapour has been examined by R. Thalén (*Pogg. Ann.* cxxxix. 503). The absorption affects only the half of the spectrum lying between the red and green; and even when it has reached its maximum and this half has completely disappeared, the violet portion remains quite unaltered: hence the violet colour of iodine-vapour. At a lower degree of absorption the bands form several series mixed together, in each of which they are not equidistant, but separate more widely from one another as the length of the wave increases. Each band may be resolved into a number of very fine lines, arranged in more or less regular groups.

Reactions, Detection, and Estimation. Iodine dissolves in concentrated sulphuric, nitric, hydrochloric, phosphoric, acetic, tartaric, and citric acids. Some of it crystallises from its solution in sulphuric or nitric acid on standing. The sulphuric and nitric solutions do not give the blue reaction with starch, even when the starch is in excess and unchanged, and water is added, unless the acid is present in very small quantity only. The hydrochloric solution gives the colour with starch unless large quantities of concentrated acid are present. All the solutions yield the iodine to carbon sulphide. From concentrated aqueous or alcoholic solutions of iodine in potassium iodide, concentrated sulphuric or nitric acid precipitates a portion of the iodine.

In presence of *tannin*, iodine cannot be recognised by the ordinary tests, but it is immediately separated by the addition of a few drops of a neutral solution of *ferrie chloride* at a temperature of 37.5°, and may then be recognised by the starch reaction (Tessier, *Zeitschr. Anal. Chem.* xi. 313).

To test *potassium bromide* for iodine, 0.1 gram of the sample may be dissolved in 10–12 c. c. of a 10 p.c. solution of ammonia, and a drop of silver nitrate added. A turbidity, which does not disappear on agitation, indicates the presence of iodine (H. Hager, *Chem. Centr.* 1872, 617).

In presence of *copper salts*, iodine is separated from its compounds by hydrochloric or hydrobromic acid, iodised starch-paste mixed with a small quantity of cupric sulphate turning blue, either immediately or after a short time, on addition of either of those acids. The same effect is produced by addition of hydrocyanic acid or potassium cyanide (Schönn, *Zeitschr. anal. Chem.* ix. 212).

Detection of Iodine in the form of Potassium Iodide in Urine (Pelloggio, *Gazzetta chimica italiana*, ii. 75; Giannetti, *ibid.* 253). Pelloggio, in 1870, published a method of detecting iodine in the state of potassium iodide, by subjecting the liquid under examination to the action of an electric current, after addition of starch-paste and slight acidulation with sulphuric or hydrochloric acid. This method was applied to the detection of iodine in urine by Campani, who found it to be inferior in delicacy to the method of testing by bromine-water with addition of starch or of carbon sulphide (*ibid.* i. 472).

Pelloggio, in the paper above referred to, describes experiments on the detection of iodine, both in normal urine to which potassium iodide had been added, and in the urine of patients to whom potassium iodide had been administered, from which he draws the following conclusions:—

1. That for the detection of iodine in urine, the method with carbon bisulphide and bromine-water is not so delicate as that with bromine-water and starch. Moreover, the former method is not to be depended upon, because it is next to impossible to hit the exact quantity of bromine-water required to develop the red coloration without again destroying it; and lastly, it is incapable of detecting very minute quantities of iodine in urine.

2. That the method with bromine-water and starch, though more delicate than that with carbon sulphide, is inferior to that which consists in the use of starch-paste, hydrochloric acid, and the electric current.

Five cubic centimeters of urine containing 0.05 gram of potassium iodide having been diluted with something more than a five-fold quantity of water, and the liquid being divided into two equal portions, one portion treated with starch-paste and a drop of bromine-water did not give any blue coloration, whereas the other portion mixed

with starch-paste and hydrochloric acid and electrolysed, exhibited a number of slender filaments of iodide of starch.

3. That these reactions are less delicate in iodised urine than in the pure solution of potassium iodide, because the urea contained in the urine interferes with them. Hence the colour disappears on agitation, but reappears on further addition of bromine-water.

The superior delicacy exhibited, according to Pelloggio, by the electrolytic method, is attributed by him to the circumstance that the current likewise acts on the urea in such a manner as to prevent its action on the iodide of starch.

A still more delicate test for iodine in presence of urea is, however, afforded by nitromuriatic acid and starch-paste, the nitromuriatic acid decomposing the urea, with formation of nitrous products, and at the same time furnishing the chlorine required to decompose the potassium iodide. With this reagent a distinct blue colour is produced with three drops of iodised urine containing 0.00016 gram. of potassium iodide, and dissolved in 12 c. c. of water (Pelloggio).

The relative delicacy of these tests has also been examined by Giannetti, who has arrived at results opposite to those of Pelloggio. Operating on 5 c. c. of urine containing 0.05 gram of potassium iodide, and diluted with various quantities of water, he obtains the results given in the following table:—

Experiments	Ratio of urine to water	Urine liquid used in each experiment	Potassium iodide contained in each sample	Reactions	
				With starch-paste and bromine-water	With carbon bisulphide and bromine-water
1. Normal urine . . . 50 c.c. Potassium iodide, 0.05 grm.	—	5 c.c.	gram 0.005	Very deep	Very deep
2. Urine of the first } experiment . . . } 5 c.c.		5 c.c.	0.008333	Deep	Deep
3. Urine of the second } experiment . . . } 5 c.c.	1 : 5	5 c.c.	0.008333	Deep	Deep
4. Urine of the third } experiment . . . } 5 c.c.	1 : 11	5 c.c.	0.0041666	Very plain	Deep
5. Urine of the fourth } experiment . . . } 5 c.c.	1 : 23	5 c.c.	0.0020833	Plain	Very plain
6. Urine of the fifth } experiment . . . } 5 c.c.	1 : 47	5 c.c.	0.0010416	Weak colour	Plain
Distilled water . . . 5 c.c.	1 : 95	5 c.c.	0.0005208	Nothing	{ Very perceptible rose colour

From these experiments it appears that the reaction with bromine-water, with addition either of starch-paste or of carbon bisulphide, is more delicate than the electrolytic method, inasmuch as it gives distinct colorations with the iodised urine, diluted in the one case with 47, and in the other with 95 volumes of water, whereas, according to Pelloggio's statement, the limit of the electrolytic reaction appears to be reached when urine containing the same proportion of potassium iodide is diluted with somewhat more than five times its bulk of water. Moreover, the reaction with bromine and bisulphide of carbon appears to be the most delicate of all.

The following are the conditions most favourable to success in these experiments:—
The undiluted urine (5 c.c.) containing the potassium iodide in the proportion above-mentioned, requires eight drops of saturated bromine-water to produce the red coloration with carbon bisulphide, and six drops to produce the blue colour with starch-paste; a somewhat larger quantity deepens the colour, a large excess destroys it. By diluting the urine more and more, a point is at length reached (Experiments 5 and 6) when a single drop of the bromine-water is too much, and destroys the reaction; but by diluting the bromine with four or five times its volume of water, and adding the liquid drop by drop, the reaction soon shows itself. Strong agitation interferes with

2nd Sep.

X X

the reactions, especially when the proportion of potassium iodide is small; but by gentle agitation fine colorations are obtained; this indeed is an essential condition for obtaining a delicate reaction with bromine and bisulphide of carbon.

When the experiment is made with undiluted urine, a considerable quantity of bromine-water is required to obtain the reaction, either with starch-paste or with carbon bisulphide. This fact was observed by Pelloggio, who attributed it to the presence of urea (see above). Giannetti also finds that urea destroys the colour of iodide of starch, but that urine destroys the colour of this compound more quickly than it would be destroyed by the corresponding quantity of pure urea in aqueous solution. Stale urine gradually loses the power of decolorising the iodide of starch. The colour produced by bromine with sulphide of carbon is also destroyed by pure urea and by fresh urine, but not quite so quickly as that of iodide of starch.

Lastly, Giannetti has compared Pelloggio's reaction with nitromuriatic and starch-paste with that obtained by the use of bromine-water and carbon bisulphide, and still finds that the latter is the most delicate test hitherto proposed for the detection of iodides in urine.

On the Detection of Iodine in Sea-water (see p. 670).

Estimation of Iodine in presence of Chlorine and Bromine.—Potassium iodide is converted by potassium permanganate into free potash and potassium iodate, with separation of manganese dioxide:

As bromide and chloride of potassium are not attacked by the permanganate, this reaction may serve for the estimation of iodine. The solution, which must be slightly alkaline and must contain the chlorine, bromine, and iodine in the state of chloride, bromide, and iodide of an alkali-metal, is heated to boiling, and a solution of 2.5 grams of the permanganate in 497.5 grams of distilled water is added, the liquid being brought to the boiling point after each addition. When the liquid, after repeated boiling, remains distinctly reddish, the excess of permanganate is estimated by titration with sodium thiosulphate, and the iodine is calculated from the quantity of permanganate solution used, each gram of this solution answering to 2 milligrams of iodine (W. Rönige, *Zeitschr. anal. Chem.*, ix. 58). This process slightly modified is applied by E. Sonstadt to the estimation of iodine in Kelp-liquors (*Chem. News*, xxvi. 173; *Chem. Soc. J.* [2], x. 1116).

According to G. M. Donald, on the other hand (*Zeitschr. anal. Chem.*, ix. 377), potassium permanganate cannot be advantageously used for the separation of iodine from bromine and chlorine. He finds that this reagent acts on moderately concentrated solutions of chlorides, bromides and iodides in such a manner as to form a chlorate, bromate, or iodate, with separation of a small quantity of the free halogen. He made use of two solutions of the haloid salts, one containing 1 part of salt in 80 parts of water, the other 1 part of salt in 240 water; also a concentrated solution (1 : 16) of permanganate, and a very dilute one. In solution of sodium chloride, the strong permanganate solution produces a brown coloration, and after long standing, a precipitate. Dilute solutions remain unaltered even after a day or two. In solution of potassium iodide, concentrated or dilute, the strong permanganate solution produces a brownish precipitate, the odour of iodine being at the same time evolved. The strong solution of potassium bromide likewise gives with the strong permanganate solution, a brown precipitate. A solution of potassium bromide mixed with nitric acid, immediately deposits bromine on addition of permanganate. Dilute solutions of potassium bromide are not altered by the permanganate, the liquid merely becoming coloured by free bromine on addition of a little nitric acid. It would appear then from these experiments that the reactions of the permanganate with moderately strong solutions of the three classes of haloid salts are so very much alike, that this reagent cannot be used as a means of separating iodine from chlorine or bromine.

H. Hübner (*Zeitschr. anal. Chem.*, xi. 397) separates iodine from chlorine and bromine by means of a soluble thallous salt, the separation depending on the fact that thallous iodide, TlI , is perfectly insoluble in cold water, whereas the corresponding chloride and bromide are soluble. To a cold neutral solution of an alkaline iodide and chloride or bromide, thallous nitrate solution is added drop by drop from a burette, with constant agitation of the liquid, until the precipitate changes in colour from yellow to white. The precipitate is collected, after 8 to 12 hours, in a weighed filter thoroughly washed with water, dried at 100° , and weighed as thallous iodide. To the filtrate silver nitrate is added, and the ensuing precipitate of silver chloride or bromide is collected and weighed as usual. In a well-conducted experiment the error in the quantity of iodine found does not exceed 0.01 p.c.

The separation of iodine from bromine may also be effected by adding to the solution

of alkaline iodide and bromide first a saturated, then gradually a dilute solution of lead nitrate, until the precipitate just begins to change colour from yellow to white. After standing for 12 to 18 hours, the precipitate, which is almost pure lead iodide, is collected on a weighed filter, washed thoroughly, dried at 110° , and weighed. The bromide is in the filtrate chiefly as alkaline bromide. Especial care must be taken not to add more lead nitrate than is sufficient to precipitate all the iodide, since if lead bromide is also thrown down, it will be necessary to add a considerable quantity of water to dissolve this bromide, and then the lead iodide will also be partly dissolved. Altogether, this process is not so exact as the preceding.

Iodine and chlorine cannot be separated by the use of lead nitrate.

Estimation of Iodine, Bromine, and Chlorine by Carius' Method (i. 47).—Iodide of silver is partially soluble in nitric acid and silver nitrate. The best results are obtained by taking 0.5 to 0.8 gram of iodide, $1\frac{1}{2}$ equivalent of silver nitrate, 2 c.c. water, and 2 c.c. nitric acid of sp. gr. 1.29. The silver nitrate is dissolved in the water in the tube, and the nitric acid added, whereby much of the nitrate is precipitated in fine crystals; the heating is continued for three hours at 180° – 200° ; and the contents of the tube, after dilution with 200 c.c. of lukewarm water, are boiled for ten minutes. Even with these precautions the percentage of iodine is frequently found to be 0.6 to 1.0 p.c. too small; with bromine and chlorine, the errors are much less (E. Linnemann, *Zeitschr. anal. Chem.* xi. 325).

C. R. A. Wright also finds that a smaller percentage of iodine is obtained if the silver iodide be precipitated in a solution containing much silver nitrate and nitric acid, a higher percentage being obtainable by greatly diluting such a liquid (*Chem. Soc. J.* [2], xi. 527).

Estimation of Insoluble Iodides.—The following method is based on the fact that mercuric iodide, lead iodide, silver iodide, and cuprous iodide, dissolve easily even at ordinary temperatures in aqueous sodium thiosulphate (the silver salt less easily than the rest). It is best to take a very small quantity of water, and as little as possible of the sodium salt. On adding ammonium sulphide to the solution, the four metals are completely precipitated, while the whole of the iodine remains in solution. The liquid is evaporated with addition of ammonia, to expel the sulphur as ammonium sulphide, caustic soda is then added and the solid residue is heated in a platinum dish to decompose the salts of polythionic acids. On treating the ignited mass with water, a solution is obtained which quickly reduces ferric chloride, and on mixing it with a large excess of the latter, the whole of the iodine is after a short time set free. The iodine can then be distilled over into a solution of potassium iodide, and estimated in the usual way (E. Meusel, *Deut. Chem. Ges. Ber.* iii. 125).

On the Estimation of Iodine in Sea-water, see p. 671.

Hydrogen Iodide, or Hydriodic Acid. The specific gravities of aqueous solutions of hydriodic and hydrobromic acids have been determined by C. R. A. Wright (*Chem. News*, xxiii. 242, 253). The hydriodic acid was prepared by the action of hydrogen sulphide on iodine in presence of water; in the weak acid thus obtained iodine was dissolved; and the solution was digested with phosphorus till its colour disappeared, and finally several times distilled.

The hydrobromic acid was prepared by the action of hydrogen bromide on excess of bromine, and purified by rectification over potassium bromide. The percentages of acid were determined by titration with a normal alkaline solution. The following table gives the values directly obtained:—

Hydriodic Acid		Hydrobromic Acid	
Sp. gr. at 15°	HI per cent.	Sp. gr. at 15°	HBr per cent.
1.708	51.9	1.516*	49.8
1.551	47.2	1.475	48.5
1.442	39.2	1.385	40.8
1.297	30.3	1.248	30.0
1.175	18.5	1.190	23.5
1.053	5.9	1.080	10.4

From these data tables have been constructed by graphic interpolation, showing the densities of the two acids for differences 5 of percentage from 0 to 50; and from these

* The statement of Löwig (l. 678), that a saturated aqueous solution of hydrobromic acid has a sp. gr. of 1.40, is regarded by Wright as erroneous, the error having probably arisen from the presence of hydrochloric acid in the acid employed.

tables it appears that both in hydriodic and in hydrobromic acid the increase in specific gravity is not proportional to the increase in strength, which is the case with hydrochloric acid, as appears from Ure's table (i. 893). The tables also show that for a given specific gravity, the percentage of HI in the aqueous acid is less than that of HBr, and this again less than that of HCl, thus:

Sp. gr.	Percentage of HCl	Proportionate percentage of HBr	Proportional percentage of HI
1.050	1	0.64	0.54
1.100	1	0.63	0.54
1.150	1	0.62	0.53
1.200	1	0.60	0.52

The specific gravity of hydrobromic acid of given strength is always greater than the mean between those of the corresponding aqueous hydriodic and hydrochloric acids. No simple numerical relation can be traced between the atomic weights of these three acids and the percentages of anhydrous acid contained respectively in the aqueous acids of equal specific gravity.

The specific gravity of aqueous hydriodic acid of different strengths has also been determined by Topsoë (*Zeitschr. für Chem.* [2], vi. 635). The hydriodic acid was prepared by treating 1 part of phosphorus with 19 parts of iodine and 20 parts of water. The specific gravities are those obtained by direct observation at the given temperatures, referred to water at the same temperature as unity. The fourth column of the following table, headed 'Equivalent,' gives the weights of the several aqueous acids containing 1 mol. of HI = 128.

Specific Gravity of Aqueous Hydriodic Acid.

Temperature	Specific Gravity	Percentage	Equivalent
12°	1.708	57.74	221.7
13.7	1.706	57.64	222.1
12.5	1.703	57.42	222.0
13	1.696	57.28	223.6
13.7	1.674	56.15	228.0
14	1.630	53.93	237.3
12.5	1.603	52.43	244.2
13	1.5727	50.75	252.2
13.5	1.542	49.13	260.5
13	1.528	48.22	265.5
13	1.4865	45.71	280.0
13	1.451	43.30	295.5
13	1.413	40.45	313.6
13	1.382	38.68	330.9
13	1.347	36.07	354.8
13	1.309	33.07	387.1
13.5	1.274	30.20	423.9
13.5	1.2535	28.41	450.6
13.8	1.225	25.86	494.9
13.8	1.191	22.63	565.6
13.5	1.164	19.97	641.0
13.5	1.126	15.73	813.1
13.5	1.102	13.09	977.6
13	1.095	12.21	1048.3
13.5	1.077	10.15	1261.0
13.5	1.0524	7.019	1823.7
13.5	1.017	2.286	5545.6

Hydriodic acid, after distillation in a stream of carbon dioxide, is nearly colourless, but the stronger solutions quickly decompose and become coloured. The strongest aqueous acid that can be obtained by distillation boils at 127°, and contains 57.74 p.c. HI, which is equivalent to $\text{HI} + 4.7 \text{ H}^2\text{O}$ (Topsoë). Roscoe found it to contain 57 p.c. (iii. 286).

Metallic Iodides. When an iodide mixed with starch-paste is treated with ether, iodine is set free with a blue coloration, at once if concentrated, slowly if

dilute. By filtration and further addition of ether and starch, the iodine can finally be completely removed. The reaction, which applies equally well to natural iodine-waters, but does not affect chlorides and bromides, is probably due to the formation, and subsequent decomposition, of ethyl iodide (E. Ferrière, *Compt. rend.* lxxiv, 1106).

Periodides. *Potassium Tri-iodide, KI^3 .*—The solution of iodine in aqueous potassium iodide appears not to contain any definite periodide, inasmuch as when shaken with carbon sulphide it gives up its excess of iodine and becomes colourless (Baudrimont, *Compt. rend.* li. 827). Piffard, indeed (*Zeitschr. Chem. Pharm.* 1861, 151), supposed it to contain a definite periodide, because he found that it gave, with solution of lead acetate, a dark-coloured precipitate which did not give up any excess of iodine to solvents; he regarded this precipitate as PbI^3 , but did not analyse it. Dosios a. Weith, on the other hand (*Zeitschr. f. Chem.* 1869, 379), find that this precipitate gradually gives up its excess of iodine to solvents, and therefore regard it merely as lead iodide, PbI_2 , mixed with free iodine.

A solution of iodine in alcoholic potassium iodide appears, on the other hand, to contain the tri-iodide. Such a solution containing potassium mono-iodide and iodine in proportion to form the tri-iodide, may be agitated with carbon sulphide without colouring the latter, whereas a saturated solution of iodine in carbon sulphide is very easily and completely decolorised by agitation with alcoholic solution of potassium iodide. An aqueous solution of iodine in potassium iodide is decolorised by agitation with mercury, with formation of potassio-mercuric iodide $KI.HgI^2$, and separation of mercurous iodide; but an alcoholic solution of potassium tri-iodide shaken with mercury becomes decolorised without yielding a trace of mercurous iodide, the only compound formed being the double iodide above mentioned, $KI^3 + Hg = KI.HgI^2$ (Jørgensen, *J. pr. Chem.* [2], ii. 347).

Periodides of Copper and Mercury.—Cuprous iodide, Cu^2I_2 , is insoluble in water and in alcohol; nevertheless, considerable quantities of it are dissolved when an alcoholic solution of iodine is digested with it for some hours or days at ordinary temperatures, or at a temperature not above 30° . The solution contains nearly 18 atoms of iodine to 1 mol. Cu^2I_2 . At higher temperatures a smaller quantity is dissolved, and after prolonged heating to 100° the solution contains no copper and the cuprous iodide becomes crystalline. From the copper solution mixed with alcohol, water separates nothing, but alcoholic solution of potassium iodide throws down all the cuprous iodide, with formation of potassium tri-iodide. On pouring this liquid, turbid from suspended cuprous iodide, into a large quantity of water, the whole dissolves, the potassium tri-iodide being decomposed, and the higher iodide of copper reproduced.

Cuprotetrammonium Tetriodide, $CuI^3.I^3.4NH^3$.—When the brown solution of cuprous iodide in alcoholic iodine is heated to 30° , and an alcoholic solution of ammonia heated to the same temperature is added in moderate quantity, there is formed, in the course of a few hours, a brown-black crystalline precipitate, which must be quickly washed with cold alcohol and dried over calcium chloride. The crystals form rhombic tables of $74^\circ-75^\circ$ and 106° , which appear olive-green in polarised light when the plane of polarisation is parallel to the longer diagonal: dark brown and almost opaque when it is perpendicular thereto. On exposure to the air, they become dull on the surface and give off a small quantity of iodine.

Cuprotetrammonium Hexiodide, $CuI^3.I^3.4NH^3$.—On mixing a solution of cuprotetrammonium nitrate heated to 50° with a solution of iodine and potassium iodide at the same temperature, and filtering immediately, the filtrate in a few hours deposits a quantity of beautiful brown crystals which, however, must not be dried, but quickly washed with cold water. Under water, in a closed vessel, they may be kept for some time. It is not known whether they contain water, the analysis having been limited to the determination of the proportion between the copper, iodine, and ammonia. The crystals are rectangular plates, often having two opposite angles, or all four, truncated. The rhombus thereby formed has the angles $76^\circ 30'$ and $103^\circ 30'$. They absorb polarised light, but rather feebly, and only when they are of a certain thickness. They are dark brown by transmitted light, or opaque, according as the longer axis of the plate is parallel or perpendicular to the plane of polarisation.

Cuprotetrammonio-mercurio Iodides.—a. $CuI^3.2HgI^3.4NH^3$ is easily obtained by mixing warm solutions of $KI.2HgI^3$ and sulphate of cuprotetrammonium. As the solution cools, green shining crystals separate, which must be quickly washed with water and dried over calcium chloride in the dark. b. $CuI^3.HgI^3.4NH^3$. When the brown crystals of cuprotetrammonium tetriodide are drenched with alcohol and mercury is added to them, they change in a few hours into a blue crystalline mass which, when recrystallised from hot alcoholic ammonia and washed therewith, forms blue shining laminar prisms. The same compound is obtained by mixing a warm solution of

euprotetrammonium sulphate with 2KI.HgI_2 , adding also an excess of potassium iodide, as otherwise the green salt α is very apt to form.

Mercury Hexiodide, HgI_6 , is formed when to an alcoholic solution of potassium triiodide warmed to 50° , there is added first an excess of solution of mercuric chloride, then cold water, and the liquid is left at rest for a quarter of an hour. The brown crystalline precipitate which then forms must be washed as quickly as possible with cold water, till the wash-water, after decoloration with sulphurous acid, becomes only a little darker on addition of ammonium sulphide. Even in that case the precipitate retains small quantities of mercuric iodide; indeed, according to Jørgensen, it does not appear possible to obtain the hexiodide quite pure. The crystals are rhombic tables of 66° and 112° – 113° , generally having the acute angles truncated; twins are of frequent occurrence. The crystals absorb polarised light and appear light havannah-brown by transmitted light, or perfectly opaque, accordingly as the plane of polarisation is parallel or perpendicular to the shorter diagonal of the rhombus. The compound is decomposed by alcohol, by aqueous potassium iodide, and by prolonged washing with cold water, and gradually loses iodine on exposure to the air (Jørgensen).

Periodides of Organic Bases.—These compounds are formed by precipitating the hydrochlorides of the several bases in neutral or acid solution with a solution of iodine in potassium iodide. For the description of the individual compounds, see the several alkaloïds in this volume and in the *First Supplement*.

Of the cinchona bases, the only one which forms a simple tri-iodide is cinchonine, the compound being formed when a neutral alcoholic solution of cinchonine hydriodide is mixed with the calculated quantity of iodine-solution. The other cinchona-bases give black tarry precipitates. Quinine and cinchonine, however, yield periodides containing chlorine as well as iodine. When very dilute solutions of the hydrochlorides of these bases are mixed with about 3 mol. hydrochloric acid and 3 mol. potassium iodide, and left at rest for some time, the compounds,

and

are deposited in brown prisms and laminae. Herapathite may be formed in a similar manner.

The methylic and ethylic derivatives of quinine, quinidine, cinchonine and cinchonidine form crystalline periodides, which have already been noticed (p. 342).

Triethylphosphonium tri-iodide, $\text{P}(\text{C}^2\text{H}^5)^3\text{I}^3$, and **Triethylarsonium tri-iodide, $\text{As}(\text{C}^2\text{H}^5)^3\text{I}^3$,** are isomorphous and scarcely distinguishable from one another externally. The periodide of the corresponding antimony-base may be obtained in crystalline form, but is converted by cold water or alcohol into a tarry mass. The *mercury double salts* obtained by agitating the tri-iodides $\text{N}(\text{C}^2\text{H}^5)^3\text{I}^3$, $\text{P}(\text{C}^2\text{H}^5)^3\text{I}^3$, and $\text{As}(\text{C}^2\text{H}^5)^3\text{I}^3$ with metallic mercury are isomorphous. The *bismuth double salts* obtained by mixing the warm alcoholic solutions of the same periodides with solutions of bismuth hydrate in strong hydriodic, hydrobromic, or hydrochloric acid, all crystallise in regular six-sided tables (see p. 192).

Tetretethylsulphine iodide forms only a tarry periodide, but crystalline bismuth double salts of it are easily prepared, e.g. $3\text{S}(\text{C}^2\text{H}^5)^2\text{Br}.3\text{HBr}$.

For detailed descriptions of all these organic periodides, see Jørgensen (*J. pr. Chem.* [2], ii. 433; iii. 146, 328).

Iodine Monochloride, ICl .—This compound has been carefully examined by Hannay (*Chem. Soc. J.* [2], xi. 815), who finds that it possesses the same properties, whether it be prepared by passing chlorine over iodine, and distilling the product off iodine to free it from tri-chloride, or by heating iodine with potassium chlorate, and distilling the product off that salt. When recently prepared it remains fluid for several days, but subsequently solidifies. It melts at 24.7° , boils at 109.5° – 101.6° , has a specific gravity of 3.263 at 0° , 2.958 at 98° , and expands equally for equal increments of temperature between 0° and 100° . Its vapour-density is 80.27 ($\text{H}=1$), the formula requiring 81.2.

According to Garnes (*Compt. rend.* lxxiv. 660) iodine monochloride heated to 40° gives off so much vapour that a thickness of 30 c. m. is sufficient to produce an absorption-spectrum. This spectrum consists of 20 fine lines between the extreme red and a point a little beyond the line D, nearly equidistant, and of sensibly equal intensity. No others are observable throughout the spectrum. This system of lines resembles those of the iodine-spectrum more than those of the chlorine-spectrum. It differs, however, from the iodine-spectrum in the absence of lines in the green, and in the fact that the lines of the spectrum of iodine chloride begin sensibly nearer to the red than do those of the iodine-spectrum.

Reactions.—Iodine monochloride acts on the oxygen-acids of chlorine and their salts, with evolution of chlorine and formation of oxygen-acids of iodine, especially iodic acid and its salts. With *hypochlorous acid* the reaction is brisk even at ordinary temperatures; with *chloric acid* it is slow in the cold, energetic at higher temperatures. When chlorine is passed into cooled water containing iodine in suspension till the iodine is completely dissolved, a calculated quantity of solid *potassium chlorate* (1 mol. to 1 at. of iodine dissolved) added to this solution, and the liquid heated, chlorine is evolved and potassium iodate is formed, according to the equation,

Trichloride of iodine acts in the same manner. The expulsion of chlorine by the chlorides of iodine takes place much more easily than with iodine alone. On the other hand, hydrogen iodide and metallic iodides in solution are immediately decomposed by iodine chloride, with liberation of iodine and formation of a chloride (L. Henry, *Deut. Chem. Ges. Ber.* iii. 892).

Iodine monochloride acts on many metals, as potassium, sodium, magnesium, aluminium, copper, mercury, tin, antimony, and bismuth, with various degrees of energy, forming a chloride and iodide of the metal. With *arsenic* it forms arsenious chloride and gives off iodine. *Ordinary phosphorus* treated with iodine chloride bursts into flame, but *amorphous phosphorus* only hisses and emits fumes mixed with iodine-vapour. With *galena* iodine chloride forms chloride of sulphur and iodide of lead. With *sulphur* it reacts feebly, forming iodide and chloride of sulphur. *Selenium* and *tellurium*, especially the latter, act strongly on it, forming chlorides. *Bromine* mixes with iodine chloride in all proportions, without apparent action. Iodine chloride dissolves in *carbon tetrachloride* without action, forming a red solution. When iodine chloride is added to *carbon bisulphide* till saturated, small quantities of white fumes, which smell like sulphur chloride, are evolved, and on treating the product with water, sulphur is precipitated, and a heavy oily body sinks to the bottom, consisting of a mixture of carbon bisulphide, tetrachloride, and sulphochloride. This action of iodine chloride on carbon bisulphide is still more decided on distilling the mixture, when the distillate fumes distinctly, and emits a distinct smell of the sulphochloride while iodine remains in the retort.

On distilling the chloride of iodine from *potassium iodide* several times, it is entirely converted into iodine, while potassium chloride is formed: $\text{KI} + \text{ICl} = \text{KCl} + \text{I}_2$. The distillation requires to be repeated several times before the conversion is complete. Iodine chloride acts violently on the *skin*, causing a sharp burning pain, and forming sores difficult to heal (Hannay, *loc. cit.*)

Iodic and Periodic Acids. The following determinations of the specific gravities and molecular volumes of these acids have been made by J. Thomsen (*Deut. Chem. Ges. Ber.* vii. 71):—

TABLE I.—*Specific Gravity and Volume of Solution of Iodic Acid at 17° C.*

Number of molecules of water	Specific gravity	Molecular weight	Molecular volume	Increase in volume of the water
$\text{IO}^3\text{H} + 10\text{H}^2\text{O}$. .	1.6609	356	214.34	34.34
" + 20 " . .	1.3600*	536	392.37	32.37
" + 40 " . .	1.1945	896	750.09	30.09
" + 80 " . .	1.1004	1616	1468.5	28.5
" + 160 " . .	1.0512	3056	2907.2	27.2
" + 320 " . .	1.0258	5936	5786.8	26.8

The last column shows the increase in the volume of water when a molecule of iodic acid is dissolved in it. As the numbers decrease with the increase of water, it follows that contraction takes place when solutions of iodic acid are diluted with water.

Expressing the composition of the iodic acid solution by the formula $\text{IO}^3\text{H} + a\text{H}^2\text{O}$, the volume of the solution is expressed by the formula—

$$V_a = 18 \cdot a + 39.1 - \frac{a}{a + 18} \cdot 13.1;$$

* Compare Kümmerer (p. 593). Thomsen thinks there must be some error in Kümmerer's calculated numbers.

and if the formula holds good for all values of a , then iodic acid IO^3H in the liquid state will have the volume 39.1 . Dividing the molecular weight 176 by this number, we find the specific gravity of hydrate of iodic acid in the liquid state to be 4.50 . Ditte found it to be 4.869 for the crystallised salt at 0° (*Ann. Chim. Phys.* [4], xxi. 22).

The contraction is expressed by $\frac{a}{a+18} \cdot 13.1$: it therefore increases with the quantity of water present, and when $a = \infty$, that is, on unlimited dilution, it becomes 13.1 , or very nearly $\frac{1}{3}$ rd of the volume of the iodic acid, IO^3H .

TABLE II.—*Specific Gravity and Volume of Solution of Periodic Acid at 17°C .*

Number of molecules of water	Specific gravity	Molecular weight	Molecular volume	Increase in volume of the water
$\text{IO}^3\text{H}^5 + 20\text{H}^2\text{O}$. . .	1.4008	588	419.77	59.77
" + 40 " . . .	1.2165	948	779.30	59.30
" + 80 " . . .	1.1121	1068	1409.0	59.29
" + 160 " . . .	1.0570	3108	2940.9	60.2
" + 320 " . . .	1.0288	5988	5820.0	60.0

The last column shows that the volume of water increases by a constant number for each molecule of dissolved acid, and, therefore, that no contraction takes place on solution.

The volume of the solution containing $\text{IO}^3\text{H}^5 + a\text{H}^2\text{O}$ is therefore—

$$V_a = 18a + 59.6.$$

The specific gravity being equal to the quotient of the molecular weight by the volume, we have accordingly:

$$\begin{aligned} \text{for } \text{IO}^3\text{H} + a\text{H}^2\text{O} \quad & \left\{ \begin{aligned} \text{Volume} &= 18a + 39.1 - \frac{a}{a+18} \cdot 13.1. \\ \text{Specific gravity} &= \frac{18a + 176}{18a + 39.1 - \frac{a}{a+18} \cdot 13.1}. \end{aligned} \right. \\ \text{for } \text{IO}^3\text{H}^5 + a\text{H}^2\text{O} \quad & \left\{ \begin{aligned} \text{Volume} &= 18a + 59.6. \\ \text{Specific gravity} &= \frac{18a + 22.8}{18a + 59.6}. \end{aligned} \right. \end{aligned}$$

These formulæ give the specific gravities of the solutions of the two acids at 17° correct to four decimal places.

Basicity and Constitution of Iodic Acid.—The close resemblance exhibited by chlorine, bromine, and iodine, both in the free state and in their combinations with hydrogen, the metals, and many organic bodies, might lead us to expect a similar correspondence in their behaviour to oxygen. In reality, however, iodine differs greatly in this respect from chlorine and bromine.

The composition of the most important oxygen-acids of the three bodies may be expressed by the empirical formula RO^3H ; but the chemical and physical properties of iodic acid are so different from those of chloric and bromic acids that its molecular constitution can scarcely be the same.

(1). Chloric and bromic acids are monobasic, as is shown by the easy solubility of their salts, the non-existence of acid salts, and the impossibility of producing the anhydride directly from the hydrate. Iodic acid, on the contrary, forms salts the greater number of which dissolve with difficulty. It gives with the alkalis chiefly acid salts, and the anhydride can be easily obtained by heat from the hydrate. In all these properties it resembles the polybasic acids.

(2). Iodic acid forms rhombic crystals, and is, in fact, isomorphous with the bibasic succinic and itaconic acids, the constants of the three being—

Itaconic acid . . .	α	β	γ	Boep.
" . . .	0.581	1	1.255	
Iodic acid . . .	0.590	1	1.231	Schabaz.
" . . .	0.589	1	1.190	
Succinic acid . . .	0.574	1	1.197	Ramond.

There is only one case of isomorphism between the iodates on the one hand, and the chlorates and bromates on the other, viz., in the case of the barium salt; but the molecules of these salts must, on account of the presence of barium, contain 2 atoms of the haloid element, and will therefore have the same composition, R^2O^2Ba , whether iodic acid be represented by the ordinary or by the doubled formula.

(3). The relations of affinity, so far as they are exhibited in the heat produced in the formation of the acids of chlorine, bromine, and iodine, show that the last-named element differs from the two former in the constitution of its oxygen-acid.

The following table shows that in the formation of the hydrogen-acids, the heat decreases as the atomic numbers increase, but in the case of the oxygen-acids, while the same rule holds good for chlorine and bromine, iodine shows a remarkable departure from it, the heat evolved in its formation being nearly double of that evolved in the formation of chloric acid:

R	(R,H,Aq)	(R,O ² H,Aq)
Cl	39,320 heat-units.	23,940 heat-units.
Br	28,380 "	12,420 "
I	13,170 "	55,710 "

This difference becomes still more striking if the numbers of one of the acid groups are subtracted from those of the other, so as to give the heat of oxidation of the hydrogen-salts into the oxygen-salts—

$$(R,O^2H,Aq) - (R,H,Aq) = (RHAq,O^2).$$

R	(RHAq,O ²)
Cl	-15,380 heat-units.
Br	-15,960 "
I	+42,540 "

From this it appears that if a solution of hydrochloric or hydrobromic acid could be converted by free oxygen into the corresponding oxygen-acid, there would be in the two cases an equal *absorption* of heat, whereas in the conversion of hydriodic into iodic acid, there is a very considerable *evolution* of heat. It is clear, therefore, that the reactions taking place in the latter case are very different from those which take place in the former, and that the constitution of iodic acid must differ considerably from that of chloric or bromic acid.

(4). If, in accordance with what is above stated, we regard iodic acid as bibasic, and double its usual molecular formula, we obtain one which agrees in a remarkable manner with the formula of periodic acid, H^2IO^4 :—

Iodic acid	$I \cdot IO^2H^2$.
Periodic acid	$H^2 \cdot IO^4H^2$:

i.e., periodic acid is formed by the substitution of three hydrogen-atoms for one iodine-atom in iodic acid. This substitution is in accordance with the trivalence of iodine in other compounds, the trichloride for example.

This mode of derivation of periodic acid explains the peculiar relations of that acid to bases. Periodic acid, in fact, retains the bibasic character of iodic acid and its normal salts have a constitution represented by that of the sodium salt, $H^2IO^4Na^2$. The three atoms of hydrogen which have taken the place of the one atom of hydrogen of iodic acid may, however, be also replaced by metals, giving rise to a large number of so-called basic periodates.

The same view of the constitution of periodic acid agrees with Thomsen's results respecting its heat of neutralisation, inasmuch as the replacement of the first two hydrogen-atoms by sodium gives the normal neutralisation-heat of acids (*Deut. Chem. Ges. Ber.* vi. 2; *Pogg. Ann.* cxl. 90; *Chem. Soc. J.* [2], xi. 595).

The relation between iodic and periodic acid above developed is corroborated by Thomson's investigations on the specific gravities and molecular volumes of their solutions (p. 680). When periodic acid is dissolved in water, the volume of the water increases by 60 c.c. for every molecule of acid dissolved, i.e., for every 228 grams ($H=1$ gram). If, on the contrary, iodic acid is dissolved in water, the increase in volume of the water is greater for concentrated than for dilute solutions. For every 176 grams of iodic acid (= 1 mol. IO^2H^2) there is a variation of from 34 to 27 c.c. if the quantity of water rises by tens up to 320 molecules. The mean value, however, is just half of that of periodic acid, and the two solutions—

have exactly the same volume, viz., 1490.9 and 1500.2, so, that with this quantity of water, a molecule of periodic acid and a double molecule of iodic acid take up exactly the

same volume. When more concentrated, the volume of the periodic acid solution is somewhat smaller, when more dilute somewhat larger, than the corresponding solution of iodic acid.

The facts above detailed all tend to the conclusion that iodic acid is bibasic, and that its molecular formula is $\text{I}^{\text{O}}\text{O}^{\text{H}}_2$.

Properties and Reactions of Iodic Acid and Anhydride.—(A. Ditte, *Ann. Ch. Phys.* [4], xxi. 5.) Iodic anhydride, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2$, is a white powder, easily soluble in water, insoluble in ether, chloroform, carbon sulphide, and liquid hydrocarbons. Sp. gr. = 4.487 at 0° . Expansion-coefficient, between 0° and 51° = 0.000066. It is a powerful oxidising agent.

Iodic anhydride is commonly said to form two hydrates, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot\text{H}_2\text{O}$ and $3\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot\text{H}_2\text{O}$; but by observations on the tension of the aqueous vapour given off by iodic acid at a determinate temperature (according to the method of Debray and Isambert, 1st *Suppl.* 425, 426) Ditte finds that, however great may be the quantity of anhydride mixed with the monohydrate, the tension at any given temperature is always the same as that of the monohydrate alone: hence it may be inferred that the hydrate $3\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot\text{H}_2\text{O}$ does not exist.

The monohydrate, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot\text{H}_2\text{O}$, or *iodic acid*, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2$, has a specific gravity of 4.629 at 0° : its coefficient of expansion between 0° and 51° is 0.000237. It dissolves easily in water without perceptible alteration of temperature, forming a solution which [? when saturated] boils at 104° under a pressure of 760 mm. and has a specific gravity of 2.842 at 12.5° .

A concentrated solution of iodic acid oxidises common as well as red phosphorus at ordinary temperatures, pulverised arsenic at 160° , sugar-charcoal between 175° and 180° , anthracite at 210° , graphite at 240° , amorphous boron at 40° , crystallised boron at 200° , amorphous and crystallised silicon at 250° , sulphur and selenium at 150° , and acetylene at 220° . Diamond withstands its action even at 160° . Potassium, sodium, magnesium, aluminium, bismuth, zinc, cadmium, iron, copper, mercury, and silver, are attacked by a concentrated solution of iodic acid, some at ordinary temperatures, others when heated; tin, lead, gold, and palladium, are not attacked (Ditte).

According to Thorpe (*Chem. Soc. J.* [2], xi. 548), iodic acid is completely reduced to hydriodic acid, and metallic iodates to iodide by a copper-zinc couple in presence of water, and this mode of reduction may be used for the quantitative analysis of iodates.

Compounds of iodic and sulphuric acid, represented by the formulæ $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot 3\text{SO}^{\text{H}}_2$ and $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot 3(\text{SO}^{\text{H}}_2\cdot 2\text{H}_2\text{O})$, are described by Millon (*Ann. Chim. Phys.* [3], xii. 330). Ditte, however, did not succeed in preparing either of these compounds. A solution of iodic acid in very strong sulphuric acid prepared at 310° began at 200° to deposit needle-shaped crystals, which, when left for 5 or 6 days on a porous plate under a bell-jar, lost all their adhering sulphuric acid, and were found to contain 5.4 p.c. of that acid, which does not agree with either of Millon's formulæ. The complex compounds of sulphuric acid with the oxides IO^{H} and $\text{I}^{\text{O}}\text{O}^{\text{H}}$, described by Millon (iii. 298), as well as these oxides themselves, appear to have no existence. Iodic acid separates unaltered from solution in *nitric acid*, without forming either of the compounds described by Millon and Kämmerer (iii. 209). Neither does iodic acid unite with phosphoric or arsenic acid. Sulphurous, arsenious, sulphydric, hydrochloric, and hydriodic acids are oxidised by it: acetic acid also at 210° - 220° . It likewise oxidises oil of turpentine and paraffin.

For Ditte's determinations of the heat of combination and solution of iodic acid, &c., see p. 616.

Iodates. *Neutral potassium iodate*, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\text{K}$, crystallises anhydrous from its aqueous solution at all temperatures. Its specific gravity is 2.801. When it is dissolved in warm dilute sulphuric acid, the hydrated salt, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\text{K}\cdot\text{H}_2\text{O}$, crystallises out in a few days; but when the salt is heated to 100° with a larger quantity of sulphuric acid diluted with an equal volume of water till the solution begins to crystallise, iodic acid, $\text{I}^{\text{O}}\text{O}^{\text{H}}_2$, separates out. From an alkaline solution the neutral iodate crystallises unaltered. The *di-iodate*, $\text{K}^{\text{O}}\cdot 2\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot\text{H}_2\text{O}$ or $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot\text{I}^{\text{O}}\text{O}^{\text{H}}_2$, is obtained by dissolving the neutral iodate in boiling nitric acid diluted with an equal volume of water, and leaving the solution to cool slowly. The *tri-iodate*, $\text{K}^{\text{O}}\cdot 3\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot 2\text{H}_2\text{O}$ or $\text{I}^{\text{O}}\text{O}^{\text{H}}_2\cdot 2\text{I}^{\text{O}}\text{O}^{\text{H}}_2$, is formed when the neutral iodate is mixed with a large excess of iodic acid. It gives off all its water between 160° and 200° (Ditte).

According to Sonstadt (*Chem. News*, xxvi. 98) potassium iodate at high temperature is a more powerful oxidising agent than the chlorate or nitrate, inasmuch as its decomposition requires a higher temperature than that of the chlorate, and it gives off pure oxygen, whereas a nitrate when heated gives off a mixture of gases.

When a solution of an alkaline iodate is mixed with an alkaline thiosulphate, no chemical action ensues as long as the solution remains neutral, but the addition of a

small quantity of an acid causes it to become in the first place strongly alkaline; a neutral point is presently reached, after which, if the iodate is in excess, the further addition of acid liberates iodine. The products of the reaction up to neutrality are, a tetrathionate, an iodide, and a salt of the acid used.

When citric or tartaric acid is employed to acidify the mixed solution of iodate and thiosulphate, the solution becomes neutral to test-paper when two molecules of the acid have been added for every six molecules of thiosulphate present, and this neutral point is reached sensibly before iodine is set free. A trisodic salt of the organic acid is formed in both instances. In order to obtain the iodine reaction, a quarter of a molecule more of citric acid and one molecule more of tartaric acid must be added (Sonstadt.)

According to Melsens (*Ann. Chim. Phys.* [4], xxv. 157), potassium iodate is reduced in the animal organism and converted into iodide.

Calcium Iodate.—On the existence and quantity of this salt in sea-water, see p. 670. According to Sonstadt (*Chem. News*, xxviii. 397), it is a powerful antiseptic and may be advantageously used for preserving meat, fish, eggs, &c., from putrefaction. The sodium, potassium, and magnesium salts do not act so powerfully in this way as the calcium salt.

Erbium Iodate, $\text{I}^{\text{O}}\text{Eb} + 2\text{H}^{\text{O}}$, is uncrystallisable (Clève, *Bull. Soc. Chim.* [2], xix. 289).

Glucinum Iodate remains, on evaporation, as a gummy mass (Atterberg, *ibid.* 497).

Thallium Iodates.—**Thallous iodate**, $\text{TI}^{\text{I}}\text{O}^{\text{O}}$, is obtained as a white non-crystalline powder by heating thallious hydrate with iodic acid; or by decomposing a thallous salt with a soluble iodate. It is nearly insoluble in water, and dissolves but sparingly in nitric acid: it remains unaltered at 150° , but when more strongly heated it melts to a brown liquid, gives off oxygen and iodine, and yields a sublimate of thallous iodide, and a residuo of thallous oxide which strongly attacks glass.

Dithallic Iodate, $(\text{TI}^{\text{I}})^{\text{I}}\text{I}^{\text{O}}\text{O}^{\text{O}}$, is formed by heating thallous iodate or freshly precipitated thallous oxide with aqueous iodic acid. It is a brownish-grey, heavy, crystalline salt, which is not altered by water, and is nearly insoluble in nitric acid. When heated it gives off water, and behaves in other respects like the thallous salt (Rammelsberg, *Pogg. Ann.* cxlvi. 532).

Ferric Iodates. The normal salt, $\text{Fe}^{\text{O}}\text{O}^{\text{O}}\cdot 3\text{I}^{\text{O}}\text{O}^{\text{O}}$ or $(\text{Fe}^{\text{O}})^{\text{I}}\text{I}^{\text{O}}\text{O}^{\text{O}}$, is obtained as a yellow precipitate by heating a solution of ferrous iodide in 5 or 6 pts. water with 2 pts. potassium chlorate dissolved in a little hot water and $1\frac{1}{2}$ pt. strong nitric acid. It is tasteless, scentless, and perfectly stable. By using smaller quantities of nitric acid, salts are obtained containing smaller proportions of iodic acid; one of a deep red colour appears when dried at 100° to contain $\text{Fe}^{\text{O}}\text{O}^{\text{O}}\cdot \text{I}^{\text{O}}\text{O}^{\text{O}}$, but decomposes during washing. The salt, $\text{Fe}^{\text{O}}\text{O}^{\text{O}}\cdot 2\text{I}^{\text{O}}\text{O}^{\text{O}}$ + 3H^{O} , obtained by precipitating ammonia-iron alum with potassium or sodium iodate (iii. 302), is somewhat liable to alteration on exposure to the air. These basic salts are converted into the normal salt by digestion with warm dilute nitric acid (C. A. Boll, *Pharm. J. Trans.* [3], i. 624).

PERIODATES. K. Ihre (*Deut. Chem. Ges. Ber.* iii. 316) describes the preparation of a number of these salts, all of which have, however, been previously described, except the following:

formed by the action of concentrated alcoholic potash on the salt $\text{K}^{\text{O}}\text{O}^{\text{O}}\cdot \text{I}^{\text{O}}\text{O}^{\text{O}}$;

prepared by the action of barium nitrate and aluminium on the ordinary sodium salt, $\text{Na}^{\text{O}}\text{O}^{\text{O}}\cdot \text{I}^{\text{O}}\text{O}^{\text{O}}$ + 6H^{O} .

With regard to the *triargentic salt*, $\text{Ag}^{\text{O}}\text{IO}^{\text{O}}$, described by Fernlund (*1st Suppl.* 746), as produced by boiling the straw-yellow diargentic salt $\text{Ag}^{\text{O}}\text{H}^{\text{O}}\cdot \text{IO}^{\text{O}}\text{H}^{\text{O}}$ with water, Ihre finds, in accordance with Rammelsberg (*Jahresh.* 1867, p. 166), that the product obtained by boiling the yellow salt with water as long as anything is dissolved is the *pentargentic salt*, $5\text{Ag}^{\text{O}}\text{O}^{\text{O}}\cdot \text{I}^{\text{O}}\text{O}^{\text{O}}$ or $\text{Ag}^{\text{O}}\cdot \text{IO}^{\text{O}}\text{Ag}^{\text{O}}$. From the results of his own experiments and those of other chemists, Ihre concludes that periodic acid forms salts containing either 1, 2, 3, 4 or 5 atoms of metal.

Blomstrand (*Deut. Chem. Ges. Ber.* iii. 317) agrees with this view, which is also in accordance with Thomsen's results (p. 681).

Thallium Periodates.—The *thallous salt* has not been isolated. The precipitate

formed either by adding thallous hydrate to periodic acid, or by mixing solutions of thallous nitrate and tetrapotassic periodate, seems to be a mixture of the iodate $\text{Ti}^{\text{I}}\text{O}_3$, and the compound $\text{Ti}^{\text{I}}\text{O}_3^{\text{II}}$. A thallous salt, said to have the composition $\text{Ti}^{\text{I}}\text{O}_3^{\text{II}} + 90\text{H}_2\text{O}$, is formed, as a light-brown precipitate by warming freshly precipitated thallous oxide with periodic acid (Rammelsberg, *vogg. Ann.* cxlvi. 592).

Periodates of Yttrium and Erbium.—Two yttrium periodates are formed according as the periodic acid used in their preparation is in excess or not. The most stable, formed with excess of acid, is said to contain $\text{Y}^{\text{I}}\text{O}_3^{\text{II}} + 24\text{H}_2\text{O}$; the other, $\text{Y}^{\text{I}}\text{O}_3^{\text{II}} + 6\text{H}_2\text{O}$. Erbium-periodate is said to have the composition $\text{Eb}^{\text{I}}\text{O}_3^{\text{II}} + 2\text{H}_2\text{O}$ (Clève, *Bull. Soc. Chim.* [2], xix. 193).

IODOFORM, CHI_3 .—This compound treated with bromine at ordinary temperatures gives rise to bromiodoform, CIBrI_2 ; but an excess of bromine at high temperatures removes the hydrogen and the whole of the iodine, producing carbon tetrabromide CBr_4 (Bolas a. Groves, p. 256).

Iodosulphuric Acid, $\text{H}^2\text{SO}^3\text{I}^2$. (Silvestro Zinno, *N. Repert. Pharm.* xx. 449).—Pelouze a. Frémy obtained the anhydride of this acid, SO^3I^2 , by distilling an intimate mixture of iodine and lead sulphite and rectifying the distillate over mercury: the anhydride dissolved in water yielded iodosulphuric acid. Zinno obtains the same acid by dissolving the proper quantity of iodine in concentrated aqueous sulphurous acid; also, by treating iodide of starch with sulphurous acid, and distilling the decolorised liquid. The acid when concentrated at a moderate heat, dissolves sulphur, and acquires thereby a yellow colour.

The iodosulphates of the alkali-metals may be prepared by neutralisation of the aqueous acid with the corresponding bases; the sodium salt also, by adding to a solution of sodium sulphite as much iodine as it is capable of dissolving, keeping the liquid cool; * also by the action of sodium sulphite on iodide of starch suspended in water.

Sodium Iodosulphate, $\text{Na}^2\text{SO}^3\text{I}^2 + 10\text{H}_2\text{O}$, crystallises in colourless elongated perfectly uniform prisms, the taste of which is rather bitter, but much less disagreeable than that of sodium sulphate. 100 parts of water at 15° dissolve 27.5 parts of the salt; it is also slightly soluble in aqueous alcohol. When heated it gives off vapours of iodine, leaving sulphide and sulphate of sodium. With mercuric nitrate it forms a yellowish-white, with silver nitrate a yellow, and with lead acetate a white precipitate (Zinno).

IRIDIUM. Separation from Platinum.—The separation of these metals may be effected by the method originally suggested by Birnbaum, which consists in converting them into cyanides, combining the latter with barium cyanide, and then mechanically separating the one double cyanide from the other.

To prepare the cyanides, a mixture of crude iridium oxide and potassium cyanide is fused in a small crucible, and kept at a high temperature until all the metallic oxide is taken up. The fused mass when cold is dissolved in water, filtered from unattacked iridium oxide, and hydrochloric acid is added in sufficient quantity to destroy the excess of potassium cyanide. The liquid is then mixed with concentrated solution of copper sulphate; the violet-coloured precipitate, consisting of the mixed double cyanides of iridium and platinum with copper, is washed by decantation with boiling water; and while it is suspended therein, a strong solution of caustic baryta is added. The copper is thus precipitated as oxide, and the double cyanides of iridium and platinum with barium are formed. Carbonic anhydride is then passed through to precipitate the barium, and the solution concentrated to crystallisation. The yellow platinum salt crystallises first, in small dichroic crystals, and afterwards the iridium salt in large colourless prisms, the crystallisation of both salts being so distinct and separate, that they can easily be picked out one from the other (S. P. Sadtler, *Sill. Am. J.* [3], ii. 338).

Ethylene-compounds of Iridium.—Sadtler has endeavoured to prepare iridium-salts analogous to the ethylene-platinum compounds obtained by Zeise (ii. 598). Pure iridium was prepared by igniting the crystals of barium-iridium cyanide obtained as above, and washing out the barium cyanide with boiling water. The metallic iridium,

* In a note to the abstract of Zinno's paper in the *Jahresbericht für Chemie*, 1871, p. 316, Michaelis says: 'I have had this statement tested by G. Köthe, and it has not been found correct. On adding to aqueous sulphurous acid, either concentrated or dilute, the quantity of iodine required to form iodosulphuric acid, with or without cooling, potassium iodide and sodium sulphate were always formed, and consequently the precipitate formed on adding lead acetate to the liquid was always yellow, not white as stated by Zinno. When on the other hand, a smaller quantity of iodine was added to the solution of sodium sulphite, lead acetate formed a white precipitate. This result, however, was due to the fact that lead iodide and sodium sulphite react so as to form sodium iodide and lead sulphite.'

after having been strongly ignited to effect its oxidation, was heated with nitromuriatic acid to 200° in a sealed tube, to convert it into chloride; and this compound was treated with absolute alcohol, with addition of potassium or ammonium chloride. The following reaction then appears to take place:

and the compound $\text{IrCl}^2.\text{C}^2\text{H}^4$ unites with the chloride of potassium or ammonium. At the same time, however, part of the iridium tetrachloride unites with the ethylene and the alkaline chloride without undergoing reduction to dichloride, so that a mixture of salts is obtained. With ammonium chloride two salts were obtained, agreeing nearly in composition with the formulæ:

With potassium chloride only the salt $\text{IrCl}^4(\text{C}^2\text{H}^4)^2(\text{KCl})^2$ was obtained, anhydrous, and combined with $3\text{H}^2\text{O}$.

IRON. *Properties of Pure Iron.*—Caron (*Compt. rend.* lxx. 1263) fused 50 to 150 grams of reduced iron by the heat of a hydrogen gas blow-pipe. The reguli obtained were free from blisters, a proof that hydrogen gas is not absorbed by melted iron. The pure fused iron had a high specific gravity.

	Sp. gr. at 16°
Pure iron (88.879 grams) fused in hydrogen	7.880
The same forged	7.868
The same drawn out into wire	7.847
Pure iron (117.54 grams) fused in a crucible, and therefore exposed to the action of atmospheric oxygen penetrating through the sides of the crucible	7.833

Pure iron fused in hydrogen is soft, easily drawn out into wire when cold, very malleable at a red heat. Iron fused in a crucible, on the other hand, is hard, and yields water by prolonged heating in hydrogen, showing that it has absorbed oxygen during fusion in the crucible.

Action of Cold on Iron.—Experiments on the action of cold on iron and steel have been made by Brockbank (*Chem. News*, xxiii. 62), Fairbairn (*ibid.* 89), Joule (*ibid.* 101, 143), and Spence (*ibid.* 124). Brockbank concludes that cast iron when cooled below the freezing point exhibits a considerable and increasing loss of tenacity and elasticity. An iron bar which had been exposed to hard frost was incapable of bearing more than one blow of a 12-lb. hammer, whereas when warmed to the temperature of the workshop, it bore fourteen blows of the same hammer without the least sign of fracture. Cold bars appeared crystalline without any indication of fibrous structure, whereas warm bars were fibrous and appeared somewhat crystalline only on the fractured surface. Fairbairn and Joule contradict those assertions, and Spence even comes to the conclusion, that the tenacity of iron is increased by lowering of temperature. The editor of *Engineering*, in which Journal (Feb. 1871, p. 82) the remarks above cited are collected together, observes with reference to them, that on comparing the results of former investigations, and the experience of the railways in Canada, the United States, Russia, and other countries where the winters are severe, there can be but little doubt that cold does diminish the power of iron to resist percussion and shaking, and that this is especially the case with the kinds of iron generally used for wheel-tires, and above all with iron which contains a somewhat considerable proportion of phosphorus. Steel, on the other hand, appears to be less influenced in this way.

Compounds of Iron.

Antimonate. An amorphous argillaceous mass from Nador, in the province of Constantine in Algeria, contains according to two analyses by Flajolot:—

Sb^2O^3	Fe^2O^3	As^2O^3	Al^2O^3	PbO	CaO	Loss by ignition
63.50	31.40	—	—	—	—	6.10 = 100
59.30	33.40	2.50	1.80	0.45	trace	3.05 = 100

Flajolot represents these numbers by the formula $2(\text{Fe}^2\text{O}^3.\text{Sb}^2\text{O}^3) + 3\text{H}^2\text{O}$ (*Compt. rend.* lxxi. 237; *Ann. Min.* [6], xx. 29).

Ferric Chloride. From the changes in the depth of colour of solutions of ferric chloride resulting from dilution with water, hydrochloric acid, sal-ammoniac, and a mixture of sal-ammoniac and hydrochloric acid,—also from rise of temperature, and from the age of the solution, A. Müller (*Deut. Chem. Ges. Ber.* ii. 178) infers that ferric chloride in its solutions must undergo chemical alteration. Acetic acid in its action on such a solution exhibits only $\frac{1}{16}$ th of the energy of hydrochloric acid. Experi-

ments made under similar conditions have shown that 5 mol. acetic acid are capable of displacing 1 mol. sulphuric acid from its combination with ferric oxide: hence it appears that at medium temperature, and in solutions in which it has only a small tension, hydrochloric acid is nearly twice as strong an acid as sulphuric acid. A similar conclusion may be drawn, according to Müller, from the more powerful action of (dilute) hydrochloric acid on cellulose, starch, and sugar.

From former experiments (*J. pr. Chem.* cvi. 321) Müller considers that neutral ferric acetate, $\text{Fe}^3\text{O}^2 \cdot 3\text{C}^2\text{H}^3\text{O}^2$, can exist permanently in aqueous solution only in presence of a considerable quantity of free acetic acid, and the quantity of the latter must be greater in proportion as there are more salts present which are capable of fixing the acid by formation of acid salts, *e.g.* acetates and sulphates of alkali-metal. Contrary to the ordinary assumption (made in accordance with Berthollet's law), ferric acetate in a solution containing a large excess of acetic acid does not exchange its acid (or only to a slight extent) with the sulphates of potassium, sodium, ammonium, and magnesium, or with the chlorides of sodium, ammonium, barium, and calcium, or nitrate of ammonium. On the contrary, ferric oxide dissolved in acetic acid withdraws phosphoric acid, which at ordinary temperatures is a weaker acid, in greater or lesser proportion from stronger bases (in spite of their excess), and unites with it, in the form of a basic compound, which is gradually precipitated from the acid solution. Any disturbance of the equilibrium of affinity taking place in a solution is slower in coming to an end, in proportion as the affinities of the reacting substances are less energetic.

Decomposition of Ferric Chloride by Heat in Aqueous Solution (Krecks, *J. pr. Chem.* [2], iii. 286).

All solutions of ferric chloride are decomposed on heating, the more readily the more dilute they are, the phenomena varying according to the strength of the solutions, the degree of heat to which they are raised, and the length of time during which they are exposed to this heat. The first effect observed in all solutions, when their temperature is raised, is a greater or lesser degree of darkening, owing to the formation of soluble ferric oxide (Graham's oxide) and free hydrochloric acid. If the temperature be now raised still higher, or continued for some length of time at the same degree, the solution becomes turbid, and deposits, according to concentration or temperature, either difficultly soluble ferric oxide (Péan's), or oxychloride, or dense anhydrous ferric oxide. The following table gives the temperatures at which these various phenomena are observed in solutions of different degrees of concentration:—

Concentration in per cent.	Formation of Graham's Ferric oxide	Separation of Péan's Ferric oxide	Formation of oxychloride	Formation of dense Ferric oxide
32	100—130°	—	Above 100°	140°
16	100—120°	—	—	120°
8	100—110°	—	—	110°
4	90—100°	—	90°	?
2	87°	—	87°	?
1	83°	100°—130°	—	—
$\frac{1}{2}$	75°	100°—130°	—	—
$\frac{1}{4}$	64°	—	—	—
$\frac{1}{8}$	54°	—	—	—
$\frac{1}{16}$	36°	—	—	—

Solutions containing $\frac{1}{16}$ per cent. or less of ferric chloride are decomposed under the influence of light, even at a temperature of 5° or 6° only, though in the dark they keep perfectly at that temperature. Solutions of $\frac{1}{4}$ per cent. and upwards are permanent when exposed to light at ordinary temperature, and a more or less elevated temperature is required for their decomposition.

The alterations in the specific gravity of solutions resulting from decomposition are in most cases so slight, and the changes taking place so complicated, that but little help can be derived from this property in estimating the amount of change produced. Nevertheless alterations in the specific gravity, due to decomposition, may be observed in solutions of ferric chloride, as shown in the following table, which gives the specific gravities at various temperatures, of two solutions of ferric chloride, each containing $\frac{1}{4}$ per cent. of the salt. One of the solutions was freshly prepared, the other was old and decomposed:—

Specific Gravity of Solutions of Ferric Chloride.

Temperature	Freshly prepared and normal	Old and decomposed	Temperature	Freshly made and normal	Old and decomposed
0	1.00086	1.00060	60	—	0.98468
10	1.00080	1.00041	70	—	0.97937
20	0.99888	0.99850	80	—	0.97394
30	0.99682	0.99644	90	—	0.96776
40	0.99452	0.99386	100	—	0.96114
50	—	0.98920	—	—	—

The property possessed by colloidal ferric oxide, to be precipitated from its solutions by the addition of neutral salts of the alkalis, discovered by Graham, affords, however, the means of estimating the amount of colloidal oxide present in a solution; and after its removal the amount of unaltered ferric chloride remaining may be estimated as usual. Since solutions containing more than 1 per cent. require to be heated to a temperature above 100° before they are decomposed, the experiments were limited to solutions containing 1 and a $\frac{1}{2}$ per cent. of ferric chloride respectively. The solutions were heated in an apparatus which permitted a careful regulation of the temperature, and allowed the taking of samples at any desired temperature, at the same time preventing any evaporation. The experimental results may be summed up as follows:—

1. In solutions of ferric chloride the amount of decomposition produced increases with the rise in temperature, but is not proportional to this rise.

2. With a constant temperature the amount of decomposition increases with the time up to a certain maximum. The increase is rapid at first, becomes gradually slower, and reaches the maximum after the lapse of about twelve hours.

The method sometimes employed for separating ferric oxide from manganese, cerium, nickel, and cobalt, by carefully neutralising the solution with ammonium or sodium carbonate, and boiling, whereby the ferric oxide is precipitated, while the other metals remain in solution, may be regarded as depending on the formation of colloidal ferric oxide, which is then precipitated by the alkali-salt present. The method proposed by Hofmann and Frankland of purifying sewage by the addition of ferric chloride also illustrates the same phenomena. The very dilute solution of ferric chloride produced is decomposed, as before described, even at ordinary temperature, and the ferric oxide precipitated carries down the other impurities.

On the decomposition of ferric salts by heat, see also Tichborne (*Chem. News*, xxix. 209).

Nitrosulphides. Roussin, by dropping a solution of a ferric salt into a mixture of ammonium sulphide and potassium nitrite, obtained a salt (dinitrosulphide of iron) in black needle-shaped crystals to which he assigned the formula $\text{Fe}^3\text{S}(\text{N}^2\text{O}^2)\cdot\text{H}^2\text{S}$ or $\text{FeSN}^2\text{O}^2\cdot\text{Fe}^3\text{S}^2\text{N}^2\text{O}^2\cdot\text{H}^2\text{S}$ (iii. 301). According to Porczynsky (*Ann. Ch. Pharm.* cxv. 302; *Jahresb.* 1863, 259) this salt has the composition $\text{Fe}^3\text{S}^2(\text{N}^2\text{O}^2)^2\cdot 2\text{H}^2\text{O}$ or $\text{Fe}^3\cdot\text{Fe}^3\text{S}^2(\text{N}^2\text{O}^2)^2\cdot 2\text{H}^2\text{O}$, and when treated with potash gives off ammonia, and yields black triclinic crystals of the potassium salt, $\text{K}^1\text{S}\cdot\text{Fe}^3\text{S}^2(\text{N}^2\text{O}^2)^2$. Rosenberg (*Deut. Chem. Ges. Ber.* iii. 312) assigns to Roussin's salt the more complex formula $\text{Fe}^3\text{S}^2(\text{N}^2\text{O}^2)^2\cdot\text{H}^2\text{O}$, and to the potassium salt obtained by treating it with potash, the formula $\text{K}^1\text{Fe}^3\text{S}^2(\text{N}^2\text{O}^2)^2 + 19\text{H}^2\text{O}$. The corresponding sodium salt has the formula $\text{Na}^1\text{Fe}^3\text{S}^2(\text{N}^2\text{O}^2)^2 + 24\text{H}^2\text{O}$.

Oxides. Monoxide or Ferrous oxide.—This oxide may be obtained in the anhydrous state by the action of carbon dioxide on pure iron at a red heat:

The oxide thus obtained is black, crystalline, and magnetic, and agrees exactly in composition with the formula FeO . Heated to redness in the air, it is converted into Fe^2O^3 (Tissandier, *Compt. rend.* lxxiv. 531).

Ferric Oxide.—A native compound of this oxide with cuprous oxide, named *Deafossite*, is contained in the mineralogical collection of the *École des Mines*, and in that of the *Musée d'Histoire Naturelle* at Paris. It consists of 47.99 p.c. Fe^2O^3 , 3.52 Al^2O^3 , and 47.45 Cu^2O , agreeing with the formula $(\text{Fe}; \text{Al})^2\text{O}^3\cdot\text{Cu}^2\text{O}$. Sp. gr. = 5.07; hardness = 2.5; streak, greyish-black. It splits easily into very thin perfectly opaque laminae, soils the fingers, dissolves easily in acids.

Attempts to prepare this mineral artificially by heating a solution of ferric chloride with cuprous oxide to 250° in a sealed tube resulted in the formation of *atacamite*, the iron being all precipitated. This may possibly be the natural mode of formation

of atacamite, $\text{Cu}^2\text{ClH}^2\text{O}^2$, especially as it is often found associated with ferric oxide (Friedel, *Compt. rend.* lxxvii. 211).

Ferroso-ferric Oxides.—H. Sainte-Claire Deville (*Ann. Ch. Pharm.* clvii. 71) has examined the action of water on iron and of hydrogen on ferroso-ferric oxide. The apparatus employed for oxidation-experiments consisted of a glass or porcelain tube containing the iron, and communicating at one end with a Geissler's or Sprengel's air-pump, at the other with a retort containing water kept at a constant temperature by surrounding the retort with ice or cold water. For reduction experiments the iron was replaced by ferroso-ferric oxide and the retort by a hydrogen-apparatus. The tube containing the iron or oxide was kept at a constant temperature by immersion in an oil- or mercury-bath for the lower temperatures, and for higher temperatures by means of the vapour of mercury (360°), sulphur (440°), cadmium (860°), zinc (1040°); for the highest temperature the tube was exposed to the direct flame of petroleum, the flow of which was regulated by stop-cocks. As soon as the tension of the gases became constant at any particular temperature, it was measured, and thence the tension of the dry hydrogen could be calculated, since the tension of the aqueous vapour was known from the temperature of the water in the retort, which was always lower than that of the other parts of the apparatus.

The following table gives the results of Deville's experiments, placed together in pairs: the numbers in the first line of each pair relating to a water-temperature of 0° , that in the second to a somewhat higher temperature, between 10.6° and 19° . This table shows (1) the temperature of the iron for each pair of experiments; (2) the tension of the water-vapour e and e' , as well as the tension of the dry hydrogen h and h' ; (3) the relation $r = \frac{h}{e}$ and $r' = \frac{h'}{e'}$, that is, the ratio of the tension of the hydrogen to that

of the water-vapour, and lastly (4), the ratio $\frac{r'}{r}$, which is an expression of the alteration taking place in the relative quantities of the hydrogen- and water-vapours when the tension of the latter is altered while the temperature of the iron remains constant.

Temperature of the Iron	Tension of the Water-vapour e	Tension of the dry Hydrogen h	Ratio of the Tensions $r = \frac{h}{e}$	Ratio $\frac{r'}{r} = \frac{e}{e'}$
200°	{ 4.6	195.9	20.848	0.965
	{ 9.7	95.3	20.134	
265°	{ 4.6	64.2	13.966	1.073
	{ 15.7	235.1	14.974	
360°	{ 4.6	40.4	8.783	0.915
	{ 9.5	76.3	8.031	
440°	{ 4.6	25.8	5.609	1.022
	{ 10.1	57.9	5.732	
860°	{ 4.6	12.8	2.783	0.661
	{ 13.1	23.9	1.838	
860°	{ 4.6	12.8	2.783	0.656
	{ 12.7	23.2	1.827	
1040°*	{ 4.6	9.2	2.000	0.752
	{ 12.7	10.1	1.804	
1040°	{ 4.6	9.4	2.043	0.667
	{ 12.7	17.3	1.362	
1600°	{ 4.6	5.1	1.109	0.647
	{ 13.3	11.7	0.718	

The numbers in this table show that iron decomposes less water the higher it is heated, and that when the tension of the water-vapour is increased (by heating the water in the retort) the tension of the hydrogen likewise increases, and that the higher the temperature of the iron, the less is the increase in the tension of the hydrogen compared with that of the aqueous vapour.

The total result is independent of the quantity of iron or iron oxide employed, and the tensions of the hydrogen gas and aqueous vapour are always in the same ratio to one another so long as the temperature remains constant. This state of equilibrium is the same at a given temperature whether aqueous vapour be made to act upon iron or hydrogen upon iron oxide.

* In these two experiments iron oxide was reduced by hydrogen; in all the others, water acted on metallic iron.

Furnace-product containing Magnetic Oxide of Iron.—This mineral was found in a cleft of the hearth-stone (consisting of quartz and clay) of the coke-fed blast-furnace of Prevali in Carinthia, and had doubtless been formed there. It consists of fine steel-grey closely intergrown crystals, strongly magnetic and having a sp. gr. of 5.63. It gave by analysis 76.2 p.c. Fe and 23.8 O, or 79.83 FeO and 20.11 $\text{Fe}^{\text{II}}\text{O}^{\text{II}}$ (H. Völker, *Ann. Ch. Pharm.* clxv. 356).

Lieben, in a note to Völker's paper, observes that the occurrence of crystallised magnetic iron oxide as a furnace-product has often been noticed before, but that such products have hitherto been found to agree in composition with the natural mineral $\text{Fe}^{\text{II}}\text{O}^{\text{II}}$, or $\text{FeO}.\text{Fe}^{\text{II}}\text{O}^{\text{II}}$. The product above described differs, however, both from this and from the common scale-oxide (generally regarded as $\text{Fe}^{\text{II}}\text{O}^{\text{II}}$ = $6\text{FeO}.\text{Fe}^{\text{II}}\text{O}^{\text{II}}$, or by some chemists as $\text{Fe}^{\text{II}}\text{O}^{\text{II}}$ = $4\text{FeO}.\text{Fe}^{\text{II}}\text{O}^{\text{II}}$), its specific gravity being higher, and its composition agreeing with the formula $\text{Fe}^{\text{II}}\text{O}^{\text{II}}$ or $9\text{FeO}.\text{Fe}^{\text{II}}\text{O}^{\text{II}}$.

The constitution of these three varieties of ferroso-ferric oxide may be represented by the following formulæ:—

Absorption of Salts from Solution by Ferroso-ferric Oxide.—Official ferroso-ferric oxide completely absorbs the nitrates of lead, silver, copper, and zinc, also zinc chloride and the sulphates of copper, ferrous, and zinc. Common alum, chrome-alum, and tartar-emet, are decomposed by the oxide in such a manner that the filtrate contains sulphate or tartrate of potassium. The salts above mentioned cannot be washed out of the iron oxide by water either cold or hot. The salts of the alkaline earth-metals are slowly absorbed, those of magnesium and the alkali-metals, also mercuric chloride, not at all. Ignited ferroso-ferric oxide appears to exert this absorbing power less strongly. Ferroso-ferric oxide likewise absorbs organic matters with great facility (J. B. Schöber, *N. Rep. Pharm.* xix. 345).

Estimation of Iron and Analysis of its Compounds. 1. *Estimation by means of Soluble Ferrocyanides.*—When to a solution of potassium ferrocyanide, with or without the addition of a mineral acid, a ferric solution is slowly added, the blue precipitate at first formed disappears again, the solution remaining blue and clear; on further addition it becomes muddy, but still always preserving its character as a blue solution, till suddenly a drop more of the iron solution causes sudden coagulation, the liquid soon separating into a clear colourless layer, and the blue flocculent precipitate settling to the bottom. In the clear solution neither iron nor ferro-cyanogen is present. This coagulation may, therefore, be used as an indication of the termination of the reaction. The experiment is best made in a porcelain basin.

To determine the quantitative relation of this reaction and its applicability to the estimation of iron and of ferro-cyanogen, solutions of known strength were prepared from pure potassium ferrocyanide and ammonio-ferrous sulphate. The latter was oxidised with nitric acid. Of the two salts 0.1 gram-equivalent was taken, i.e. 2.11 grams of the former and 1.96 gram of the latter dissolved to 530 c.c. Experiment showed that 26 c.c. of the potassium ferrocyanide solution required for complete decomposition 32.3 c.c. of the iron solution, consequently that the number of equivalents of ferro-cyanogen and iron concerned in the reaction are as 26 : 32.3, or nearly as 3 : 4; in other words, that 3 eq. ferro-cyanogen require 4 eq. Fe or 2 eq. $\text{Fe}^{\text{II}}\text{O}^{\text{II}}$. To obtain concordant results, the solution of the ferro-cyanide must be diluted with water to a certain extent, or the reaction denoting the completion of the experiment will be obtained too soon, i.e. the quantity of ferric solution required to attain this point will be less than that which is equivalent to the ferro-cyanogen present. The addition of acid is requisite even when the above precaution is observed. (H. Rheineck, *Dingl. pol. J.* cii. 164).

2. *Estimation of Ferrous Oxide in presence of Ferric Oxide in Silicates.*—For this purpose Wilbur a. Whittlesey (*Chem. News*, xlii. 2) mix
2nd Sup.

the finely pounded silicate in a platinum crucible with an equal or a larger quantity of pulverised fluorspar or crysolite, and such a quantity of hydrochloric acid that the crucible is about two-thirds filled by the mixture. The crucible is placed on a water-bath and heated in a stream of carbon dioxide or coal-gas till all the iron is dissolved, which takes place in $\frac{1}{2}$ to $1\frac{1}{2}$ hour, according to the nature of the mineral. The ferrous oxide is then estimated by titration in the ordinary way with solution of permanganate. The method of solution here described is said to be applicable even to ferric oxide which has previously been ignited.

H. Allen (*ibid.* 57) regards this method as very exact, but suggests that it is better to titrate the solution of ferrous chloride with potassium bichromate, since, as is well known, the titration with permanganate does not always give exact results, excepting when the iron oxide is dissolved in sulphuric acid. Difficultly soluble ferrous compounds may be dissolved by heating them with hydrochloric acid under pressure. The finely powdered substance is sealed up in a glass tube with fuming hydrochloric acid and heated, first in a water-bath, then to 140° – 150° .

3. *Analysis of Chrome-Iron Ore.*—To estimate the iron and chromium in this ore, J. Blodget-Britton (*Chem. News*, xxi. 266) mixes 0.5 gram of the finely pounded substance with 4 grams of a flux consisting of 1 part potassium chlorate and 3 parts soda-lime, and heats the mixture to bright redness in a platinum crucible for an hour and a half or longer. The mass, which does not fuse and is easily loosened from the crucible by gentle tapping, is to be finely pulverised and drenched in a beaker glass with 18 c.c. of water, the whole boiled for two or three minutes, and mixed, on cooling, with 15 c.c. of hydrochloric acid of ordinary strength, which, on stirring, dissolves the whole, except a little gelatinous silica.

a. To estimate the chromium, the liquid containing all the iron and chromium in the highest state of oxidation is diluted to 3 ounces in a porcelain basin, and a solution of 1 gram of metallic iron in dilute hydrochloric acid is added, mixed with a quantity of water sufficient to raise the volume of the entire liquid to 8 ounces. On titrating with permanganate, the difference between the quantity of iron found and that which was weighed out gives the quantity of iron converted into ferric oxide by the chromic acid. Every 1 part of ferric oxide thus formed represents 0.320 part metallic chromium, or 0.4663 chromic oxide. The iron, in the form of turnings, is dissolved in a test-tube closed with a caoutchouc stopper, through which there passes a glass tube bent at right angles. To accelerate the reaction, and at the same time exclude the air, the liquid is heated to boiling.

β . To estimate the iron, the mineral, ignited with the flux as before, is dissolved in 15 c.c. hydrochloric acid after boiling with 10 c.c. water; the whole of the iron and chromium are reduced by zinc after cooling; and the resulting ferrous salt is titrated with permanganate. For diluting the liquid previous to this last operation, cold water acidulated with sulphuric acid is used, as the end of the reaction is thereby rendered more distinct.

4. *Analysis of Pig-Iron and Steel.* a. *Estimation of the Iron.*—F. Kessler (*Zeitschr. anal. Chem.* xi. 249–270) effects this by a modification of the volumetric method depending on the use of potassium bichromate. Pure potassium bichromate is prepared by fusing the salt in a glass bulb placed in a bath of fused bichromate; the inner part of the salt thus prepared is found to be perfectly dry and undecomposed. A weighed quantity of this pure salt is added to the solution containing the iron (reduced to the ferrous state by the action of stannous chloride, excess of this latter being decomposed by the addition of mercuric chloride), and then a normal solution (4.01 gram per litre) of the bichromate is run in. The end of the reaction is noted by adding excess of bichromate, then a ferrous chloride solution till the blue colour with potassium ferricyanide reappears. If copper be present in any quantity, it must be removed by precipitation with sulphuretted hydrogen, before the iron is estimated. Kessler estimates the oxidation-equivalent of potassium bichromate as equal to 49.1.

β . *Estimation of Manganese.*—For this purpose Kessler employs the following solutions:—

a. A decinormal solution of potassium permanganate, containing 3.16 grams of pure salt per litre.

β . A solution of antimonious chloride, prepared by dissolving 14.6 grams of pure antimonious oxide in concentrated hydrochloric acid, and diluting to 1 litre. This solution is titrated against the permanganate.

Solutions of sodium carbonate, sulphate, and acetate are required, containing respectively 200 and 600 grams of the crystallised salts per litre; also concentrated and dilute acetic and hydrochloric acids, sulphurous acid, and saturated bromine water. 0.66 gram of the iron or steel is dissolved, the solution diluted to 100 c.c., and neutralised with sodium carbonate solution, until a slight permanent precipitate is pro-

duced; this is dissolved by cautious addition of dilute hydrochloric acid; 1·2 c.c. of concentrated sodium acetate solution and 1·2 c.c. acetic acid, or in their place 3 c.c. of sodium sulphate solution are then added, and the liquid, after dilution and boiling, is made up to 300 c.c. and filtered. 250 c.c. (= ·55 gram of the substance) are placed in a 600 c.c. flask; 150 c.c. water, 100 c.c. bromine-water, and 2 c.c. sodium acetate solution added; after an hour, 6 c.c. of the latter solution are added, and at the end of another hour, 12 c.c. of the same substance; the liquid is then warmed in the water-bath till all excess of bromine is driven off. The precipitate is collected and well washed with dilute solution of sodium acetate. The filter, with the precipitate, is then treated in a porcelain basin with 5, 10, or 15 c.c. of the antimony solution, 15 c.c. strong hydrochloric acid are added after a while, and the whole is digested till no trace of an undecomposed precipitate remains. 100 c.c. water are then added, and the solution titrated with the permanganate solution. If the process is thus carried out, half the difference between the number of c.c. permanganate corresponding with the c.c. of antimony solution used, and the number of c.c. of permanganate actually employed, gives the percentage of manganese (1 c.c. of the permanganate being equal to 0·5 per cent. manganese).

Cobalt, nickel, or copper, if present, is precipitated together with the manganese; but, except in the case of cobalt, their influence on the manganese estimation is scarcely perceptible.

Colorimetric Estimation of the Manganese.—Pichard (*Compt. rend.* lxxv. 1821) describes a method depending essentially on the conversion of the manganese into an alkaline permanganate, and the comparison of the colour of the resulting solution with that of a similar solution containing a known weight of manganese: 0·1 gram of finely divided material is first carefully oxidised by calcination, and then fused with 2 or 3 decigrams of sodium carbonate. The mass is dissolved in 5 c.c. of nitric acid, to which one drop of hydrochloric acid has been added, and the manganese is oxidised after the addition of 10 c.c. of water, by boiling the solution for a short time with 0·5 gram of lead peroxide. The clear liquor is subsequently decanted into a test-glass graduated into 500 c.c. The standard solution of permanganate is prepared of such a strength that 10 milligrams of manganese are contained in 1 litre of the solution.

Specimens of iron, or of iron-ore, seldom contain more than 5 per cent. of manganese. If, therefore, 0·1 gram of material be taken for analysis, and the solution obtained therefrom be diluted until the tint corresponds exactly with that of the standard liquor, then every 100 c.c. observed will represent 1 per cent. of manganese in the sample under examination.

γ. Estimation of Carbon in Cast Iron and Steel.—The mode of estimating the carbon by dissolving the iron in cupric chloride and oxidising the separated carbon by a chromic acid solution (iii. 372), has been modified by A. H. Elliott (*Chem. Soc. J.* [2], vii. 182). To avoid the loss of carbon, which may possibly result from the elimination of part of it in the form of hydrocarbons by the action of the free acid in the cupric chloride solution, Elliott uses a solution of cupric sulphate, which does not contain free acid. He then removes the precipitated metallic copper by means of cupric chloride, before proceeding to oxidise the carbon with chromic acid solution.

Eggertz (*Dingl. pol. J.* clxxx, 350) has devised a colorimetric method of estimating the carbon, founded on the fact that cast iron and steel dissolve in nitric acid with a brown colour darker in proportion to the quantity of carbon they contain: 0·1 gram of the iron or steel is dissolved, with aid of heat, in nitric acid of sp. gr. 1·2, and the brown colour of the solution is compared with that of a solution of cast steel containing a known amount of carbon, both being diluted to the same degree.

This method has been modified by J. B. Britton (*Dingl. polyt. J.* cxi. 182) as follows:—He uses sixteen glass tubes, 2½ inches long and ¼ inch diameter, placed in a wooden stand; these tubes are filled with a mixture of alcohol and water coloured with burnt coffee. The solution in the first tube at the left side corresponds in colour with a liquid containing 1 gram of iron with 0·5 per cent. combined carbon dissolved in 15 c.c. nitric acid. The liquid in the next tube to the right corresponds with the same amount of iron, but containing ·07 per cent. combined carbon, dissolved in the same amount of nitric acid, and so on, each solution varying in colour so as to correspond with an increase of 0·2 per cent. carbon. The back of the stand is covered with thick white paper.

The sample to be tested must be obtained in fine powder, 1 gram dissolved in 15 c.c. pure nitric acid of specific gravity 1·42, diluted with 30 c.c. water. This solution is filtered into a test-tube 4 inches long and of a diameter the same as that of the tubes in the stand, and the depth of colour is compared with that of the standard solution. Care must be taken that the nitric acid used is always of the strength given above.

that the liquid to be tested is at the ordinary atmospheric temperature, that the testing is performed soon after dissolving the sample, and that all circumstances under which the standard solutions and the solutions of the samples are made, are the same in both cases.

W. D. Hermann (*Chem. Soc. J.* [2], viii. 376) considers that the carbon in steel may be most correctly estimated by combustion in a stream of oxygen, the carbon dioxide thereby produced being absorbed as usual by caustic potash. The iron is at the same time oxidised to ferric oxide, the amount of which is very constant, and serves as a check on the completeness of the combustion.

8. *Estimation of Sulphur and Phosphorus in Iron.*—A. H. Elliott estimates the sulphur by liberating it in the form of hydrogen sulphide, absorbing the gas in a solution of pure soda (prepared from sodium) and determining the hydrogen sulphide in the acidified solution by means of a standard solution of iodine (*Chem. News*, xxiii. 76).

Meineke (*Zeitschr. anal. Chem.* x. 280) dissolves the iron by means of a solution of cupric chloride, and determines the sulphur and phosphorus by precipitation.

5 grams of iron in fine powder are dissolved in from 1 to 1½ hour by gentle warming with a concentrated solution of cupric chloride. After carefully decanting off the iron solution, the separated copper is removed by the renewed addition of cupric chloride, cuprous chloride being formed, which is kept in solution by adding common salt.

The insoluble residue is separated by means of an asbestos filter, washed, thrown with the filter into a beaker, oxidised with strong nitric acid and chlorate of potassium, evaporated to dryness; and in the solution filtered therefrom the sulphur is estimated as barium sulphate. To the filtrate ammonia is added, which precipitates iron oxide together with the phosphoric acid; this precipitate is dissolved in hydrochloric acid, and the phosphoric acid estimated by a molybdic acid solution.

The results obtained by this method show a somewhat higher percentage of sulphur than those obtained by the older process of driving off the sulphur as sulphuretted hydrogen, absorbing it in an ammoniacal silver solution, and estimating the sulphur in the silver sulphide formed. Meineke therefore supposes that, in the old process, there always remains a certain amount of sulphur not driven off as sulphuretted hydrogen.

If phosphorus only is to be estimated, the insoluble residue together with the separated copper is washed, oxidised as formerly, and evaporated to dryness with hydrochloric acid, and the residue is treated with aqueous ammonia. There is always sufficient iron oxide present to precipitate all the phosphoric acid. In the hydrochloric acid solution in which the precipitate is re-dissolved, phosphoric acid is estimated by a molybdic acid solution.

F. Kessler (*Deut. Chem. Ges. Ber.* iii. 11) precipitates the iron and accompanying metals in acid solution with potassium ferrocyanide, and estimates the phosphorus in the filtrate: 5.6 grams of the iron or steel are dissolved in nitric acid; the liquid is evaporated to dryness; the residue dissolved in hydrochloric acid; the ferric solution reduced with hydrogen sulphide; 42 grams of potassium ferrocyanide are added; and the whole is diluted to 518 c.c. (the precipitate occupies 18 c.c., and therefore the solution is diluted to 518 and not merely to 500 c.c.). 250 c.c. of the filtrate mixed with magnesium sulphate and ammonia yield crude ammonio-magnesian phosphate, which must be purified by solution in nitric acid, filtration, and precipitation with ammonia, and converted by ignition into magnesium pyrophosphate: ¼ decigram answers to 1 p.p. phosphorus in the iron. For further details of the process, see *Chem. Soc. J.* [2], x. 80.

e. *Estimation of Silicon.*—H. Boussingault estimates the amount of silicon in cast iron and steel in the dry way. A quantity of the iron weighed out in a platinum boat is oxidised by ignition for several hours in a muffle, and the resulting oxide is moderately heated in a stream of dry hydrogen chloride. The iron is thereby volatilised as chloride, while the silica remains as a pure white mass having the structure of the iron particles. The purity of the silica may be tested by moistening it with hydrofluoric acid and a drop of sulphuric acid, and heating it; if pure, it will volatilise without residue (*Ann. Chim. Phys.* [4], xxii. 457).

IRON METALLURGY. I. Cast or Pig Iron. 1. *Chemistry of the Blast-Furnace.*—Several important points relating to the Chemistry of the Blast-Furnace have been explained by I. Lowthian Bell in a Lecture delivered before the Chemical Society, June 1869 (*Chem. Soc. J.* [2], vii. 208). He disputes the correctness of the assumption made by Scheerer, Tunner, and Ebelmen, respecting the existence of different zones of action in the blast-furnace,—namely, an upper zone, in which the reduction of the ore takes place, and a lower one, in which the reduced iron becomes carbonised,—on the ground that such an assumption implies the descent of

all the lumps of ore at a uniform rate. This, however, is prevented by the friction of the lumps against the sides of the furnace, and by their different forms and sizes; it is likewise at variance with all practical experience. Neither is it possible to admit the existence of distinct zones of temperature, inasmuch as the temperature at any particular part must vary with the different chemical processes which go on, now in one part, now in another, accordingly as the stream of hot gases meets with greater or less resistance. Mr. Bell's experiments indicate that the temperature required for the reduction of iron oxide has hitherto been estimated too high. Cleveland iron ore, in lumps of the size of hemp-seed, converted carbon monoxide almost completely into dioxide, even at 300° C. and lost in 15 minutes 39 p.c. of its oxygen. In the gases from the blast-furnace the reduction of various iron ores began at the melting point of bismuth, more quickly at that of zinc; but experiments made with ores in perforated boxes according to the method of Tunner and Ebelmen, gave much less reduction at the same temperatures.

Mr. Bell further denies that hydrogen, ammonia, or cyanogen, plays any essential part in the reduction of the ore. He finds that the temperature at which iron separates carbon from its monoxide is lower than it has been placed by former observers, and that it lies between the melting points of lead and zinc (i.e. at about 360°). The union of the iron with carbon takes place simultaneously with its reduction, and the conversion of the carbon into graphite depends only on the temperature at which the fusion and subsequent cooling take place.

The composition of the gases collected at different depths of a blast-furnace exhibits considerable variation; and it is only from the composition of those which issue from the mouth that any trustworthy inference can be drawn respecting the chemical changes going on in the furnace.

The saving of fuel by the use of the hot blast appears, from Mr. Bell's observations, to be due, not to the production of a comparatively high temperature, but to the fact that the fuel which serves to heat the blast is completely burnt, and gives up all its heat of combustion to the blast; whereas, in the furnace, the final product of the combustion is only the monoxide, not the dioxide of carbon, and consequently the heating effect of the same quantity of carbon is reduced to one-third of its total amount. Moreover, the gases from the mouth of a furnace worked with the hot blast carry away less heat than those from a cold-blast furnace, probably because the specific heat increases rapidly with rise of temperature, and an increased charge of ore involves greater absorption of heat. As a consequence of the preceding considerations, and in accordance with extended experience, it is recommended that the height of blast-furnaces be increased beyond their usual limits.

2. Utilisation of the Residues from the Burning of Iron Pyrites for Smelting in the Blast-Furnace.—An account of experiments made for this purpose is given by E. Richters (*Dingl. pol. J.* cxix. 292; *Jahresb. f. Chem.* 1871, 991). These residues usually contain from 3 to 6 p.c. sulphur, partly in the form of iron monosulphide, or, if the pyrites contained blende, in the form of unaltered zinc sulphide or of basic zinc sulphate. Arsenic and copper are also often present. The copper must be removed before the residues are smelted for iron. The experiments were made in a blast-furnace in which 450 cwts. of iron were smelted daily with a blast-pressure of 4 lbs. per square inch, a blast-temperature of 300°–400° C., a consumption of coke amounting to 150–160 lbs. to 100 lbs. of pig-iron, and with a production of slag amounting to between 100 and 110 lbs. In addition to the sulphur contained in the pyrites residues, a considerable quantity was also introduced into the charge from the ash of the coke, which contained from 10 to 12 p.c. sulphuric acid.

The ore mixed with the pyrites residues consisted of magnetic iron ore, a small quantity of black band, roasted clay ironstone, bog iron ore, and red hematite. The working of the furnace was greatly impeded by the complete want of manganiferous ores, which are well known to assist in carrying the sulphur into the slag. The facility of this transference of the sulphur from the charge to the slag depends very much on its mode of occurrence. Sulphur belonging to the ore passes into the iron much more easily than that which is contained in the fuel or the fluxes. A high temperature of the zone of fusion, and a basic constitution of the charge, are the chief conditions for obtaining iron as free as possible from sulphur from a charge rich in sulphur.

In the experiments under consideration the object in view was to obtain a pig-iron containing not more than 0.04 p.c. sulphur, such as could be used in Bessemer steel works. The experiments were so conducted that the proportion of pyrites residues in the charge, and the proportion of lime were gradually increased, till, on the one hand, further addition of lime was forbidden by the difficult fusibility of the slag, and, on the other, the proportion of sulphur in the iron began to exceed the maximum assigned. A charge which, independently of the coke, contained 38.0 p.c. roasted magnetic iron ore, 25.5 p.c. pyrites residues (with 1.63 p.c. sulphur), 1.5 p.c. raw black-band, and

35.0 p.c. limestone, and in which, including the coke-ash, 4.6 parts of sulphur were present to 100 parts of iron, yielded a grey graphitic pig-iron containing 0.022 p.c. sulphur. But as soon as the temperature of the zone of fusion was lowered, the slags became more basic, and pig-iron was obtained containing a higher proportion of sulphur. The difficulty of transferring the sulphur to the slag does not increase in proportion to the amount of sulphur present. An increase of 0.5 to 1 p.c. in the charge may be removed by increasing the basicity of the charge from 0.1 to 0.2 p.c.

To obtain iron still more free from sulphur, a number of favourable influences must co-operate, especially a high temperature. The same charge yielded at different temperatures pigs containing 0.049, 0.088, 0.096, and 0.224 p.c. sulphur. In the charge above specified the maximum quantity of lime was added, and the slag thereby rendered difficultly fusible. To ascertain whether, with the use of a given quantity of lime, a more acid and more fusible slag might not be used, clay capsules from a porcelain manufactory were added to the charge. It was found, however, that, according to the quantity of burnt clay added, the amount of sulphur in the pig was increased to 0.037 and even to 0.110 and 0.146 p.c.

The pig-iron obtained in these experiments was very rich in silicon: a result due simply to the circumstance that the proportions of the charge which tend to remove sulphur from the iron are exactly those which tend to introduce silicon into it. The smallest proportion of sulphur in the iron obtained was 0.013 p.c., and this iron contained 3.485 p.c. silicon.

Richters has also analysed a blast-furnace slag very rich in sulphur, and the iron obtained from it, with the following results:—

Slag	SiO ²	Al ² O ³	CaO	MgO	FeO	MnO	CaS
	33.18	13.28	42.63	5.93	0.22	0.04	5.90
Pig-iron	Fe	C (graphite)	Mn	Si	P	S	
	93.631	4.021	0.791	0.961	0.246	0.079	

The slag was crystalline, light grey, and smelt strongly of hydrogen sulphide, especially when pounded. Although very basic, it did not disintegrate in contact with the air. The 5.90 p.c. calcium sulphide contained in it answers to 2.62 p.c. sulphur. Nevertheless, the proportion of sulphur in the iron smelted from it did not exceed the ordinary limits. The result shows that even with a highly sulphuretted raw material a good iron may be obtained by proper adjustment of the basicity of the charge.

3. *Composition of Pig-Iron.*—Investigations on the influence of the elements associated with iron in the pig, and the part they play in the conversion of the pig into wrought iron and steel, have been published by E. Riley (*Chem. Soc. J.* [2], x. 533).

Analyses of different numbers or qualities (No. 1 denoting the best quality) of cold-blast pig-iron from the Low Moor Bowling works in Yorkshire, show that the composition in the different numbers is practically the same, the only apparent difference being a slight decrease in the proportion of silicon as the quality becomes lower.

Bowling Pig-Iron.

	1	2	3	4
Carbon, as graphite	3.421	3.155	3.361	3.308
Carbon, combined	0.583	0.581	0.393	0.319
Silicon	1.708	1.646	1.382	1.381
Iron	92.070	92.644	92.962	93.292
Manganese	1.606	1.472	1.475	1.169
Phosphorus	0.630	0.636	0.602	0.602
Sulphur	0.073	0.073	0.070	0.081
Titanium	trace	trace	trace	trace

The diminution in percentage of silicon with the quality of the iron is much more apparent in hot-blast pig, as may be seen from the following analyses of Seend pig, which likewise show that the proportion of sulphur is greater in the lower qualities:—

Pig-Iron from Seend, Wiltshire.

	Silicon	Sulphur	Phosphorus
1	4.717	0.86	0.87
2	3.659	0.77	0.17
3	3.209	0.96	0.68
4	3.140	1.06	0.72
5	2.257	1.60	0.26
6	2.197	2.48	0.89

In Welsh pig-iron also the percentage of sulphur increases as the quality of the pig deteriorates.

Analyses of South Wales Pig from Clay Ironstone.

	Gray	Mottled	White	Gray
Carbon	3.14	2.95	2.84	3.08
Silicon	2.16	1.96	1.21	2.22
Sulphur	0.11	0.28	0.46	0.09
Phosphorus	0.63	0.63	0.64	0.63
Iron	94.56	95.39	95.10	94.35
Manganese	0.50	0.23	0.14	0.33
Nickel and Cobalt	0.05	0.04	0.03	0.07
	101.15	101.48	100.42	100.77

These results tend to show that the difference between grey and white cast iron is due, at least in part, to the larger proportion of sulphur in the latter. Difference of temperature in the smelting has, however, some effect, a high temperature favouring the production of grey pig. Mr. Bell has shown, indeed, that white pig-iron may be converted into grey pig by exposing it to a very high temperature (*Journal of the Iron and Steel Institute*, Nov. 1871, p. 277).

It is generally admitted that the best pig-iron is made from the clay ironstones of the coal-measures. Now this pig-iron contains both silicon and phosphorus, and Mr. Riley finds, by analysis of various kinds of pig from which the best wrought iron is made, that their average composition approximates very closely to that of the pig made from clay band ironstone. On the other hand, pig iron which is chemically very pure and nearly free from silicon and phosphorus, such as Swedish iron, yields very red-short wrought iron, and quite unfitted for the manufacture of wrought iron of the best quality, unless it be mixed with other kinds of pig-iron containing both silicon and phosphorus. These two elements appear therefore to play an important part in the manufacture of iron.

Silicon, when present in large amount, as in Bessemer pig, reduces the percentage of carbon; in inferior pig-iron containing much sulphur and phosphorus the percentage of carbon is always low.

4. *Condition of Carbon and Silicon in Pig-Iron.*—It is well known that in grey pig-iron the carbon exists in two states, *free* or *graphitic*, and *combined*, or in a state of intimate mixture. The graphitic particles are much lighter and more friable than the iron, and may be separated by pulverisation, sifting, and levigation: in many instances also they may be picked out with the point of a knife. The following determinations of the proportions of free and 'combined' carbon in two kinds of pig-iron and in the lighter portions separated by sifting and levigation, have been made by G. Snelus (*Journal of the Iron and Steel Institute*, Feb. 1871, p. 28):—

	Original pig	Siftings	Levigated powder
Bessemer pig { Graphite	3.19	7.79	21.27
{ Combined Carbon	0.20	0.17	—
Middlesborough forge pig { Graphite	2.65	7.015	41.320
{ Combined Carbon	0.35	0.3	—

Snelus is of opinion that the absorption of carbon by iron is rather a case of solution than of definite chemical combination.

Silicon invariably occurs in pig-iron, and is never entirely absent even in steel and wrought iron. In good Bessemer and in tool-steel it rarely exceeds 2 or 3 pts. in 10,000. The following results were obtained by the methods above mentioned:—

Amount of Silicon per cent. in—

	1 Original pig	2 Fine siftings	3 Levigated powder
West Cumberland Bessemer pig	2.419	2.380	—
Dowlais Bessemer pig	3.849	3.639	3.158
Middlesborough pig	1.815	1.610	1.219

Here the silicon, unlike the graphite, does not increase in the finer portions, but diminishes. It remains with the iron just as the 'combined' carbon does. Hence Snelus concludes that the silicon is in combination or in solution in the iron, and is ever—except perhaps in an exceptional case—found in the free state.

Rammelsberg (*Deut. Chem. Ges. Ber.* v. 430) observed in the fracture of a rail white cast-iron roller from the 'Heinrichshütte' near Hattingen on the Ruhr, aggregations of regular octohedrons, which gave the following results by analysis:—

Graphite	Carbon	Silicon	Sulphur	Phosphorus
1·121	1·963	1·537	0·113	0·041,

the number of atoms of these elements and those of iron being in the ratio of 1 : 7·6, whilst in the crystallised iron from Gleiwitz, the ratio is 1 : 7·9; in that from Loelling, in Carinthia, 1 : 12; in that from Rothelhütte on the Hartz, 1 : 19; and in iron from Lauchhammer, 1 : 21.

This seems to be a confirmation of the view of Snelus (p. 695), also previously announced by Rammelsberg, that cast iron does not form definite compounds with carbon, but is a mixture of the isomorphous elements, iron, carbon, silicon, and phosphorus.

Another white cast iron which had been very slowly cooled under slag was also crystallised, but not so distinctly as the other, and showed the peculiar netted appearance often seen in substances crystallising in the regular system. It contained—

Carbon	Silicon	Phosphorus	Sulphur
2·820	0·334	0·086	0,

but only a trace of graphite. According to Karsten, white cast iron contains no graphite at all; but this is not correct. Bromeis a. Rammelsberg found that 'spiegeleisen' from Maegdesprung contains 16·5 p.c., and that from Lohhütte 28 p.c. of the total amount of carbon in the form of graphite.

5. *Cast Iron rich in Silicon*.—The variety of cast iron technically called 'glazed pig,' generally contains from $1\frac{1}{2}$ to $2\frac{1}{2}$ p.c. silicon, sometimes as much as 7·8 p.c. Its fractured surface is smooth to the touch, and brighter as the proportion of silicon is greater. Its production requires a very hot blast and a flux containing a considerable proportion of silica and alumina. The proportion of lime in the flux must not be too great, or the silica will combine with it. The use of the alumina appears to be to play the part of an acid in combining with the lime. A charge of 1,250 kilos. of ore containing 30 p.c. iron, with 100 kilos. coke and 800 kilos. flux consisting of 50 p.c. silica, 33 lime, 16 alumina, and 1 manganous oxide (the ratio of the oxygen in the silica to that in the bases being as 26 : 17·6) yielded a very fluid casting containing 7·90 p.c. silicon, 0·72 phosphorus, and 2·60 carbon (S. Jordan, *Compt. rend.* lxxvi. 1086).

The necessity for a very hot blast in the production of this variety of cast iron is accounted for by the fact that the oxidation of silicon evolves a large quantity of heat, and that consequently an equally large quantity will be required for the reduction of silica to silicon (p. 637). According to Troost a. Hautefeuille, 1 gram of silicon burning in oxygen to silica gives out 7,830 units of heat (p. 617); that is to say, more than twice as much heat as carbon evolves in burning to carbonic anhydride; and if, as often happens in metallurgic processes, the carbon burns only to monoxide, it gives off about three times less heat than an equal weight of silicon burning to silica.

Cast iron rich in silicon (7 to 8 p.c.), heated in a lime crucible under a flame of coal-gas and oxygen, refines quite quietly without sparkling, the surface of the metal-bath becoming covered with an iridescent film, which is continually being thrust to the sides of the vessel and replaced by a new coating. The refining of iron rich in carbon, on the contrary, is attended with vivid sparkling. The cause of this appears to be that the carbon burns to monoxide, and this gas at the high temperature of the fused metal is absorbed by it and given up again in the cooler parts of the bath, carrying with it small white-hot particles of iron which appear as sparks. Silicon, according to Caron's observations, decomposes carbon monoxide, which, therefore, in presence of silicon, cannot act in the manner just explained. Its action in preventing the formation of sparks may be immediately neutralised by adding a certain quantity of manganiferous cast iron, which quickly removes the silicon (Troost a. Hautefeuille, *Compt. rend.* lxx. 262).

By fusing red hæmatite with sand and charcoal, Riley has succeeded in preparing a silicide of iron containing as much as 21·7 p.c. silicon. This compound is quite insoluble in hydrochloric acid, and dissolves but slightly in aqua regia, even after long boiling (*Chem. Soc. J.* [2], x. 549).

* *Copper in Iron*.—According to C. Rump (*Arch. Pharm.* [2], cxlv. 231) the purest iron of commerce is not free from copper. This is especially the case in iron smelted with coke, since coke always contains iron pyrites, and the latter always contains copper. In one case 100 grams of iron yielded 0·1 gram copper; two samples of Swedish iron (cast and wrought) and two kinds of Hartz pig (smelted with charcoal) contained only traces of copper.

6. *Malleable Cast Iron*.—The difficultly fusible pig-iron smelted with charcoal at Ulverstone in Lancashire may be rendered malleable by melting it in crucibles,

casting it, and then heating the very hard metal in cast-iron crucibles with pulverised quartziferous red hematite in such a manner that a bright red heat may be attained in 24 hours. This temperature is kept up for three to five days. For thick pieces, which are afterwards to be bored, the heating must be several times repeated. The metal thus obtained is very much like good wrought iron; its density is that of cast iron; colour somewhat lighter than that of wrought iron; fracture mostly white and fine-grained; pieces more than 8 to 10 mm. thick have an external zone of wrought iron with a nucleus of cast iron: thick pieces cannot, therefore, be welded. According to Weddington, the metal to be made into malleable cast iron must be as free as possible from silicon, phosphorus, and sulphur. The method above described is best adapted for castings which are to retain their exact form after being rendered malleable; but for metal which is afterwards to be shaped by forging, a simpler method of preparation is to melt pig-iron with bar-iron (*Dingl. pol. J. exv. 281*).

Poulet, Nagant and Co. prepare malleable cast iron by immersing the castings in a bath of easily fusible slag rich in iron (*Génie industriel*, 1870, Mars, 148).

II. Wrought Iron. 1. *Preparation of Pig-Iron for the Puddling process.*—J. P. Budd (*Dingl. pol. J. exvi. 479*) describes a method of preparation intended chiefly to diminish the proportion of silicon in pig-iron. For this purpose the iron is run from the blast-furnace into moulds, on the sides of which a paste of ground hematite and water (sometimes with addition of Chile saltpetre) has been dried. The metal, when run into these moulds to the depth of $3\frac{1}{2}$ to 4 inches, boils up strongly, gives out flames (? burning silicon), and a coating of slag is formed on the surface of the purified cast iron. By this process the amount of silicon in white pig-iron may be reduced from 1 to 0.002-0.003 p.c. without perceptibly altering the proportion of carbon. Pig-iron thus prepared is very easily puddled.

P. Tunnor (*Dingl. pol. J. cci. 245*) describes Henderson's process, much used in North America, for removing phosphorus from pig-iron. The mould into which the iron is run from the blast-furnace is filled to the depth of $\frac{1}{4}$ to $\frac{3}{8}$ of an inch with a mixture of 1 part by weight of fluorspar and 2 parts of iron ore (red hematite or roasted spathic iron ore), which is so finely pounded as to pass through a sieve of 400 meshes to the square inch. The iron is run from the furnace in quantity sufficient to form a layer an inch deep in the mould. By the high temperature of the iron, fluorine and oxygen are said to be liberated from the mixture, and thereby the silicon and phosphorus are volatilised. A pig-iron containing 2.3096 p.c. silicon and 0.4196 p.c. phosphorus yielded by this process a refined iron containing no silicon and only 0.1029 p.c. phosphorus. The bar iron prepared from it contained only 0.0087 p.c. phosphorus.

Removal of Phosphoric Acid from Iron Ores.—This may be effected by treating the ores with sulphurous acid either gaseous or in aqueous solution. The phosphoric acid is then washed out with water and neutralised with lime, whereby a calcium phosphate is obtained fit for use in agriculture. The ores thus purified yield pig-iron free from phosphorus (*J. Jacobi, Dingl. pol. J. cci. 245*).

2. *Machine Puddling.*—Several attempts have been made to puddle iron by machinery, and for some time past mechanical rabbles have been attached to puddling furnaces to assist the workmen in the heavy labour of stirring the iron; their use has not, however, been very extensive, and they are useless for the purpose of bolting up the iron, which is one of the most laborious parts of puddling.

Various inventors have used a revolving chamber so as to puddle the iron mechanically, but with only partial success, the chief difficulty having been to obtain a suitable lining for the chamber. The problem has, however, at length been successfully solved by Mr. Dankes, whose rotatory puddling furnace has for some time past been used in America.

Mr. Dankes' machine consists of a revolving cylindrical chamber, made with longitudinal wedge-shaped recesses, which act mechanically in retaining the initial lining in its place. This initial lining may be composed of any ore free from silica, ground up and mixed with lime-cream; it is put in like mortar, and, when dried, becomes a refractory and sufficiently coherent material to allow of the inner lining, or fettling, being melted upon it without either melting itself or breaking away from the plates. It is advisable to use an anhydrous ore for mixing with the lime, as when a hydrate is used and the water of combination driven off, the mixture becomes rather crumbly.

Upon the initial lining a quantity of any ore free from silica is melted. For this purpose ores containing water of combination may be used, as it is soon driven off. Into the melted bath of ore large solid lumps are thrown, and these being cold, cause the melted ore to set round them, and so fix them firmly, producing a rough internal lining, and thereby affording a greater amount of surface to act upon the iron. It is not only necessary that these lumps shall be moderately free from silica, and refrac-

tory, but also that their texture shall be such that they do not crumble by heat; this was found to be the case with ilmenite.

Best tap-cinder answers for this purpose very well, and when iron ores cannot be got free from cinder, there is no doubt that iron scrap may be profitably oxidised for the purpose: Mr. Dankes, indeed, uses scrap iron for this purpose.

The furnace is provided with a closed ash-pit, and the necessary air is supplied by a fan-blast; nine jets of air are introduced over the fire grate in front of the furnace and above the fuel, so that the puddler in charge of the machine can regulate the blast, and increase the heat when required.

This furnace is a bad melter of pig-iron, as it takes a long time and consumes much fuel in using the machine. The pig should be melted in a cupola, or run direct from the blast-furnace.

After melting the iron, a jet of water is directed against the lining on the descending side, in order to chill a portion of the cinder and cause it to be carried under the iron. This appears also to have the effect of carrying off sulphur from the cinder.

When grey pigs are used, it takes about ten minutes for the boil to commence; with white pig the time is much less, on account of the silicon present in the iron being less, and the boil commences in two minutes after melting. After tapping off the cinder, the cylinder is set revolving, and the fire is urged; the iron begins to boil violently, and the carbon quickly disappears. But little cinder is formed in this part of the process, and most of it is removed with the ball.

The removal of the iron from the chamber is effected by an ingenious arrangement consisting of a moveable piece or door at the back of the flue; this, on removal, permits the ball to be withdrawn by means of a ball fork worked with a crane, by which the ball is placed on a bogie and carried to the squeezer or hammer.

In Mr. Dankes' machine the puddling is effected entirely by the fettling, the carbon, silicon, and phosphorus being oxidized almost entirely by it and the cinder introduced. The separation of the silicon, sulphur, and phosphorus by this puddling machine is more perfect than by hand puddling.

Moreover, the impurities in the pig being oxidized at the expense of the fettling and cinder, the oxides of iron must be converted into metallic iron, and consequently the yield is increased; thus 21·602 lbs. of pig gave of puddle-bar 23·112 lbs., allowing 94 p.c. for the iron in the pig, and 1·652 lb. of iron was reduced from the fettling.

The present machinery in use at iron works is quite unfitted for dealing with such a mass of iron as a ball from Dankes' furnace; the charge used being 600 lbs., the puddle ball would weigh about 650 lbs. Mr. Dankes has invented a squeezer suitable for such masses of iron, consisting of an eccentric grooved roller, with two smaller ones, and a cam to tumble up the iron laterally.

Iron thus produced, after being thoroughly squeezed and re-heated, can be rolled out at once into a rail or large bar, and will not require, as is the case at present, rolling into puddle-bar, piling, re-heating, and rolling again.

Mr. Spencer, of the West Hartlepool ironworks, has also invented a revolving puddling machine. The converter is of a rhomboidal form on two of its opposite sides, having the axes at right angles with the ends or discs, the remaining two sides being parallel to the axis; the ends or discs are made to revolve on rollers by suitable gearing. The sides are fitted with honeycomb recesses to hold the fettling, the discs being honeycombed also for the same purpose.

The fettling used is best tap; it is fitted into the recesses, and fresh tap is melted over it. In some experiments made by Mr. Spencer, the silicon and phosphorus were found to be almost completely separated; from some Cleveland pig containing over 2 p.c. of phosphorus this element was reduced in the puddle-bar to less than ·10, and some of this was probably due to the cinder in the puddle-bar (Riley, *Chem. Soc. J.* [2], x. 557).

III. **Steel.** 1. *Manufacture from Pig-Iron.*—A new method of obtaining steel from pig-iron has been invented by A. Berard (*Dingl. polyt. J.* cc. 470). The fuel used is gas, obtained by passing over-heated steam through a layer of red-hot coke, the gaseous mixture thus produced being rich in hydrogen and carbon monoxide, poor in nitrogen, free from carbon dioxide, and capable of producing a very high temperature. By regulating the draught over the surface of the heated metal, either a reduction or an oxidising action may be obtained. The pig-iron is run direct from the blast-furnace, or from a cupola-furnace, on to a hearth capable of containing from 5,000 to 6,000 kilograms. By alternate treatment with the oxidising and the reducing flame the iron is freed from silicon, phosphorus, &c., with very little loss by oxidation. Spiegeleisen melted on a neighbouring hearth round which the heated gases circulate as they pass off, may be added to the iron on the principal hearth in proportions determined by the kind of steel required. The waste heat of the furnace may be utilized for heating the gases and the air by which they are to be burnt.

2. *Comparison of Bessemer and Heaton Steel.*—The two methods of manufacture are alike in this respect, that the refining agents are brought into much more intimate contact with the iron than was possible in the old puddling process. The Bessemer process requires the use of purer pig-iron than that of Heaton. Bessemer effects the oxidation by means of various oxides of iron; Heaton by the use of salt-petre, which is dearer. The greater costliness of Heaton's method is, however, partly compensated by the lower price of the less pure pig-iron which can be used in it (C. Schinz, *Dingl. pol. J.* cxcv. 126).

3. *Use of Ferromanganese or Spiegeleisen in the Manufacture of Steel.*—Alloys of iron and manganese are extensively used in the manufacture of steel. W. Henderson in Glasgow prepares them by reducing a mixture of ferrous oxide and manganoan carbonate on the hearth of a Siemens' furnace, and fusing the spongy mass to a regulus under a reducing flame. It does not appear possible to obtain all the manganese of the charge in the metallic state, a slag rich in manganese being obtained which may be utilised in subsequent operations. At the works of the Torre noire, in Voulte and Besièges Company in France, iron alloys containing 23-25 p.c. manganese are prepared by Henderson's process, and used for the manufacture of steel. The pig-iron is worked direct from the blast-furnace, and the re-heating and sorting are avoided by the use of large quantities of manganese alloys. The steel produced is soft and specially available for the manufacture of boiler-plates, armour-plates for ships, &c. From experiments by W. Fairbairn it appears that this steel is inferior to the best sorts in tenacity, but that this deficiency is compensated by greater extensibility and malleability. It appears to be particularly well adapted for wire-making (F. Kohn, *Dingl. pol. J.* cxviii. 205; cc. 280).

4. *Gases evolved in the Bessemer Process.*—The gases evolved from the converter at various stages of the process have been examined by G. Snelus (*ibid.* cxii. 145). A fire-proof tube was sunk into the converter deep enough to prevent the access of the external air; and the gas given off was passed through an iron tube into glass tubes in which the quantities required for analysis could be sealed up. The results of the analyses are given in the following table:—

	I. 2 min.	II. 4 min.	III. 6 min.	IV. 10 min.	V. 12 min.	VI. 14 min. after the beginning of the blast
CO ²	10.71	8.57	8.20	3.58	2.30	1.34
O	0.92	—	—	—	—	—
CO	—	3.95	4.52	19.59	20.30	31.11
H	88.37	0.88	2.00	2.00	2.16	2.00
N		88.58	85.28	74.83	66.24	65.55
Hydrocarbons	—	—	—	—	—	—

The accompanying spectra exhibited the following characters:—

I. Continuous Spectrum	II. Sodium line	III. Sodium Potassium Lithium lines	IV. Complete Spectrum with Carbon lines	V. Complete Spectrum	VI.
------------------------------	-----------------------	---	--	-------------------------	-----

These analyses show that at the commencement of the blast, nothing but carbon dioxide is formed, afterwards chiefly carbon monoxide, but no hydrocarbons. Snelus is of opinion that this proportion is independent of the temperature, which is lower at the beginning of the blast than afterwards. Alteration of the temperature produces alteration of the spectrum. Observations on these results have been made by W. M. Williams (*Chem. News*, xxiv. 174), and J. Parry (*ibid.* 203). Roscoe (*Chem. News*, xxiii. 174, 182) gives the following results of observation of the Bessemer flame with the naked eye and with the spectroscope:—

Time in Minutes	Naked Eye	Spectroscope
First stage 0 to 4	Small flame visible	Faint continuous spectrum, with sparks proceeding from ignited metal
4 to 6	Small pointed flame	Bright spectrum with flashes of the sodium line
6 to 8	Unsteady flame with explosions	Spectrum bright, sodium line permanent, red lithium and potassium lines
Second stage 8 to 10	Bright dense flame	Besides the lines above mentioned, bright carbon lines* appear in the red, green, and blue
10 to 14	Flame bright in the lower part, but less dense	The green carbon lines brighter than before
Third stage 14 to 16	Flame less bright and smaller	The carbon lines in the green become indistinct
16 to 18	The flame disappears: blast discontinued	The bright carbon lines in the green disappear suddenly. Spectrum continuous

The observations of the alterations in the flame afford the means of ascertaining the precise moment at which the blast should be discontinued.

Similar observations on the spectroscopic appearances of the Bessemer flame have been made by J. M. Silliman (*Sill. Am. J.* [2], v. 297; *Chem. News*, xxii. 313; xxiii. 5), who has also studied the colours of the flame when viewed at different stages of the process through yellow and blue glasses. He points out that both the colours thus seen, and the lines in the spectrum, disappear in the reverse order to that in which they were developed. The similarity of the appearance of the flame and its spectrum in the last stage to that which it exhibited at the beginning is the characteristic indication of the termination of the process. The colours and lines disappear much faster than they appear.

5. Phosphoretted Steel.—The properties of phosphoretted steel have been examined by L. Gruner (*Compt. rend.* lxx. 571), with the following results:—1. Phosphorus to the amount of 2 or 3 parts in a thousand renders steel strong and elastic. It increases the elasticity and extensibility without altering the hardness. Steel of this kind, however, is deficient in tenacity, and is brittle without being hard. 2. To judge of this want of tenacity, it is not sufficient to submit the steel to a longitudinal stretch or to transverse pressure, but it must be subjected to the action of a blow or a thrust. 3. The quantity of saltpetre employed in Heaton's process is not sufficient to remove the whole of the phosphorus.

6. Burnt Iron and Steel.—This term is applied to iron which has been damaged by re-heating, or by being excessively heated and exposed in the puddling furnace balling.

Burnt iron is brittle, it displays the so-called crystalline structure, and has lost the fibrous structure and silky fracture of good iron. When steel has been raised to a yellow or white heat, and then suddenly cooled, it becomes brittle, and no longer capable of tempering, and is worthless for the ordinary uses of steel until again raised to a welding heat, rolled or hammered, and allowed to cool gradually. Burnt steel has a coarse granular fracture, the facets of the granules being, for the most part, either rounded or conchoidal.

W. M. Williams (*Chem. Soc. J.* [2], ix. 700) infers, from the examination of a large number of samples of burnt iron and steel, that the burnt iron is penetrated throughout by ferric oxide, and that burnt steel is much poorer in carbon than ordinary steel. He attributes the change in both cases to the absorption of oxygen by the heated metal, giving rise in the one case to ferric oxide, in the other to carbon monoxide. When such steel, still containing carbonic oxide, is quickly cooled, some of the bubbles of gas may be retained, giving rise to the cavities called 'toad's eyes.' W. H. Johnson

* Dr. W. M. Watts has lately shown that the lines in this spectrum, formerly supposed to be carbon lines, are really due to the presence of an oxide of manganese (see *Spectral Analysis*).

(*Chem. News*, xxiv. 250) considers that the oxidation taking place in the interior of a mass of iron is due, not to free oxygen, but to carbon dioxide, which is always present in the furnaces together with monoxide; if the dioxide predominates, oxidation may take place, but in presence of excess of carbon monoxide the burning of the iron is impossible. Riley (*Chem. Soc. J.* [2], x. 561) failed to discover the presence of oxide in burnt iron, and thinks that the change in burnt iron is more probably due to the particles of iron becoming soft enough to arrange themselves in a highly crystalline form, and that possibly some gas may remain between the interstices of the crystals. Brittle iron may be rendered fibrous by mechanical working, and fibrous bar iron may be made red-short by fusion. In considering the quality of wrought iron and steel, it is therefore necessary to look to the mechanical treatment to which it has been submitted, as well as to its chemical composition.

II. Caron (*Compt. rend.* lxxiv. 662) finds that good fibrous wrought iron, whether heated in the furnace of an ordinary forge, or in a porcelain tube through which nitrogen or hydrogen is passed, has a crystalline structure after cooling. All the pieces thus treated, when forged at a red heat or broken cold, exhibited the same qualities and the same defects, and all were restored to their primitive state by heating to whiteness. Since then burnt iron is obtained by heating iron in a reducing as well as in an oxidising atmosphere, its properties cannot well be attributed to oxidation, but appear rather to be due to a modification of its molecular structure by heat.

7. *Spitting of Steel*.—The following explanation of the spitting of steel during solidification is given by Caron (*Compt. rend.* lxx. 451, 453, 1263). Even in a reducing flame containing a large proportion of hydrogen, iron is oxidised by the water contained in the flame, and the ferric oxide thus produced reacts with the carbide of iron in such a manner as to produce carbon monoxide. This gas, developed during the fusion in the interior of the mass, breaks through the thin solid layer of metal, and thus produces the spitting. The carbon oxide is not absorbed by the iron during fusion and given off again on solidification, but is continually evolved during the fusion. The same phenomena take place even when every trace of excess of oxygen is prevented from coming in contact with the metal, by the use of lime dishes instead of porous crucibles. The fused ferric oxide in the lime dish likewise exhibits the phenomena of spitting on cooling. Ferric oxide can, therefore, absorb gases during fusion and give them off again on cooling. The nature of these gases has not yet been determined, but the spitting of steel is perhaps due to the thin layer of oxide formed during the fusion.

IV. *Preparation of Malleable Iron and Steel direct from the Ore*. In the 1st *Suppl.* p. 756, a description is given of Siemens' method of obtaining malleable iron and steel direct from the ore, by feeding the ores (oxides) mixed with carbonaceous materials into a reverberatory furnace through hoppers of fire-clay, the intention being to effect the reduction of the ores into spongy metal during their descent, and the fusion of the spongy metal so produced, on the open hearth of the furnace, pig-metal being used to facilitate the fusion. It was found, however, that the quantity of heat which had to be transmitted through the sides of the fire-clay hopper was so great, that the process of reduction proceeded very slowly, and the hoppers themselves were rapidly destroyed by the intense heat of the furnace. The reduction of the metallic iron in closed chambers of this or any other form which has been tried cannot be effected in less than about 36 hours, and that at a great expenditure of fuel for heating the chamber externally.

This unsatisfactory result led to the adoption of another method of producing spongy iron by means of a rotative furnace. This furnace consisted of a long cylindrical tube of iron of about 8 feet diameter, mounted upon antifriction rollers; the brick lining of it was provided with longitudinal passages for heating currents of air and gas, prior to their combustion at the one extremity of the rotating chamber. The flame produced passed thence to the opposite or chimney end, where a mixture of crushed ore and carbonaceous material was introduced. By the slow rotation of this furnace the mixture advanced continually to the hotter end of the chamber, and was gradually reduced to spongy iron. This dropped through a passage constructed of refractory material on to the hearth of a steel-melting furnace, where a bath of fluid pig-metal had been provided. The supply of reduced ore was continued till the carbon in the mixture was reduced to the minimum point. The rotation was then arrested to prevent further descent of reduced ore; spiegeleisen was added; and the contents of the melting furnace tapped into a ladle and thence into ingots.

This rotatory furnace was erected at the Landore Works in Sheffield in 1869, and it was so far successful, that the reduction of the ore was accomplished in a comparatively short time. A difficulty, however, presented itself, which led to its immediate abandonment; it was found that the spongy metal produced absorbed sulphur from

the heating gases, and was rendered unfit for the production of steel; the spongy iron, moreover, upon its introduction into the steel-melting furnace, floated upon the metallic bath without being readily absorbed into it, and was in great part reoxidised and converted into slag by the action of the flame in the furnace.

These experiments showed that the successful application of reduced ores could not be accomplished through their conversion into spongy metal. On the other hand, it had been observed that in melting iron ores no sulphur is absorbed from the flame; and it was ultimately found that by melting ores mixed with fluxing materials in a furnace so arranged as to accomplish its fusion in a continuous manner, and on a large scale, the fused ore might be acted upon by solid carbonaceous matter, so as to separate the metallic iron in a more compact form, while the earthy constituents of the ore would form a fusible slag with the fluxing material. Experiments proved that this reduction by precipitation of the iron could be accomplished only at an intense heat, exceeding the welding heat of iron, but that the iron so produced was almost chemically pure, although the ores and the fuel used might contain a very considerable percentage of sulphur and phosphorus.

The rotatory furnace in which the smelting is performed consists of a set of four regenerators, of the construction shown in the 1st *Suppl.* (p. 756). The rotative chamber, a vertical section of which is shown in figure 17, is constructed of iron, and rests upon four anti-friction rollers. Wheel-gearing is applied by which either a very slow rotative velocity of from four to five revolutions per hour can be imparted to the chamber, or a more rapid velocity of about 60 to 80 revolutions per hour. The chamber is about 7' 6" in diameter and 9' 0" long, and is provided with a very refractory lining made of bauxite mixed with about 3 p.c. of clay, or water-glass, and 6 p.c. plumbago (p. 126).

FIG. 17.

A tap-hole is placed on the working side for discharging the slag into a cove below, where it is received in vessels mounted on wheels. At the two extremities of the cylindrical rotative chamber with its truncated ends, are large orifices, one of which, on the side of the regenerators, serves for the introduction of the heated gas and air, as well as for the exit of the products of combustion, and the other, facing the working platform, is closed by a stationary door hung before it in the usual manner.

This rotative furnace is worked as follows:—

The ore to be smelted is broken up into fragments not exceeding the size of peas or beans; to it is added lime or other fluxing material, in such proportion that the gangue contained in the ore and flux combines with only a little protoxide of iron into basic and fluid slag. If the ore is hæmatite, or contains silica, it is best to add alumina in the shape of aluminous iron ore; manganiferous iron ore may also be added with advantage. A charge of about 20 cwts. of ore is put into the furnace when fully heated, while it is slowly revolving. In about forty minutes this charge of ore and fluxing material will have been heated to bright redness, and at this time from 5 cwts. to 6 cwts. of small coal of uniform size (not larger than nuts) are added to the charge, whilst the rotative velocity is increased in order to accelerate the mixture of coal and ore. A rapid reaction is the result: the ferric oxide being reduced to magnetic oxide

begins to fuse, and at the same time metallic iron is precipitated by each piece of carbon, while the fluxing materials form a fluid slag with the siliceous gangue of the ore. The slow rotative action is again resorted to, whereby the mass is turned over and over, presenting continually new surfaces to the heated lining and to the flame within the rotator.

During the time of this reaction, carbonic oxide gas is evolved from the mixture of ore and carbon, and heated air only is introduced from the regenerator to effect its combustion within the rotating chamber. The gas from the gas-producers is entirely or almost entirely, shut off during this portion of the process. When the reduction of the iron ore is thus nearly completed, the rotator is stopped in the proper position for tapping off the fluid cinder; after this the quick speed is imparted to the rotator, whereby the loose masses of iron contained in it are rapidly collected into two or three metallic balls. These are taken out and shingled in the usual way of consolidating puddled balls; the furnace is tapped again, and is ready to receive another charge of ore. The time occupied in working one charge rarely exceeds two hours; and supposing that 10 cwt. of metallic iron is got out per charge, the apparatus is capable of turning out at least 5 tons of puddled bar per diem. If anthracite or hard coke is available for effecting the reduction of the ore, it should be crushed much finer than when coal or brown coal is used, the idea being that each particle of the reducing agent should be fully consumed during the period of chemical reaction. If wood is used, it has to be charged for the same reason in still larger pieces.

If it is not intended to make iron, but cast steel, the balls may be transferred from the rotator to the bath of a steel-melting furnace in their heated condition, and without subjecting them to previous consolidation under a hammer or shingling machine.

It is feasible, however, to push the operation within the rotator to the point of obtaining cast steel. If this is intended, the relative amount of carbonaceous matter is somewhat increased in the first instance, so that the ball, if shingled, would be of the nature of puddled steel, or contain even some carbon mechanically enclosed.

If now, after removing the cinder by tapping, from 10 to 15 p.c. of ferro-manganese or spiegeleisen is thrown in, and the heat within the rotator is rapidly raised by urging the influx of heated gas and air from the regenerator, the metallic balls will soon be seen to diminish, and presently a metallic bath only will be found in the furnace, which may be tapped into moulds and hammered and rolled into steel blooms or bars in the usual manner. Experience alone can determine which mode of working will ultimately prove the best; but it is probable that, for the production of cast steel on a large scale, it will always be more profitable to transfer the metallic balls to a separate melting furnace, a series of rotating furnaces working in concert with a series of steel-melting furnaces, to produce charges of 5 to 6 tons of fluid steel.

In comparing upon theoretical grounds this method of producing metallic iron with the operation of the blast-furnace, it will be at once perceived that, whereas in the blast-furnace the products of combustion consist chiefly of carbon monoxide, and issue from the top of the furnace at a temperature exceeding 350° , the result of combustion in the rotative furnace is carbon dioxide, which issues from the regenerative furnace into the chimney at a temperature rarely exceeding 175° . This proves at once a great possible saving of fuel in favour of the proposed method, and to this saving has to be added the fuel required in converting pig-metal into wrought iron by the puddling process.

It may, however, be asked why the rotating furnace should admit of the complete combustion of carbon, whereas in the blast-furnace such complete combustion is, as is well known, not possible, because each atom of carbon dioxide formed would immediately split up into two atoms of carbon monoxide by taking up another atom of carbon from the coke present. The following explanation will serve to elucidate this point:

In the rotative furnace streams of carbon monoxide are set up within the mass under reaction; and this gas on reaching the surface meets the current of intensely heated air proceeding from the regenerators, and effects with it perfect combustion within the free space of the chamber. The carbon dioxide thus generated comes into no further contact with carbon; consequently, it cannot be split up, but is drawn away unchanged into the chimney, while the evolved heat is taken up by the sides of the chamber, and transmitted by reverberation and conduction to the mixture of ore, fluxes, and coal.

In this process there are, therefore, two things to be accomplished, viz., the deoxidation of the ore, and the fusion of the earthy matter mixed with it. Taking, for example, hematite ore, consisting of ferric oxide with 10 p.c. of silica, the quantity of carbon necessary for its reduction will be determined by the formula

which gives

According to this formula, the consumption of carbon (taking its atomic weight at 12 and that of iron at 56) amounts to:

$$\frac{3 \times 12}{9 \times 56} = 0.32 \text{ lb. per lb. of iron reduced.}$$

The heat absorbed in this reaction amounts, according to Debus, to 892 units per lb. of iron produced; but, on the other hand, the further combustion of 0.32 lb. of carbon from the condition of CO to that of CO² by means of the free oxygen introduced into the rotative chamber from the regenerator, yields:

$$0.32 \times 5,600 = 1,792 \text{ units of heat,}$$

leaving $1,792 - 892 = 900$ units

available for heating the materials and for melting the slag.

The quantity of materials to be heated per lb. of iron produced would amount to—

Ore	1.59
Lime or other fluxing materials	0.16
Total	1.75

and taking the specific heat of Fe²O³ as 0.154, as determined by Kopp, and the temperature to which the materials have to be raised as 1,500° C., the heat required for this purpose would not exceed

$$1.75 \times 0.154 \times 1,500 = 404.5 \text{ units.}$$

To this consumption would have to be added the latent heat absorbed in liquefying the slag. The slag would amount to 0.16 lb. silica and 0.16 lb. lime = 0.32 lb. per lb. of iron produced; and, although we have no precise data from which to ascertain the latent heat absorbed in liquefaction, we can hardly estimate it at more than 150 units per lb., or at $0.32 \times 150 = 48$ units, which, with the above 404.5, makes 452.5 units, or 447.5 units under the 900 heat-units which are available, proving that 0.32 lb. of pure carbon would, theoretically speaking, amply suffice to produce 1 lb. of puddled bar from ordinary hematite ore, without counting, however, losses of heat by radiation and from other causes.

In the production of cast steel three operations are essentially involved, viz.: the deoxidation of the iron, the fusion of the slags, and the fusion of the metal itself with such proportion of carbon and manganese as is necessary to constitute steel of the temper required.

The theoretical quantity of fuel required to accomplish these operations would exceed that of making wrought iron, by the fusion of heated metal, which may be estimated at about 1,000 units, or at $\frac{1,000}{8,000} = 1.25$ lb. of carbon per lb. of steel produced, which have to be added to the 0.32 lb. used in reduction. In fine, a ton of iron ought to be producible from hematite ore with 6.4 cwts. of carbonaceous matter, or about 8 cwts. of common coal, and a ton of cast steel with 8.91 cwts. of carbon or say 11 cwts. of coal.

These figures may never be completely realised; indeed, taking incidental losses by radiation, through imperfect combustion, and through imperfect absorption of heat, into account, we find that the actual consumption exceeds the theoretical limits about three times, or that a ton of iron can practically be produced with a consumption of 25 cwts. of coal, and a ton of cast steel with 40 cwts. of coal; but this consumption still represents a great reduction as compared with other methods of production. (Siemens, *Chem. Soc. J.* [2] xi. 662-678.)

ISATIN. On the constitutional formula of this body and its reduction to indigo-blue, see Indigo (p. 666).

IETHIONIC ACID. *Oxethylsulphonic acid*, C²H⁵SO⁴ = CH³OH.CH²SO³H.—The sodium salt of this acid is formed by heating the hydrochloride of ethylene oxide (ethylene-chlorhydrin) with sodium sulphite to 170°–180° in sealed tubes:

The evaporated solution treated with boiling alcohol yields sodium isethionate, from which the pure acid may be obtained by treatment with sulphuric acid, evaporation, exhaustion with alcohol, saturation with barium carbonate, and decomposition of the resulting salt with sulphuric acid (A. Collmann, *Ann. Ch. Pharm.* cxlviii. 191).

Ammonium Isethionate, $\text{CH}^2\text{OH}.\text{CH}^2\text{SO}^-\text{NH}^+$, melts, according to Strecker, at 130° , and when heated to 210° gives off water and is converted into taurine, $\text{C}^2\text{H}^4\text{NSO}^2$ (r. 609). H. Seyberth, on the other hand, states that it melts at 135° , is not altered by heating to 210° – 230° for several days, but when heated to 230° – 240° , is decomposed with frothing, and converted into isethionamide $\text{CH}^2\text{OH}.\text{CH}^2\text{SO}^-\text{NH}^2$, isomeric with taurine (*Deut. Chem. Ges. Ber.* vii. 391).

Homologues of Isethionic Acid.—**Amyl-isethionic acid**, $\text{C}^2\text{H}^{12}\text{SO}^4 = \text{C}^4\text{H}^4\text{OH}.\text{ClI}^-\text{SO}^-\text{H}$, is formed by the action of sodium sulphite on amyleno-chlorhydrin (Falk), and by the action of sulphuric anhydride on amyl alcohol (E. Schwarz, p. 65).

Methyl alcohol is strongly attacked by sulphuric anhydride, but when the action is made to go on very slowly by pressing the anhydride into a narrow glass tube, and introducing this into a wider tube containing methyl alcohol, crystals form after a while, apparently consisting of methylene sulphite $\text{CH}^2(\text{SO}^2)^2$; these, however, afterwards disappear, and the alcohol becomes more viscid; and if, after all the anhydride is absorbed, the liquid be diluted with water, boiled for some hours, saturated with barium carbonate, filtered, concentrated, mixed with alcohol, again filtered, and then left to stand over sulphuric acid, a hygroscopic crystalline mass is obtained, which may be purified by recrystallisation from dilute alcohol, and probably consists of barium methyl-isethionate. Similar results are obtained with *butyl alcohol* (Schwarz).

Propyl-isethionic acid, $\text{C}^2\text{H}^{10}\text{SO}^4 = \text{C}^2\text{H}^4\text{OH}.\text{CH}^2\text{SO}^-\text{H}$, is formed by the union of propylene oxide with the acid sulphite of an alkali-metal $\text{C}^2\text{H}^4\text{O} + \text{HSO}^-\text{Na} = \text{C}^2\text{H}^4\text{OH}.\text{SO}^-\text{Na}$ (Erlenmeyer, *Ann. Ch. Pharm.* clviii. 260).

ISOBIURET. See BIURET (p. 193).

ISOCLASE. A basic calcium phosphate, $4\text{CaO}.\text{P}_2\text{O}_5 + 5\text{H}_2\text{O}$, said to come from Jochimssthal. Forms colourless triclinic crystals, having a specific gravity = 2.95, hardness = 1.5 (F. Sandberger, *J. pr. Chem.* [2], ii. 125).

ISODINAPHTHYL. See NAPHTHYL.

ISOMORPHISM. *Structure of Isomorphous Crystals.*—Kekulé (*Deut. Chem. Ges. Ber.* ii. 652), from an examination of the isomorphism of certain ferrous salts with magnesium or calcium salts, was led to infer that a like crystalline form does not necessarily imply a similarity of the molecules on all sides, but may be a consequence of partial similarity, and perhaps even of similarity on one side only of the molecules. This view is supported by certain observations made by H. Baumbauer (*ibid.* v. 859) on the form of the corrosion figures produced by the action of solvents on various isomorphous crystals. These corrosion figures are mostly microscopic hollows bounded by regular surfaces, the form of which evidently bears a certain relation to the general proportions of symmetry of the crystal. The figures produced on isomorphous crystals always exhibit a certain similarity of form, but have not always the same position relative to the surfaces of the crystal. Thus there is no important difference between the figures produced by water on the isomorphous members of the monoclinic group, including sulphate of iron, sulphate of iron and ammonium, sulphate of nickel and potassium, and sulphate of nickel and ammonium. The figures correspond in position, although the analogous surfaces of these bodies do not behave in exactly the same manner (which is in accordance with the slight differences of angle existing between them). In particular the figures on the two latter salts resemble each other very closely.

The group calcspar, dolomite, and spathic iron ore exhibits a contrary behaviour. Hydrochloric acid produces on the rhombohedral cleavage-planes of calcspar, hollows of the form of an isosceles triangle, with the apex towards the terminal summit of the crystal. Similar figures are produced by hydrochloric acid on the rhombohedral cleavage-planes of spathic iron ore, but in this case the base of the triangular hollow is towards the terminal summit of the crystal. According to Haushofer, dolomite behaves similarly to spathic iron ore.

The resemblance or difference in the position of the corrosion figures in these isomorphous bodies appears to point to a resemblance or difference in the structure or molecular form of the crystals.

ISONITRILS, ISOCYANATES, or CARBIMIDES. *Allyl-triethyl-sul-*

phocarbophosphamide, $\text{N} \begin{Bmatrix} (\text{CS})^2 \\ \text{C}^2\text{H}^2 \\ (\text{C}^2\text{H}^2) \end{Bmatrix} \text{P}$, formed by the union of allyl sulphocarbimide (volatile mustard-oil) with triethylphosphine (iv. 611), is resolved by heat into triethylphosphine sulphide, and the isonitril of the allyl series:

The isonitrils of *methyl*, *ethyl*, and *amyl* are formed in like manner. On mixing the corresponding sulphocarbimide with triethylphosphine, a rise of temperature takes place, and the odour disappears, owing to the formation of a compound analogous to the sulphocarbophosphamide above mentioned. When the mixture is further heated under pressure, magnificent crystals of triethylphosphine sulphide are deposited on cooling, and at the same time the pungent odour of the isonitril of the series is developed (Hofmann, *Zeitschr. f. Chem.* vii. 29).

ISOPHTHALIC ACID. See PHTHALIC ACID.

ISOPURPURATES. See PURPURATES.

ISOPYRE. Under this name are included various massive minerals found in European collections. The original specimens from St. Just in Cornwall, to which the name was given in 1827 by Haidinger, were analysed by Turner, who found in them 47.69 p.c. SiO_2 , 13.91 Al_2O_3 , 20.07 $\text{Fe}^{\text{O}}\text{O}_3$, 1.94 CuO and 15.43 CaO (Wi. 435). The colour of this mineral is jet-black, with a few red spots resembling those of blood-stone; lustre vitreous; streak pale grey; hardness 6.5; sp. gr. 2.912; fracture conchoidal; slightly magnetic. One specimen occurs on granite associated with tourmalin (Schorl). An analysis by Maskelyne & Flight (*Chem. Soc. J.* [2], xi. 1049) gave:

SiO_2		Al_2O_3	$\text{Fe}^{\text{O}}\text{O}_3$	FeO	CuO	MgO	K ² O	Na ² O	Li ² O	CuO	F.	H ² O
uncombined	combined											
14.33	31.82	12.59	3.03	15.91	13.21	1.66	1.15	0.70	trace	1.10	2.28	0.85 = 98.65.

The reaction of the mineral with potash showed that 15.19 p.c. of the silica was present as opal, and that it was mixed with a mineral approaching in composition to the felspar type.

Other minerals designated as isopyre consist mainly of silica.

a. From St. Just. Dark brown, compact, massive, and with conchoidal fracture and semi-vitreous lustre. It carries opal in botryoidal forms in cavities, and a dendritic accompaniment, probably of pyrolusite, or perhaps melaconite, occurs occasionally as an infiltration. Native copper occurs with it very sparsely. Hardness = 7. Contains

SiO_2	$\text{Fe}^{\text{O}}\text{O}_3$	CuO	H ² O
93.04	3.23	1.38	2.72 = 100.37.

Part of the iron appears, however, to be present as monoxide: the powdered mineral has a buff colour, changing on ignition to light brick-red.

B. From Suckasunny, New Jersey. Dark olive-green compact mass, with a conchoidal and rather splintery fracture, slightly translucent, and with a waxy lustre. A similar mineral from the same locality closely resembles the brown Cornish variety in colour and characters. The green variety, when finely powdered, is of a pale greenish grey colour, changing by ignition to buff. It contains:

SiO_2	$\text{Fe}^{\text{O}}\text{O}_3$	CuO	MgO	H ² O
92.79	2.10	0.35	0.35	4.07 = 99.66.

No portion of the small amount of iron in this mineral appears to be present as monoxide.

A liver-brown mineral (γ) associated with one (δ) having the appearance of jasper, and also coming from St. Just, closely resembles the mineral α . The jasper-like mineral associated with it presents in parts the dull aspect and other characters of massive ferruginous quartz; elsewhere its characters are those of a jasper opal. Iron ochre, pyrolusite, and melaconite accompany it in the former specimens. It occurs in a siliceous matrix with some of the characters of a gossan, and is associated with quartz and a finely grained chlorite and ferric oxide.

These two minerals have the following composition:—

	γ	δ
Silica	73.15	76.22
Alumina	0.06	0.15
Ferric oxide	9.53	9.05
Ferrous oxide	10.02	8.86
Lime	0.30	0.32
Magnesia	0.11	0.20
Water	5.46	4.76
Copper oxide	—	0.63
	99.23	100.19

After treatment with potash, γ left a residuc amounting to 25 p.c., and δ one of 25.63 p.c. It is evident that these minerals consist of opal in different degrees of impurity.

The presence of ferrous oxide in all these varieties of opal may explain the mineralogical similarity to which their association under the name of isopyro in our collections is due. Their source has probably been mineral waters charged at once with silica and a ferrous carbonate. That they are only the more characteristic specimens, occurring in large deposits of the same kind, is evidenced by the character of the lodes charged with copper ores at Botallack or the Bilston mines, where the neighbouring granites offer the conditions for furnishing the material (Maskelyne n. Flight).

ISOPYRINE. An alkaloid obtained by boiling the mashed roots of *Isopyrum thalictroides* with water, filtering, evaporating to a syrup, and precipitating with ammonia. The isopyrine may be dissolved out of the dried precipitate with ether. It has a bitter taste, and forms an amorphous hydrochloride.

Pseudoisopyrine.—When the residuc obtained by boiling the roots with water is digested with alcohol, the resulting liquid evaporated till all alcohol is removed, ammonia added to the watery residuc, and the ensuing precipitate treated with ether, another alkaloid is dissolved out, which crystallises in stellate groups of needles. The two alkaloids may, if present together in solution; be separated by adding very dilute hydrochloric acid and ammonium chloride, whereby pseudoisopyrine only is thrown down as chloride.

These alkaloids have not yet been further examined (F. A. Hartsen, *Chem. Centr.* 1872, 523).

ISOTAURINE. See TAURINE.

ISURETINE, $\text{CH}^{\text{NH}}_2\text{N}^{\text{O}} = \text{C} \begin{Bmatrix} \text{NH} \\ \text{NH.OH.} \\ \text{H} \end{Bmatrix}$ (Lossen a. Schifferdecker, *Zeitschr. für*

Chem. vii. 594; *Ann. Ch. Pharm.* clxvi. 295). A base isomeric with urea produced by digesting an alcoholic solution of hydroxylamine with strong hydrochloric acid at 40° – 50° . On evaporating the liquid, isuretine is deposited in large crystals which may be purified by recrystallisation from aqueous alcohol.

Isuretine is very soluble in water, less soluble in alcohol, slightly in ether, insoluble in benzene. It has a strong alkaline reaction, and melts with incipient decomposition at 104° – 105° . The crystals, which somewhat resemble those of urea, have been examined by Klein (*Ann. Ch. Pharm.* clxvi. 179). They have very smooth faces, which reflect moderately well, but after a few minutes' exposure to the air, become dull, from absorption of moisture, and the previously sharp edges begin to melt off. The angular measurements are therefore attended with considerable difficulty.

The crystals (fig. 18) belong to the rhombic system, $a : b : c = 0.65563 : 1 : 1.12041$. Fundamental angles: $\infty P : \infty P = 113^\circ 30'$; $P_\infty : P_\infty = 83^\circ 30'$. Observed faces: ∞P (m), P_∞ (a), $P_{\frac{1}{2}}$ (o), more rarely OP , still more rarely $r \frac{P}{2}$. Character prismatic in the direction of ∞P . Colour white; only the small crystals are perfectly transparent. No distinct cleavage perceptible.

The plane of the optic axes is $a b$. The first positive median line is at right angles to the perpendicular truncation of the acute lateral edge, and therefore coincides with b . The optic axes are more divergent for the red than for the blue rays.

Very remarkable is the occurrence in this body of the rhombic sphenoid, $1 \frac{P}{2}$, which is much more frequently developed than its correlative, $r \frac{P}{2}$. Here, indeed, it is impossible to overlook a certain tendency to hemihedral formation, which is common to the two isomeric bodies, urea and isuretine; in the former the quadratic primary pyramid likewise occurs as a sphenoid.

Solutions of isuretine give with copper sulphate a dirty green, with lead nitrate a white

Fig. 18.

precipitate, with *mercuric chloride* a precipitate which is at first bulky and yellowish-white, afterwards denser and dark yellow. With *silver solutions* no precipitate is deposited, but on applying heat the silver is reduced. *Ferric chloride* gives a reddish-brown colour, which disappears on addition of hydrochloric acid.

Isurettine hydrochloride, $N^2CH^2O.HCl$, crystallises in deliquescent rhombic tables, excessively soluble in water, melting at about 60° . The *sulphate*, $(N^2CH^2O)^2H^2SO_4$, *acid oxalate*, $N^2CH^2O.C^2O^2H^2$, and *picrate*, $N^2CH^2O.C^6H^3(NO^2)^3O$, are all crystallisable.

Decomposition by Heat.—Isurettine heated beyond its melting point, readily decomposes, evolving a small quantity of permanent gas, and giving a considerable sublimate of ammonium carbonate. A yellowish amorphous residue is left, from which boiling water extracts a yellowish substance very slightly soluble in water, and presenting the composition and essential characters of ammeline, $N^2C^2H^2O^2$. The portion of the residue insoluble in boiling water has substantially the composition of ammeline. This residue boiled with nitric acid furnishes cyanuric acid.

Decomposition by Hot Water.—A solution of isurettine in its own weight of water evaporated on a water-bath undergoes decomposition, with evolution of nitrogen, ammonia, and carbonic anhydride. The mother-liquors contain urea, ammonia, guanidine, and other substances apparently uncrystallisable. When dilute solutions are employed, very little urea is formed, the isurettine takes up the elements of water, and a solution of ammonium formate is produced; hydroxylamine, NH^2O , which is formed at the same time, being represented only by its products of decomposition, viz., nitrogen, ammonia and water:

A similar reaction takes place when isurettine is boiled with dilute sulphuric acid, formic acid distilling over, and the residual solution containing ammonia and hydroxylamine.

An aqueous solution of isurettine, shaken up with *benzoyl chloride*, deposits dibenzhydroxamic acid, $NH(C^6H^3O)^2O$ (p. 155).

ITACONIC ACID, $C^3H^2O^4$. When a saturated solution of potassium itaconate is submitted to *electrolysis*, carbon dioxide is evolved from the positive electrode, together with a modification of allylene which does not precipitate ammoniacal silver nitrate. This allylene unites with bromine, forming a dibromide, $C^3H^2Br^2$, and this, when heated with excess of bromine, forms a crystalline tetrabromide, $C^3H^2Br^4$. During this reaction a small quantity of hydrobromic acid is formed, indicating probably that the allylene is accompanied by propylene. After the electrolysis has proceeded for some time, a modification of allylene capable of precipitating ammoniacal solution of silver nitrate is evolved. This may perhaps be due to the decomposition of mesaconic acid, which, together with acrylic acid, is found in the solution after the electrolysis. No pyrotartaric acid has hitherto been found among the products, but if we suppose it to be formed, the propylene, carbon dioxide, and acrylic acid may be regarded as products of its decomposition:—

Potassium *citraconate* gives by electrolysis carbon dioxide and an allylene containing an atom of hydrogen replaceable by metals, apparently also acrylic and mesaconic acids. Potassium *mesaconate* gives carbon dioxide and allylene, which is precipitated by a silver solution. The other products of the decomposition are probably acrylic and itaconic acids.

The formula of the three allylenes is not decided, but the one obtained from itaconic acid is not identical either with ordinary allylene or with those obtained from citraconic and mesaconic acids (G. Aarland, *J. pr. Chem.* [2], iv. 376; vi. 236; vii. 142).

Neutral itaconate of sodium or ammonium gives with *ferric chloride* a brown precipitate soluble in excess of the reagent. This solution when heated redeposits the precipitate, which, however, dissolves again as the solution cools (Aarland).

Itaconic acid in moderately strong solution heated for some hours with *neutral potassium sulphite*, yields the potassium salt of sulpho-pyrotartaric acid, $C^3H^2SO_3$, which is obtained as a syrupy liquid by evaporation, and as a gummy mass by precipitation with alcohol (Wieland, *Ann. Ch. Pharm.* clvii. 34).

When itaconic acid is heated with anhydrous *hydrocyanic acid* to a temperature of

140°-150°, a syrupy mass is obtained, which, after exposure to the air to allow the excess of hydrocyanic acid to escape, yields by fractionation citraconic acid. The syrupy mass probably contains a hydrocyanic addition-product, $C^6H^7NO^4$, although all attempts to isolate this compound failed; but if this syrupy mass is allowed to remain under the air-pump till it has lost the odour of hydrocyanic acid, a gentle warmth suffices to reproduce this odour, and treatment with soda causes the liberation of ammonia and the production of mesaconic acid (Barbaglia, *Deut. Chem. Ges. Ber.* vii. 465).

ITAMALIC ACID, $C^6H^6O^4$. *Chloritamalic acid*, $C^6H^7ClO^4$, is obtained by passing chlorine into a solution of sodium itaconate, adding hydrochloric acid, evaporating to dryness in a retort over the water-bath, and exhausting the residue with ether. The ethereal solution after some time deposits chloritamalic acid in the crystalline form.

Chloritamalic acid differs from chlorocitramalic acid in forming very much smaller crystals, and in not giving a crystalline precipitate with barium acetate, even when the solution is very concentrated. It forms salts with difficulty, chiefly because of its proneness to decomposition in presence of bases.

J

JADEITE. See NEPHRITE.

JEFFERSONITE. This mineral, a variety of augite (iii. 443), occurs at Franklin, New Jersey, in laminae formed by the cleavage of monoclinic crystals in the direction of the orthopinacoid $\infty P\infty$. The cleavage is perfect in this direction, difficult in the direction of the clinopinacoid ($\infty P\infty$). Angle $\infty P\infty : (\infty P\infty) = 90^\circ 45'$. The mineral is translucent in thin layers, with a vitreous lustre, and breaks with an unctuous but unequal fracture. Colour, deep green; hardness, 5.5; density, 3.63. Before the blowpipe it melts to a slightly magnetic black enamel, and gives with sodium carbonate and nitre a strong reaction of manganese. It is not attacked by acids.

Analysis gave—

SiO ²	AlPO ⁴	CaO	MnO	FeO	MgO	ZnO	H ² O
45.95	0.85	21.55	10.20	8.91	3.61	10.15	0.35 = 101.57

The oxygen ratio calculated from these numbers leads to the formula $RO.SiO^2$. The percentage of zinc here given is much larger than that found in former analyses (Pisani, *Compt. rend.* lxxvi. 237).

JERVIC ACID. An acid occurring in white hellebore root (p. 641).

JERVINE. This alkaloid, first obtained by Simon from the root of *Veratrum album* (iii. 445), exists also in *V. viride*, from which may be prepared pure by the following process:—The finely powdered root is thoroughly exhausted with strong spirit, and the tincture is evaporated to a small bulk, acidulated with acetic acid, and mixed with water. The resin thereby precipitated is separated by filtration; the filtrate is concentrated, and rendered strongly alkaline with sodium carbonate; the resulting precipitate is dried, and boiled with strong spirit, till nothing more is dissolved; the alcoholic solution is evaporated to dryness; and the residue digested in hot, very dilute sulphuric acid. The granular powder, which separates on cooling, is jervine sulphate, which, after washing, is decomposed by boiling it with strong solution of sodium carbonate. Jervine then separates as a granular powder, which is washed, dissolved in acetic acid, and again precipitated by ammonia.

When a minute fragment of jervine is moistened on a glass slide, with a drop of strong sulphuric acid, it changes first to a straw-yellow, and then gradually to a green colour. This reaction is characteristic and delicate (C. Mitchell, *Pharm. J. Trans.* iv. 706).

JUGLANDIC ACID. An acid said to be obtained from the bark of *Juglans cinerea*, and described as crystallising in short orange-yellow needles, apparently related to chrysophanic acid (Thiebauld, *Pharm. J. Trans.* [3], ii. 1033).

JULIANITE. A mineral occurring in the Frederiko Juliane Mine, at Rudelstadt, in Silesia, in small botryoidal crystalline aggregations, penetrating calcite or covering druses of that mineral. Crystalline characters, indistinct; form, cube in combination with dodecahedron. Hardness very small. Brittle. Fracture, splintery or slightly conchoidal. Specific gravity, 6.12. Colour of fresh surface, dark lead-grey, with a

slight tinge of red, soon turning black. Composition: copper, 52.298; iron, 0.787; silver, 0.538; sulphur, 26.503; arsenic, 16.782; antimony, 1.421 = 98.329. The deficiency, 1.651 per cent., is believed to be due to loss of arsenic, and calculated as such in the formula, $(\frac{1}{10}\text{As}, \frac{1}{10}\text{Sb})^2 (\text{Cu}; \text{Ag})^2 \text{S}^8$.

Julianite is isomeric and isomorphous with bornite (H. Websky, *Jahrbuch f. Mineralogie*, 1872, 218).

JUNIPER. E. Donath (*Dingl. pol. J.* cccviii. 300) has analysed the berries of *Juniperus communis* with the following result:

Water	29.44	Juniperin	0.37
Essential oil	0.91	Pectin	0.73
Formic acid	1.86	Protein substances	4.45
Acetic acid	0.94	Sugar	29.65
Malic acid	0.21	Cellulose	15.83
Fat, resembling wax	0.64	Mineral constituents	2.33
Green resin	8.46		
Hard brown resin	1.29		97.11

K

KAINITE, $\text{MgSO}_4 \cdot \text{KCl} \cdot 3\text{H}_2\text{O}$. This double salt, originally found at Stassfurt (1st Suppl. 764), occurs also at Kalusz in Galicia, in two horizontal beds from 70 to 80 feet thick, without any intervening layer, and mixed with only small quantities of sylvin and rock-salt.

The first three of the following analyses are by K. v. Hauser (*Jahrb. geol. Reichsanstalt*, xx. 141). A, gives the composition of the principal deposit consisting of granular black-brown masses with small yellowish and white spots; B, light yellow laminar particles often occurring in great numbers; C, honey-yellow transparent imbedded particles occurring but rarely. D, is an analysis of the same by Tschermak (*Wien. Acad. Ber.* (1 Abth.) lxiii. 311). E, is the composition of the pure salt calculated according to the formula above given.

	A	B	C	D	E
SO_4	20.46	20.26	32.24	32.34	32.19
Cl	28.01	30.84	15.03	14.56	14.28
MgO	10.16	10.17	16.12	16.75	16.10
K	16.38	13.07	15.25	15.66	15.69
Na	7.97	11.60	0.69	0.03	—
Water	14.36	14.12	21.37	20.73	21.74
Clay	3.41	0.16	—	—	—
	100.76	100.22	100.70	100.07	100

One part of water at 17° dissolves 0.467 part of the anhydrous crude kainite; the density of the saturated solution is 1.256 (v. Hauser).

According to A. Jacot (*Compt. rend.* lxxiii. 995) the beds of Kalusz yield daily more than 1,000 Austrian centners (81,100 kilos.) of potassium chloride.

KALUSZITE. See SYNGENITE.

KARAKA. The nut of the New Zealand karaka tree (*Corynocarpus levigata*), though poisonous in its natural state, is one of the staple articles of vegetable food used by the natives. The nuts are partially baked in earth ovens, then washed for some time in a stream of water, which removes the poisonous matter, and finally dried and stored for use.

The bitter substance, karakin, removed by the water crystallises in beautiful radiate needles. It exhibits the characters of a glucoside rather than those of an alkaloid (W. Skey, *Chem. News*, xxvii. 190).

KELP. On the estimation of iodine in kelp liquors, see IODINE (p. 672).

KETONES. *Formation.*—As ketones are formed by the action of the zinc-compounds of the alcohol-radicles on the chlorides of acid-radicles (1st Suppl. 766), it might be expected that they would also be formed by the action of the same zinc-compounds on the oxides or anhydrides of the same acid-radicles, e.g.:

Sjostoff, however, finds (*Zeitschr. f. Chem.* [2], vi. 104) that the action of ready-formed zinc-ethyl on acetic oxide does not yield any definite product; but by bringing the acetic oxide in contact with zinc-ethyl in the nascent state, which may be effected by treating a mixture of ethyl-iodide and acetic oxide [$2\text{C}^2\text{H}^5\text{I} + (\text{C}^2\text{H}^5\text{O})^2\text{O}$] in a cooled vessel with pulverised zinc-sodium, the desired result may be obtained. The reaction is complete in 20–30 hours, and on carefully mixing the contents of the flask with water, distilling and treating the distillate with potash, an oil separates, part of which distils below 100° , and forms a crystalline compound with sodium bisulphite. The ketone separated from this compound by potash boils at $77\text{--}80^\circ$, and has the composition of methyl-ethyl ketone, $\text{C}^4\text{H}^8\text{O}$.

The same process, with the substitution of methyl-iodide for ethyl-iodide, yields common acetone, $\text{CO}(\text{CH}^3)^2$.

Ketones containing phenyl may be formed: α . By the action of mercury-diphenyl on chlorides of acid-radicles; e.g. diphenyl-ketone from mercury-diphenyl and benzoyl-chloride:

(R. Otto, *J. pr. Chem.* [2], i. 144).

β . By heating a mixture of an aromatic hydrocarbon and benzoic acid with phosphorus pentoxide, e.g.:

In like manner *tolyl-phenyl ketone*, $\text{C}^7\text{H}^7.\text{CO.C}^6\text{H}^5$, may be prepared from toluene, and *naphthyl-phenyl ketone*, $\text{C}^{10}\text{H}^7.\text{CO.C}^6\text{H}^5$, from naphthalene (Kollarits a. Merz, *Deut. Chem. Ges. Ber.* vi. 536).

Respecting E. Schmidt's method of preparing ketones by heating the calcium salt of the corresponding acid mixed with calcium carbonate in an iron tube, see BUTYRONNE (p. 228).

Oxidation of Ketones.—When a ketone containing only normal alcohol-radicles is treated with a mixture of potassium dichromate and dilute sulphuric acid, two fatty acids are produced, the action taking place in such a manner that the higher of the two alcohol-radicles is oxidised, while the other remains united with the carbonyl (Popoff, 1st Suppl. 765); thus:

From subsequent experiments, and a comparison of the results obtained by Kolbe, Wurtz, Erlenmeyer, Butlerow, and Wanklyn, Popoff (*Ann. Ch. Pharm.* clxi. 285; *Deut. Chem. Ges. Ber.* v. 381) deduces the following more general conclusion:—

In the oxidation of ketones in which one of the alcohol-radicles united with the carbonyl (R in the following general formulæ) is phenyl or methyl, or in some cases ethyl, viz.:

the carbonyl always remains united with the radicle R, while the other radicle is oxidised. If this other radicle belongs to a normal alcohol (1), it is oxidised to a normal acid; if it is an iso-alcohol-radicle (2), it yields an iso-acid; a secondary alcohol-radicle (3) in like manner yields a ketone; and a tertiary radicle (4) is split up.

Now when a ketone is formed by distilling a mixture of the calcium salts of two fatty acids, or of a fatty and an aromatic acid, or by the action of the zinc-compound of an alcohol-radicle on an acid chloride, the acid-radicle yields the carbonyl required to form the ketone; and when this ketone is subjected to oxidation, the carbonyl remains united with the alcohol-radicle R, while the other alcohol-radicle derived from the acid is oxidised according to the laws of the oxidation of ketones; or, in other words, the alcohol-radicles. Hence the preparation and oxidation of a properly chosen ketone

furnishes the means of first separating the oxidised carbon from an acid, and then oxidising the alcohol-radicle united with this carbonyl in such a manner that the constitution of the acid, and therefore, also, of the corresponding alcohol, may be inferred from the products of oxidation of the ketone.

As an example of this method of determining the constitution of acids and alcohols, Popoff describes the reactions of the phenyl-ketone from the valeric acid obtained from fermentation amyl-alcohol. The amyl-alcohol boiled at 130–131.5° and had a rotatory power = -2.4°; the valeric acid obtained from it boiled at 174–176° and had a rotatory power = +4.4°. It consisted, therefore, in great part of the optically inactive acid. On distilling a mixture of the calcium salt of this acid with an equivalent quantity of calcium benzoate, and rectifying the distillate, a liquid was obtained boiling at 225–226°, and having the composition of butyl-phenyl ketone, $C^6H^5.CO.C^4H^9$. This liquid yielded, by oxidation, benzoic and iso-butyric acids, the latter being recognised by the characters of its calcium and silver salts. A small quantity of acetic acid was likewise produced.

The formation of benzoic acid shows that the carbonyl and phenyl groups remain united in the butyl-phenyl ketone. The production of iso-butyric acid proves that iso-butyl was present in the ketone, and, therefore, in the valeric acid and in the amyl-alcohol. Since the valeric acid employed consisted mainly of the inactive modification, and since iso-butyric acid was produced in quantity, it follows that the inactive valeric acid and the inactive amyl-alcohol contain iso-butyl:

This result confirms the conclusions of Erlennmeyer, Frankland and Duppa, and Butlerow, respecting the constitution of fermentation amyl-alcohol. The acetic acid was perhaps due to impurity in the product, or to a secondary and irregular oxidation of the ketone, or to the presence of a small quantity of active valeric acid. This possibly may be ethyl-methyl-acetic acid:

the ketone of which would certainly yield acetic acid.

On the compounds of ketones with Mercuric Oxide, see ACETONE (p. 13).

KIDNEY-BEAN. See BEAN (p. 126).

KIESERITE. A mineral found by A. Simony in the rock-salt of Hallstatt has been recognised by Tschermak (*Jahrbuch f. Mineralogie*, 1871, 758) as kieserite. It is found in coarse-grained yellowish masses, the cavities of which are lined with monoclinic crystals whose axes $a : b : c = 0.91474 : 1 : 1.7445$; angle $ac = 88^\circ 53'$. The habit of the crystals resembles that of lazulite, and is determined by the faces $-P$ and $+P$, with $+\frac{1}{2}P$, $-P\infty$, and $(P\infty)$ subordinate. Hardness greater than 3. Analysis a is by Tschermak; b by H. Wieser (*ibid.* 642); c gives the values calculated according to the formula $MgSO^4.H^2O$:

	SO ³	MgO	FeO	Fe ² O ³	Na ² O	Cl	H ² O
a	57.92	29.09	—	0.25	—	—	13.40 = 100.66
b	57.87	28.89	0.05	—	0.05	0.06	13.24 = 100.16
c	57.97	28.99	—	—	—	—	13.04 = 100

Sp. gr. of $a = 2.569$; of $b = 2.5645$.

Kieserite forms about 12 p.c. of the refuse salt (*Abraunsalz*) of Stassfurt, and is separated therefrom by its sparing solubility in cold water. This refuse salt having been boiled down to extract the potassium salts, the residue is placed in a funnel-shaped vessel and washed with cold water; this separates the soluble salts from the mixture of other partially soluble compounds, kieserite, anhydrite, clay, sludge, &c., which may be separated to a great extent by their difference of specific gravity. The kieserite is then placed in iron frames and crystallised by heat. In this process a part of the compound is converted into the salt containing 7 mol. of water, and the mass is sent into commerce as block kieserite containing 60 p.c. $MgSO^4$. One of the principal uses of this kieserite seems to be for the washing of wool; it is also used for the preparation of 'permanent white' by precipitation with barium chloride, and for the manufacture of crystallised glauber salts, with the sodium chloride which is a by-product of the refuse salt. 2 molecules of kieserite and 1 of calcium hydrate heated with water solidify to a gelatinous mass containing $CaSO^4 + MgSO^4 + MgO$. This, on being strongly heated, powdered, and mixed with water, quickly hardens to a

marble-like mass, which may be polished and to a certain degree withstands damp (H. Grüneberg, *Deut. Chem. Ges. Ber.* v. 840).

KILLAS (J. A. Phillips, *Phil. Mag.* [4], xli. 87).—This is the name applied by Cornish miners to all sedimentary cleavable rocks. The geological age of these rocks has not been determined beyond that they belong to the palæozoic era, and it is believed that they are of Devonian age. They enclose five large and several smaller 'islands' of granite, and are, as well as the granite itself, traversed by dykes of granitic and porphyritic rock called *elvans*, by trap dykes, by copper and tin lodes, and by various cross courses, including *fucans*, or fissures filled with clay. Typical killas is a grey, bluish-grey, or greenish-grey clay-slate, and, when weathered, is brownish-yellow or buff. It is usually exceedingly fissile with the planes much contorted, but is often more compact near its junction with the granite. The sections examined in the microscope by 'a low power' were magnified 60, or by a 'high power' about 400 linear.

I. *Killas from Polgooth Mine, adit level*; sp. gr. = 2.60.—This is a very soft slate of a light-grey colour, marked in places with a darker shade or yellow tinge. By transmitted light under a low power, thin sections exhibit no structure, but appear as a milky-white mass, enclosing moss-like semi-crystalline markings of a brownish-green, and traversed by fissures filled with crystalline transparent quartz. With a high power it is found to be composed of an aggregate of minute granules intimately blended together without definite outlines, and to enclose some grains of oxide of iron and apparently fragments of hornblende, and some patches of a chloritic mineral.

II. *Killas from Polgooth Mine, 80 fathoms level*; sp. gr. = 2.74.—This specimen, much harder than the above, is of a grey colour, strongly marked with reddish-brown. Here the microscope detected no difference excepting that the grains of oxide of iron were larger but less numerous, and that there were fewer of what appeared to be broken crystals of a hornblende mineral. The granular fragments are larger and more distinct, their larger surfaces being nearly parallel with the planes of cleavage of the slate. The chloritic mineral is again very abundant, and peculiar markings are observed about its margin.

III. *Killas from Polgooth Mine, 100 fathoms level*; sp. gr. = 2.73.—At this depth the killas is much harder than that found at shallower levels, is of a greenish-grey, slightly streaked and spotted with yellow. The sections resemble those from the 80 fathoms level, but contain no hornblende and fewer chloritic patches.

IV. *Killas from Polmar Mine, 40 fathoms below the surface*; sp. gr. = 2.68.—This clay-slate is much contorted, dividing readily in curved laminae, with glossy surfaces bearing wavy lines resembling minute ripple-marks. It is of a medium grey, and slightly yellow in places. Its sections resemble those of the Polgooth specimens. Granules of quartz are disseminated through the finely-grained matrix, which derives its greyish tint from chlorite, and is minutely divided by a system of markings made up of pairs of parallel lines, each about $\frac{1}{1000}$ th of an inch long, and $\frac{1}{5000}$ th of an inch apart.

V. *Slate from 'Sanctuaries' near St. Austell*; sp. gr. = 2.52.—This is light grey and buff in colour, and appears to be weathered. It divides with difficulty into laminae, the surfaces being without polish. It is divided by headings variously coloured, apparently by infiltration of water containing oxide of iron.

VI. *Killas from Dolcoath Mine, 215 fathoms level*; sp. gr. = 2.71.—This rock is exceedingly hard, the cleavage imperfect, and its prevailing colour dark grey. Freshly fractured surfaces exhibit numerous minute, brilliant, indistinct crystals, probably of some hornblende mineral. With a low power its sections appear to be made up of transparent angular particles, giving colours with polarised light; the greenish patches disseminated through the mass are probably chlorite. With a high power are seen black grains of magnetite and titaniferous iron, and fan-like aggregations of transparent acicular crystals, often diverging from a particle of oxide of iron. Similar crystals also cross each other in all directions, and are probably hornblende or schorl. Mechanically imbedded are rounded fragments of mica, and of a semi-translucent mineral not sufficiently opaque for oxide of iron.

VII. *Killas from Botallack, Penzance, surface near lode*; sp. gr. = 2.95.—This is a very hard, dark greenish-grey rock, containing minute crystals of pyrites; its cleavage being to a great extent obliterated by metamorphism, it breaks into roughly tabular masses whose planes approximate to those of original cleavage. The low power shows an amorphous base, often green, due probably to chlorite, and enclosing transparent crystals and crystalline patches, often fringed with acicular crystals, which give brilliant colours with polarised light. With a high power long slender crystals, probably of apatite, and minute triclinic crystals, possibly of axinite, are seen.

VIII. *Rock from Botallack, 130 fathoms*; sp. gr. = 2.82.—A very dark green specimen, with traces of lighter shade and no cleavage; is slightly magnetic, and encloses in places minute crystals of pyrites. The grains of oxide of iron are more numerous than in specimens obtained nearer the surface. It contains fewer long crystals than the surface rock, and is traversed by minute veins of quartz enclosing transparent acicular crystals, probably of hornblende. From its physical constitution and the large amount of magnesia it contains, it may be regarded as an impure serpentine.

IX. '*Best roofing slate, Delahole*'; sp. gr. = 2.81.—Under a low power this slate shows no distinct structure, but is thickly dotted with dark spots; but with a high power numerous clusters, about $\frac{3}{1000}$ th of an inch in diameter, of reddish-brown crystals appear. These result from the aggregation of several hexagonal plates of a substance which, according to Mr. Sorby's examination, consists of more or less altered specular iron. The matrix is, moreover, traversed in all directions, but especially in planes parallel to the cleavage, by long transparent crystals which are brilliantly coloured by polarised light. Both brown and white crystals have been formed *in situ*.

X. *Diorite, 'Sanctuaries,' St. Mewan*; sp. gr. = 2.97.—This rock is of a dark green colour verging on black, is exceedingly hard and tough, distinctly crystalline and magnetic. Thin sections exhibit unmistakable evidence of extensive alteration. The felspar does not generally present any distinctive characteristics, although in a few instances the parallel striping peculiar to triclinic varieties was observed. The rock also contains semi-transparent yellowish-brown crystals, probably hornblende, a green mineral of fibrous structure which is believed to be a variety of hornblende, many black grains of oxide of iron, some well-defined hexagonal crystals, probably apatite, and an abundance of a green chloritic mineral. This diorite has probably undergone much alteration.

XI. '*Greenstone, Blowing-House Hill, St. Austell*'; sp. gr. = 2.89.—This stone is very similar to the 'Sanctuaries' rock, but is of a somewhat duller aspect, and is divided by a series of oblique cross-headings, which impart to it a tendency to divide into rhomboidal masses; it is also less decidedly crystalline, and exhibits a grain resembling that of some varieties of metamorphosed schist. The sections show a compact felspathic matrix enclosing a few indistinct crystals of felspar, together with large quantities of the greenish chloritic mineral observed in the St. Mewan diorite, from which the greenstone differs but little in composition. The greenish mineral is arranged in approximately parallel bands and patches, many of the latter appearing to be partially decomposed hornblende crystals, and, though retaining at their centre to a certain extent their original structure and colour, have at the edges been transformed into chlorite or an allied mineral. The rock also contains many black grains of oxide of iron, and some hexagonal crystals, probably of apatite. It is believed to be an altered clay-slate.

XII. *Serpentinous rock, Menheniot*; sp. gr. = 2.77.—This is a moderately hard stone of a dark green colour, has a somewhat crystalline fracture and schistose structure, and is slightly magnetic. It occurs more or less intermixed with clay-slate, and beds of unaltered slate are found interstratified with it. It exhibits numerous resinous headings, many of which are coated with asbestos, with fissures containing calcite. Reniform concretions of saponite are frequently found in a clay apparently resulting from the decomposition of the principal rock. The microscope shows a highly metamorphosed rock consisting of an amorphous matrix, porphyritically enclosing yellowish-brown or green patches with indistinct crystalline forms, evidently pseudomorphs, with many grains of magnetite and crystals of what is probably schiller-spar or diallage.

XIII. *Serpentine, Lizard*; sp. gr. = 2.59.—The specimen is of a very dark green colour, in places verging on black and thickly spotted with red; it has a coarsely granular structure, is without any indication of foliation, and encloses imperfectly developed crystals.

XIV. *Orthoclase, 'Glass Mine,' Roche*; sp. gr. = 2.55.—This yellowish-white felspar occurs in granite containing considerable quantities of schorl, and is traversed by veins of milky quartz enclosing tourmaline and cassiterite. Professor Miller, of Cambridge, examined it crystallographically, and pronounced it to be a monoclinic felspar.

The following table exhibits the mean results of the analyses of these rocks:

	H ² O	SiO ²	TiO ²	P ² O ⁵	Al ² O ³	Fe ² O ³	FeO	Mn ² O ³	CaO	MgO	K ² O	Na ² O

X, likewise contains traces of sulphur; XII. and XIII. traces of an oxide of manganese.

KINO. On the occurrence of pyrocatechin in this substance, see PYROCATECHIN.

KJERULFIN. A mineral from Bamlo in Norway. It occurs massive with imperfect cleavage in two directions nearly at right angles to each other. Fracture, uneven and splintery. Lustre, fatty. Colour, pale red; translucent in thin fragments. Specific gravity = 3.15. Hardness = 4-5. When warmed it exhibits a faint white phosphorescence, and melts with some intumescence to a blistered enamel. Easily soluble in hot concentrated hydrochloric acid; somewhat less easily in nitric acid. With sulphuric acid it evolves hydrofluoric acid, and forms calcium sulphate. Analysis gave:

P ² O ⁵	MgO	CaO	Na ² O	Fl	SiO ²	Al ² O ³
42.22	37.00	7.56	1.56	4.78	1.50	5.40 = 100.02

with traces of potassium, iron, and sulphuric acid.

When the non-essential constituents are deducted, this composition corresponds with the formula $2\text{Mg}(\text{PO})^2 + \text{CaF}_2$, a small portion of the calcium being replaced by sodium.

Kjerulfin differs from wagnerite, which it resembles in many respects, by containing less fluorine and sodium, and more calcium, so that its solution in hydrochloric acid gives a precipitate with sulphuric acid, which is not the case with wagnerite (F. v. Kobell, *J. pr. Chem.* [2] vii. 272).

KNOBELITE. This mineral (iii. 447), hitherto known only as occurring at Ilmenau and Dannemora in Sweden, is found, according to Igelström (*Chem. Centr.* 1870, 198), in large quantities, in veins 4 metres thick, in the iron mine of Hillärg, Gudovilla parish, Dalarne Government, Sweden, embedded in heliofinta, together with magnetic iron ore, limestone, and a small quantity of magnetic pyrites. Analysis gave:

SiO ²	FeO	MnO	CaO
33.14	40.96	19.35	6.35 = 100,

differing not inconsiderably from the former analysis of knobelite by Döbereiner 32.5 SiO², 32.0 FeO, 35 MnO, iii. 447); nevertheless Igelström regards the mineral as knobelite on account of its similarity thereto in physical characters, and its property of gelatinising with hydrochloric acid. The larger proportion of ferrous oxide he attributes to intimately mixed magnetic oxide.

KÖTTIGITE. See PHOSPHATES.

KOUMISS. Observations on this beverage have been published by V. Jagielski *Pharm. J. Trans.* [3], i. 861, 885), who had the opportunity of studying its use and its action on the human body in the Stoppes of Russia. He points out that koumiss, when kept for some time in bottles, undergoes essential alteration, its amount of alcohol and carbonic acid continually increasing at the expense of the solid constituents of the mare's milk, and that this alteration is attended with the formation of acids,

especially lactic, acetic, butyric, and succinic. Koumiss in its different stages of fermentation, and therefore koumiss of various ages, is required in the treatment of different disorders. Koumiss may also be prepared from cow's milk, but on account of the much greater proportion of casein contained in the latter, the koumiss obtained from it is very different from that prepared from mare's milk. The spirit prepared from koumiss by distillation is called 'araca.'

Koumiss manufactured in Davos, Switzerland, in imitation of the true Russian koumiss, has a mean density of 1.1286 at 50°, and contains:

	In 100 grams	Per litre
Water	90.346	1019.64 grams
Alcohol	3.210	36.23 "
Lactic acid	0.190	2.14 "
Sugar	2.105	23.75 "
Albuminates	1.860	20.90 "
Butter	1.780	20.09 "
Inorganic salts	0.509	5.74 "
Free carbonic acid	0.177	2.00 "

This koumiss contains more sugar and less lactic acid than old Russian koumiss, and is probably prepared by adding a few per cent. of sugar to skim-milk, alcoholic fermentation being induced by the addition of yeast (H. Suter-Nacfi, *Deut. Chem. Ges. Ber.* v. 286).

KRANTZITE. See RESINS, FOSSIL.

KYNURENIC ACID, and **KYNURINE**. Kynurenic acid, discovered in dog's urine by Liebig (iii. 450), has been further examined by Schmidberg a. Schulzian (*Chem. Soc. J.* [2], x. 1028) who assign to it the formula $C^9H^{11}N^2O^4$, the free acid containing $2H^2O$ of crystallisation, and the barium salt being $C^9H^{11}BaN^2O^4 + 3H^2O$. It is obtained from dog's urine by evaporation and addition of hydrochloric or nitric acid; it is practically insoluble in water, either hot or cold, or impregnated with hydrochloric or nitric acid, but slightly soluble in alcohol or ether. With baryta-water in excess it yields a soluble basic salt, which furnishes a precipitate of mixed carbonate and neutral salt on passing carbon dioxide through the solution, an appearance which misled Liebig to the idea that the free acid was thrown down from the barium salt by carbonic acid.

When heated to 265°, kynurenic acid evolves pure carbon dioxide and melts to a brown liquid. The product is mostly soluble in water, and on evaporation yields crystals having the composition $C^{10}H^{11}N^2O^2$. This substance, kynurine, is anhydrous, melts at 201°, and gives a crystalline hydrochloride, $C^{10}H^{11}N^2O^2.2HCl + 4H^2O$, and a crystalline platinum salt, $C^{10}H^{11}N^2O^2.2HCl.PtCl^4$; it also gives a crystalline gold salt.

L

LABRADORITE. See FELSPAR (p. 372). On the Labradorite rocks of Water-ville, New Hampshire, see E. S. Dana (*Sill. Am. J.* [3], ii. 48; *Chem. Soc. J.* [2], x. 227).

LACTIC ACIDS, $C^3H^4O^3$. 1. *Ethylidene-lactic acid*, $CH^3-CHOH-COOH$. *Formation from Sugar*.—a. *By Fermentation*.—The following mixture is recommended by C. O. Harz (*Vierteljahrsschrift pr. Pharm.* xx. 501; *Jahresb. f. Chem.* 1870, p. 561): 3 pts. milk-sugar, 36 pts. ordinary water, 0.5 to 0.75 pt. flour containing a large proportion of gluten, 1 or 2 tablespoonfuls of beer-yeast, 6 pts. of soda-crystals, or 3 pts. of sodium bicarbonate. When the fermentation has once been set up by milk-sugar, it may be continued by addition of cane-sugar.

b. *Without Fermentation*.—When 500 grams of grape-sugar are introduced into a capacious retort, together with $1\frac{1}{2}$ pt. soda-ley of sp. gr. 1.34, and an equal volume of water, and heated in a water-bath, a very strong reaction takes place at about 96°, so that it is advisable not to operate with larger quantities at once. The temperature rises above 116°, and the liquid boils strongly without evolution of gas, acquiring a not unpleasant odour. On mixing it, after cooling, with a quantity of dilute sulphuric acid exactly sufficient to neutralise the soda, concentrating by evaporation, and

agitating with ether, lactic acid is dissolved out, together with pyrocatechin and greasy products. The lactic acid is abstracted from the ether by agitation with water and barium carbonate; the resulting barium salt is converted into zinc salt; and the latter is purified by crystallisation. The acid obtained from this zinc salt possesses all the characters of ordinary lactic acid. Its concentrated aqueous solution does not exhibit circular polarisation. As no volatile fatty acids are formed at the same time except formic acid, the lactic acid obtained by this process is much easier to purify than that which is prepared by fermentation, but the yield does not exceed 10 to 20 p.c. of the sugar employed. Cane-sugar or milk-sugar may be used in the process instead of grape-sugar (Hoppe-Seyler, *Deut. Chem. Ges. Ber.* iv. 346).

As neither lactic acid nor calcium lactate is altered by heating to 200° for several hours with water, attempts were made to produce lactic acid by the action of water on sugar or on paper at 200°, but always with a negative result. If a sufficient quantity of magnesia is added the sugar does not blacken, but still no lactic acid is formed (Hoppe-Seyler).

Formation from Acetone.—When dichloroacetone is heated to 200° for six hours with 20 times its volume of water, and the contents of the tube are successively treated with excess of silver oxide, hydrogen sulphide, and zinc-white, a zinc salt is obtained agreeing with that of ordinary lactic acid.

The exchange of Cl for HO is in this case accompanied by a transposition of the atoms within the molecule (Linnemann a. von Zotta, *Ann. Ch. Pharm.* clix. 247).

2. Hydracrylic acid.—This acid, which Beilstein obtained by the action of silver oxide and water on β -iodopropionic acid, and to which he assigned the formula ($\text{C}^3\text{H}^2\text{O}^4$), was shown by Moldenhauer to yield, by simple neutralisation with soda, a salt of lactic acid (*1st Suppl.* 770): hence it would appear to be only a modification of lactic acid; and this view is confirmed by the experiments of Wislicenus (*Deut. Chem. Ges. Ber.* iv. 532; *Ann. Ch. Pharm.* clxvi. 6).

To prepare hydracrylic acid, an aqueous solution of β -iodopropionic acid is boiled with silver oxide, the filtrate is treated with hydrogen sulphide, and after the excess of the latter has been expolled, the liquid is neutralised with sodium carbonate and evaporated. The residue is then digested with boiling alcohol of 75 p.c. which dissolves sodium hydracrylate, leaving undissolved the salts of three other acids which will be noticed further on (p. 721). The sodium salt may be purified by two or three recrystallisations from alcohol, and the pure acid obtained by decomposing it with sulphuric acid, agitating with ether, and leaving the ethereal solution to evaporate (Wislicenus). Or equal parts of the impure acid may be neutralised with lime and zinc oxide, the two solutions mixed, whereby a crystalline precipitate is formed consisting of zinc-calcium hydracrylate; and from this salt, purified by thorough washing or by recrystallisation, the pure acid may be obtained by removing the zinc with hydrogen sulphide, and the calcium by exact precipitation with oxalic acid (Heintz, *Ann. Ch. Pharm.* clvii. 291).

Hydracrylic acid remains, on evaporation of its ethereal solution, as a strongly acid syrup exactly like ordinary lactic acid. It is distinguished, however, from this and all the other modifications of lactic acid by the fact that, when heated, it does not yield a trace of lactide, but is resolved, almost without residue, into water and acrylic acid: $\text{C}^3\text{H}^2\text{O}^4 = \text{H}^2\text{O} + \text{C}^3\text{H}^2\text{O}^3$.

Heated with iodine and potash-solution (Lieben's reaction) it does not yield iodoform. By oxidation with chromic or nitric acid it yields nothing but carbon dioxide and oxalic acid; with silver oxide it forms carbon dioxide, together with carbacetoxylic acid if the proportion of silver oxide is small, oxalic and glycollic acids if it is larger. With melting potash, the products are chiefly acetic and formic acids, together with a little oxalic acid and apparently also glycollic acid.

Sodium hydracrylate, $\text{C}^3\text{H}^2\text{NaO}^4$, crystallises in flat prisms with acuminate faces; deliquesces in moist air; is but slightly soluble in absolute alcohol, even at the boiling heat; somewhat more soluble in alcohol of 25 p.c., from which it crystallises in the anhydrous state on cooling; very soluble in dilute alcohol. It melts at 142°–143° without loss of weight to a colourless liquid, and solidifies to a crystalline mass on cooling. It gives off 1 mol. water slowly between 180° and 200°, more quickly at 50°, leaving a residue which has the composition of sodium acrylate, $\text{C}^3\text{H}^2\text{NaO}^3$, but differs from that salt in becoming heated in contact with water, and taking up again 10 water which it had lost.

Silver hydracrylate, $C^6H^3AgO^3$, forms delicate prisms and needles easily soluble in cold water, insoluble in alcohol.

Calcium hydracrylate, $C^6H^{10}CaO^3 \cdot 2H^2O$, loses water even when its solution is evaporated to a thin syrup, but on adding a little water to the residue, well-defined crystals are soon formed.

Zinc hydracrylate, $C^6H^{10}ZnO^3 \cdot 4H^2O$, also remains as a syrup when its solution is evaporated over the water-bath, but soon becomes crystalline on exposure to moist air. By spontaneous evaporation of the aqueous solution it is obtained in brilliant triclinic crystals. 100 pts. of the salt dissolve in 8 pts. water at 16.5° (Wislicenus).

Zinc calcium hydracrylate, $C^6H^{10}ZnO^3 \cdot C^6H^{10}CaO^3$, is obtained as a crystalline precipitate on mixing the concentrated solutions of its component salts, and in distinct crystals by dissolving the precipitate in the smallest possible quantity of hot water and leaving the solution to evaporate over sulphuric acid. It dissolves in 11.5 pts. of water at 15° , and is but slightly more soluble in boiling water; in ether and alcohol it is quite insoluble even at the boiling heat (Hointz, *Ann. Ch. Pharm.* clvii. 291).

Constitution of Hydracrylic acid.—The formation of this acid from β -iodopropionic acid, CH^3I-CH^2-COOH , would lead to the inference that it is identical with ethylene-lactic acid, CH^2OH-CH^2-COOH . But hydracrylic acid, as already observed, is distinguished from all other modifications of lactic acid by being resolved when heated into water and acrylic acid. From ethylidene-lactic acid, it differs in not yielding iodoform by Lieben's reaction; and from ethylene-lactic acid—synthetically prepared by combining ethylene with carbonyl chloride, and decomposing the resulting chloride, CH^2Cl-CH^2-COCl , with an alkali (1st Suppl. 770)—it is distinguished by its products of oxidation. Ethylene-lactic acid is converted by oxidation with chromic acid, nitric acid, or melting potash, into malonic acid, $COOH-CH^2-COOH$ (1st Suppl. 800); but hydracrylic acid when similarly treated yields totally different products (p. 717).

A further distinction between the two acids is afforded by the characters of their zinc salts, and zinc-calcium salts, those of hydracrylic acid being crystalline, as above stated, whereas those of synthetical ethylene-lactic acid are amorphous and never exhibit any sign of crystallisation. Lastly, hydracrylic acid or either of its salts, when heated with hydriodic acid, always reproduces β -iodopropionic acid (glycerin iodopropionic acid), 1 or 2 grams of substance being sufficient to exhibit the reaction; but synthetical ethylene-lactic acid, when similarly treated even in twenty times that quantity, does not yield a trace of β -iodopropionic acid.

The easy resolution of hydracrylic acid into water and acrylic acid shows that it is very nearly related to acrylic acid, acrolein and allyl alcohol. These compounds are now generally represented by the following formulæ (pp. 27, 47):

They do not contain the group CH^3 , which therefore cannot be present in hydracrylic acid, and this conclusion is confirmed by the fact that this acid does not yield acetic acid by oxidation, or iodoform by Lieben's reaction. Hydracrylic acid must therefore contain the group CH^2OH , which exists also, together with $COOH$, in ethylene-lactic acid. Consequently hydracrylic acid cannot contain this latter group, since if it did both acids would be represented by the formula CH^2OH-OH^2-COOH , that is to say, they would be identical. It appears, therefore, very probable that hydracrylic acid has the constitution represented by the formula:

A compound thus constituted will be an acid: for organic hydroxides are converted into acids, not only by transformation of the group CH^2OH into $COOH$, but also when negative elements or radicals accumulate near an alcoholic hydroxyl.

Admitting, then, this formula for hydracrylic acid, the compounds related to it must be constituted as follows:

These formulæ are preferable to those hitherto adopted, for the following reasons: When an alcohol undergoes oxidation, the oxygen which enters it is attracted by that carbon-atom which is already combined with oxygen. Now in glycerin, $\text{CH}^2\text{OH}-\text{CHOH}-\text{CH}^2\text{OH}$, each atom of carbon is already combined with oxygen, and therefore the oxygen which replaces the hydrogen will be as strongly attracted by one of the external carbon-atoms as by the middle ones, and thus glyceric acid will have the constitution above indicated.

Acrolein, although possessing most of the properties of the aldehydes, differs from them by not uniting with alkaline bisulphites, and by its reaction with ammonia; it may therefore be expected to differ from the aldehydes in constitution. Its reduction to allyl alcohol and oxidation to acrylic acid are explained by the new formula as clearly as by the old one. When allyl alcohol is oxidised, it yields acrolein; in this case the oxygen is attracted, not only by the group CH^2OH , but likewise by the second atom of carbon: for it is well known that in the oxidation of carbon-compounds which have some of their carbon-atoms united by two combining units, the oxygen most readily attacks the carbon-atoms thus doubly united.

Hydracrylic acid is much more easily oxidised than any other modification of lactic acid, giving off torrents of carbon dioxide and a strong smell of formic acid. The oxidation probably takes place in the manner represented by the equation:

the first products being glycollic and formic acids, which are then further oxidised to carbonic and oxalic acids. The formation of acetic acid with only a little glycollic acid, by the action of melting potash, may be explained by supposing that, before the oxidising action of the potash begins, a large quantity of hydracrylic acid is converted into acrylic acid, which, as the temperature rises, is resolved into formic and acetic acids, while the glycollic acid is formed from unaltered hydracrylic acid.

The existence of the double hydracrylate of zinc and calcium suggests the idea that hydracrylic acid may be bibasic and polymeric with lactic acid. In this case its formula may be:

The question as to its molecular weight cannot be decided by the density of its ethylic ether, as this compound is decomposed by heat.

3. *Sarcrolactic acid*.—The sarcrolactates exhibit in many respects the characters of double salts of ethylidene- and ethylene-lactic acids. According to Wislicenus (*Deut. Chem. Ges. Ber.* ii. 619), the zinc salt of sarcrolactic acid is resolved by strong alcohol into a sparingly soluble crystalline salt and an easily soluble amorphous salt. The latter, so far as it could be examined, agreed in character with that of the acid prepared from β -iodopropionic acid, that is to say, with the hydracrylate. The sparingly soluble zinc salt, on the other hand, is not identical with the ethylidene-lactate, but contains 2 mol. water of crystallisation (instead of 3 mol.) Moreover the acid separated from this zinc salt differs from all the other modifications of lactic acid in being active to polarised light; it turns the plane of polarisation to the right ($\alpha=3.5^\circ$), but its salts exert a levorotatory power ($\alpha=-8.37^\circ$).

The presence of this optically active acid renders the sarcrolactates themselves optically active, whereas the double salts formed by direct mixture of ethylidene- and ethylene-lactates are optically inactive. There are also, as Heintz has pointed out (*Ann. Ch. Pharm.* clvii. 314), other particulars in which the sarcrolactates

differ from the corresponding artificially prepared double salts. Zinc sarcosactate gives off its water at 100° , much more slowly than the artificially prepared double salt: it can also be recrystallised from water without sensible alteration of its composition, whereas the artificial double salt cannot. From the latter, indeed, it is easy, by repeated crystallisation, to obtain pure ethylidene-lactate of zinc, whereas when a solution of the sarcosactate from which half the zinc has been precipitated by hydrogen sulphide is left to evaporate, unaltered sarcosactate crystallises out, and the mother-liquor when saturated with zinc oxide yields the same salt. In the crystallisation of zinc sarcosactate, it often happens that, after part of the salt has separated out, the whole solidifies to a translucent jelly, in which the microscope shows the presence of small elongated six-sided tables and long very slender flexible needles. This appearance is never exhibited by the artificially prepared double salt.

For these reasons Hantzsch regards sarcosactate as a distinct modification of lactic acid, and proposes for it the formula :

If, on the other hand, sarcosactate acid be regarded as a mixture or compound of an ethylidene- and an ethylene-lactic acid, one of which is optically active, then there will be four modifications of lactic acid, viz.:

Inactive ethylidene-lactic acid,

Inactive ethylene-lactic acid,

Active ethylidene- or ethylene-lactic acid (paralactic acid),

Hydracrylic acid :

whereas there are only three constitutional formulæ by which these modifications may be represented, viz.:

There is, however, good reason for supposing that the difference of structure between optically active bodies and their inactive isomerides—as, for example, in the several modifications of tartaric acid—is rather physical than chemical; in other words, that it depends on difference of arrangements of the molecules amongst themselves rather than on that of the atoms within the molecules. On this view the existence of the four modifications of lactic acid above-mentioned presents no anomaly.

Lactic Anhydrides (Wislicenus, *Ann. Ch. Pharm.* clxiv. 181). When pure aqueous lactic acid is left for several months over sulphuric acid in a vacuum, it is found that, notwithstanding the loss of weight which occurs from abstraction of water, the quantity of alkali required to neutralise a given weight of the aqueous acid continually diminishes; moreover, that the neutralised liquid, if made blue by addition of litmus, becomes red after a while, and if the free acid be again neutralised with alkali, the liquid again assumes a red colour after standing, and so on for several alternations. These results are due to the formation of dilactic acid, $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$, which, as formerly shown by Wislicenus and van der Bruggen (*1st Suppl.* 772), may be regarded as an ethereal derivative of two molecules of lactic acid, one of which plays the part of an acid, the other that of an alcohol, its constitutional formula being

It is, therefore, at once a monobasic acid, a monosacid secondary alcohol, and a compound ether. Accordingly it will in the first instance be neutralised by 1 molecule of sodium hydrate; but the resulting sodium salt, like all compound ethers, will be partially decomposed by the water, and the free lactic acid thus produced will destroy the neutral reaction. If the decomposition has been complete, as for example when the

salt is quickly saponified by boiling with alkali, the neutralisation of the acid subsequently set free will require a quantity of base equal to that required for the first saturation.

It follows from these facts that when a solution of lactic acid is left to evaporate, dilactic acid forms in it even before all the water has evaporated, the quantity of the dilactic acid increasing as that of the water diminishes. Pure lactic acid, answering to the formula $C^3H^5O^3$, cannot therefore be obtained.

Further, when lactic acid is left at ordinary temperatures in an atmosphere kept constantly dry, the dehydration does not stop at the formation of the first anhydride—viz. dilactic acid, but proceeds to the formation of lactide, $C^3H^4O^2$. At higher temperatures, even in an atmosphere not perfectly dry, the dehydration goes on at an accelerated rate. This is shown by the following numbers, which represent the results of an experiment made with lactic acid which had stood for two months in the exsiccator (called in the table 'original acid').

	Water	Lactic acid	Dilactic acid	Lactide	Total
1. Original acid	26.23	69.59	4.18	—	100 .
2. After 2 hours in the water-bath	—	44.93	55.11	—	100.04
3. After 16 hours in the water-bath	—	30.00	71.40	—	101.40
4. After 15 hours at 140° – 150°	—	—	52.61	47.61	100.12
5. The resulting distillate	4.65	43.87	51.48	—	100

The acid which had remained for 16 hours over the water-bath appeared also to contain lactide; as, when more strongly heated, it yielded a sublimate of crystalline lactide, even before the temperature had reached 140° .

Salts of Dilactic acid.—Wislicenus observed several years ago that the crude product obtained by heating lactic acid to 150° gave, when neutralised with magnesia, instead of the crystalline lactate of magnesium, an amorphous saline mass consisting of magnesium dilactate. He has lately obtained and analysed the corresponding sodium salt, which is also an amorphous viscid mass. On the ethers of dilactic acid, see 1st Suppl. 773.

Action of water on Dilactic acid.—The conversion of this body into lactic acid by water at ordinary temperatures takes place very slowly. When 5 grams of a dehydrated product containing 89.86 p.c. of dilactic acid and 10.16 p.c. lactide were dissolved in 10 c.c. of absolute alcohol, precipitated by water, and the whole left to itself, the viscid precipitate did not disappear completely in six months, although it diminished considerably.

Dihydracrylic acid, $C^3H^4O^3$.—When crude hydracrylic acid, prepared according to Beilstein's directions, is carefully neutralised with sodium carbonate, there is obtained—besides the principal product, viz. sodium hydracrylate, $C^3H^3NaO^3$, which crystallises readily from alcohol—a small quantity of residue very slightly soluble in alcohol, and consisting of the sodium salts of three acids, which may with some difficulty be partially separated one from the other. One of these salts is, very deliquescent, quite insoluble in alcohol, and gives with solutions of calcium, barium, zinc, iron, copper, silver, lead, &c., amorphous, absolutely insoluble, precipitates. The copper, silver, lead, and barium salts agree with the formula $C^3H^2M^2O^4$. The acid is therefore bibasic and isomeric with adipimalic acid (p. 29). Wislicenus designates it as paradipimalic acid.

The sodium salts of the other two acids are easily soluble in dilute alcohol, very sparingly soluble, but in various degrees, in strong alcohol. The more soluble of the two is sodium acrylate; the other has the formula $C^3H^2Na^2O^4$. The acid of this latter salt, isomeric with dilactic and paradipimalic acid, is called by Wislicenus, dihydracrylic acid. Heated to 120° with hydriodic acid of sp. gr. 1.6, it is converted, like hydracrylic and acrylic acids, into β -iodopropionic acid; paradipimalic acid does not exhibit this transformation. The sodium salt of dihydracrylic acid is more permanent in the air than that of paradipimalic acid, and gives no precipitates with calcium or barium salts, but with lead salts it forms a precipitate soluble in excess of the precipitant (Wislicenus, *Deut. Chem. Ges. Ber.* iii. 809; *Ann. Ch. Pharm.* clxvi. 3; *Chem. Centr.* 1873, 331).

Lactamic Acids (Heintz, *Ann. Ch. Pharm.* clv. 25). 1. *Ethylidene-lactamic acid* or *Alanine*, which is a derivative of fermentation lactic acid, is formed, together with lactic acid, by boiling α -chloropropionic acid with aqueous ammonia—
2nd Sup.

2. *Ethylidene-dilactamic acid*, or simply *Dilactamic acid*, $\text{C}^6\text{H}^{11}\text{NO}^4$, is formed when, in preparing alanine by Strecker's method, viz. by heating aldehyde-ammonia with hydrocyanic acid and excess of hydrochloric acid (i. 63), the hydrochloric acid is added first, and the hydrocyanic acid afterwards. The chlorine having been removed in the usual manner by lead hydrate and the lead by hydrogen sulphide, any alanine that may have formed, precipitated by alcohol and ammonia, and the alcohol volatilised, the liquid is boiled with barium hydrate, the barium exactly precipitated by sulphuric acid, and the filtrate boiled with cupric oxide. The blue-green solution, when left to evaporate, deposits indistinctly crystalline grains, which, when purified by washing with alcohol and recrystallisation, have the composition of *cupric dilactamate*, $\text{C}^6\text{H}^8\text{NO}^4\text{Cu}$ (at 110°). This salt does not dissolve very easily in water, is nearly insoluble in alcohol, and does not appear distinctly crystalline, even under the microscope. When dried at 110° it loses 15.52 to 17.01 p.c. water, and therefore probably crystallises with 3 mol. water. It is very different from the copper salt of alanine.

Dilactamic acid separated from the copper salt by hydrogen sulphide, crystallises from a concentrated aqueous solution in very slender microscopic needles, from the alcoholic solution in larger needles. It dissolves easily in water, less easily in aqueous alcohol, not at all in absolute alcohol.

The formation of dilactamic acid is accompanied by that of other substances, probably including trilactamic acid.

dihydracrylamio acid, by the action of ammonia on β -iodopropionic acid:

The two acids may be separated by repeatedly boiling down the solution with lead oxide, as long as ammonia continues to escape, exhausting the residue with water, which leaves a residue of basic lead iodide, and adding alcohol, which precipitates the lead-salt of dihydracrylamio acid in colourless needles, while the hydracrylamate remains in solution.

A better method of separation, however, is to convert the two acids into the silver-salts. To effect this, the iodine and ammonia are removed as above described, and the lead is precipitated from the solution by sulphuretted hydrogen. By adding silver oxide to the filtrate, as long as silver dihydracrylamate is formed—a salt which is almost insoluble in water—and passing sulphuretted hydrogen through the filtrate, a solution of hydracrylamio acid is obtained. This solution, when evaporated, leaves the acid as a syrupy liquid, which, by agitation with ether and repeated boiling of the residue with alcohol, is converted into a solid mass.

Hydracrylamio acid is readily soluble in water, but nearly insoluble in absolute alcohol. It crystallises in transparent prisms, belonging probably to the monoclinic system. On heating it to 170° , it turns brown, and sublimes very slowly in feathery needles; at a higher temperature it is completely decomposed, leaving a very difficultly combustible charcoal. It has a sweetish taste; the faint acid reaction of its concentrated solution is probably due to the presence of a little dilactamic acid. It combines with bases as well as with acids.

The *copper salt* $(\text{C}^4\text{H}^4\text{NO}^2)^2\text{Cu} + 5\text{H}_2\text{O}$, which is much more soluble in water than the corresponding alanine compound, crystallises in large dark-blue rhombic prisms. With *silver nitrate* the acid yields the compound $\text{C}^4\text{H}^4\text{NO}^2\cdot\text{AgNO}^3$, in colourless needles, which decompose on heating.

4. *Dihydracrylamio acid*, $\text{C}^6\text{H}^{11}\text{NO}^4$, obtained by decomposing its lead or

* In Heintz's paper this acid is called *ethylene-lactamic* or *paralactamic acid*, and represented by the formula $\text{CH}^2(\text{NH}^2) - \text{CH}^2 - \text{COOH}$; but according to the explanations already given of the constitution of β -iodopropionic acid and its derivatives, it must be hydracrylamio acid.

silver salt with sulphuretted hydrogen, remains on evaporation as a thick, colourless syrup gradually solidifying on standing to a radiate crystalline mass. Once, by adding a particle of the solid acid to a concentrated solution, distinct crystals were obtained consisting of shining plates or flat needles.

If, to the solution saturated with ammonia, silver nitrate is added, a precipitate of silver dihydracrylamate, $C^4H^7N^2O^4Ag^2$, is obtained. On adding more silver nitrate to the filtrate whilst warm, the compound $C^4H^7N^2O^4Ag^2 + 1\frac{1}{2}H^2O$ separates on cooling in colourless crystals. When ammonia is added to its solution, silver dihydracrylamate is precipitated.

According to the formula of dilactic acid suggested by Wislicenus (p. 720), dilactamic and dihydracrylamic acids may perhaps be represented by the following constitutional formulae:

LACTIC FERMENTS. See FERMENTS.

LACTONIC ACID, $C^4H^5O^4$, syn. with *Isodiglycol-ethylenic acid* (iii. 414). This acid, produced by treating milk-sugar with bromine, and the product with silver oxide, is regarded by Fittig as monobasic, and by Hlasiwetz as dibasic, for reasons similar to those adduced with reference to gluconic acid, $C^6H^{12}O^7$ (p. 560). The so-called basic calcium and barium salts, $C^4H^5CaO^4$ and $C^4H^5BaO^4$, are produced in the same manner as the corresponding gluconates.

LACTURAMIC ACID, $C^4H^7N^2O^3 = CH^3-CH(NH.CONH^2)-COOH$ (Urech, *Ann. Ch. Pharm.* clxv. 99). This acid is formed by heating alanine sulphate in aqueous solution with a slight excess of potassium cyanate:

On adding a large quantity of alcohol, removing the potassium sulphate by filtration, evaporating, and crystallising the product several times from alcohol, lacturamic acid is obtained as a white indistinctly crystalline mass, slightly soluble in cold alcohol, insoluble in ether, melting with decomposition at 155° . Heated with hydrochloric acid in a sealed tube, it is resolved into alanine, carbon dioxide and ammonia:

Silver lacturamate, $C^4H^7N^2O^4Ag$, obtained by adding silver nitrate to a moderately dilute solution of the acid neutralised with sodium carbonate, crystallises gradually in needles grouped in tufts or double wedges, anhydrous and somewhat sparingly soluble in water. The lead salt $(C^4H^7N^2O^4)^2Pb + 2H^2O$ is obtained in colourless crusts by boiling the aqueous acid with excess of lead carbonate, and leaving the filtrate to evaporate. The copper salt, obtained by saturation, forms a blue solution which dries up under the exsiccator to an emerald-green mass.

LACTYL-UREA, $C^4H^7N^2O^3$, is produced by heating lacturamic acid to 140° as long as water continues to escape:

The decomposition is precisely analogous to that by which hydantoin, $C^3H^5N^2O^2$, the next lower homologue of lactyl-urea, is formed from acetyl-uramic acid. (Urech.)

Lactyl-urea is also formed in the preparation of alanine from aldehyde-ammonia by Strecker's method, when potassium cyanide is used instead of hydrocyanic acid (Heintz, *Ann. Ch. Pharm.* clxix. 120). For this purpose hydrochloric acid is added to aldehyde-ammonia and potassium cyanide dissolved in water, and after some days the solution is evaporated in order to allow ammonium chloride and potassium chloride to separate.

The syrupy liquid is treated with ether-alcohol to dissolve the alanine, and after the removal of the alcohol and ether by distillation, the substance is saturated with ammonia. The addition of alcohol now causes the separation of alanine contaminated with sal-ammoniac, and the alcoholic liquid separated from this contains lactyl-urea, together with several other substances. The lactyl-urea may be separated as follows:—The potash and ammonia are precipitated by sulphuric acid, after which the alcohol is removed by distillation, and the chlorine is separated by silver hydrate, the excess of silver being then thrown down by sulphydric acid. After the small remaining portion of ammonia has been removed by boiling with baryta, and the baryta by sulphuric acid, a syrupy residue is obtained on evaporation. This syrupy liquid dissolves in alcohol, from which it separates on addition of ether. The alcoholic filtrate separated from this syrup is freed from alcohol by distillation, and the acid residue neutralised with lime. Lactyl-urea is then deposited in long needles which, when purified by crystallisation and pressure, are converted into large colourless rhombic prisms, efflorescing in the air, and containing $C^4H^5N^2O^2 + H^2O$. When deposited from a strong hot solution it forms anhydrous microscopic needles. Its formation in this reaction is due to the presence of cyanate in the potassium cyanide employed, considerable quantities of it being formed when a solution containing potassium cyanate, potassium cyanide, and aldehyde-ammonia is treated with dilute sulphuric acid.

Lactyl-urea crystallises in cauliflower-like tufts, easily soluble in water, insoluble in ether; it melts at 140° (Heintz), 125° (Urech), and sublimes slowly at a somewhat higher temperature, the melted mass becoming brown at the same time. Its taste is bitter; it is easily soluble in water or alcohol, less soluble in ether, and it is neutral to litmus. When it is heated to 100° – 145° with barium hydrate, much ammonia is evolved, and the residue contains alanine and barium carbonate. A similar decomposition takes place when lactyl-urea is boiled for a very long time with baryta-water; but when it is boiled with baryta-water for half an hour only, barium lactamate is formed.

Lactyl-urea treated with silver hydrate forms the compound $C^4H^5AgN^2O^2$, almost insoluble in water, but soluble in ammonia, and precipitated as a white powder from its ammoniacal solution by nitric acid. Lactyl-urea does not appear to combine with silver nitrate (Heintz).

LANARKITE. This mineral, from Leadhills in Scotland, was examined more than fifty years ago by Brooke, and more recently by Thomsen, both of whom regarded it as a compound of sulphate and carbonate of lead (iii. 467). But recent analyses by Pisani (*Compt. rend.* lxxvi. 114) and by Maskelyne a. Flight (*Chem. Soc. J.* [2], xii. 103), have shown that it contains no carbonic acid, but is a compound of sulphate and oxide: $PbSO^4.PbO$.

	Pisani	Maskelyne a. Flight	Calculation
Sulphate . . .	54.17	57.70	57.605
Oxide . . .	43.66	42.89	42.395
	97.83	100.59	100.000

The older analyses were probably made upon a different mineral.

LANTANURIC ACID. On the compound thus designated by Schlieper, see ALLANTOÏN (p. 45).

LANTHANUM. For Mendelejeff's views regarding the atomic weight of this metal, see CERITE METALS (p. 273).

For Erk's method of separating lanthanum from didymium, see DIDYMIUM (p. 428).

LANTHOPINE. One of the bases obtained by Hesse from the aqueous extract of opium. See 1st Suppl. 774; also OPIUM-BASES in this volume.

LANUGINIC ACID, $C^{18}H^{22}N^{10}O^{20}$. An acid produced by the action of alkalis upon wool. When wool purified by treatment with alcohol, ether, and boiling acetic acid is boiled with concentrated baryta-water, the excess of baryta removed by carbonic acid, the filtrate precipitated by lead nitrate, and the copious precipitate washed and decomposed by hydrogen sulphide, the solution on evaporation leaves lanuginic acid as a yellowish, translucent, uncrystallisable mass. Its barium salt is $C^{18}H^{22}N^{10}O^{20}.Ba$; lead salt, $C^{18}H^{22}N^{10}O^{20}.Pb$ (P. Champion, *Compt. rend.* lxxii. 380).

LAUDANINE, LAUDANOSINE. Bases obtained by Hesse from the aqueous extract of opium. See 1st Suppl. 774, and OPIUM-BASES in this volume.

LAURYLENE. The terpene from Bay-oil. See OILS, VOLATILE.

LAWROWITE. This mineral, described by Kokscharow (1st Suppl. 775),

occurs in crystalline grains, together with small druses of vanadiolite, in quartz, on a vein of limestone in the valley of Slüdänka (or Sludjanka) near Lake Baikal. Lawrowite is cleavable parallel to the faces of a prism of 87° ; hardness 5; sp. gr. 3.04. Vanadiolite has a conchoidal fracture, blackish-green colour, greyish-green in the streak, translucent on the edges, and melts with intumescence to a black slag. Both are mixtures of augitic substance with (so-called) calcium hypovanadate, lawrowite being a grass-green diopside containing 4.20 p.c. of that salt as pigment, while vanadiolite contains 1 mol. of the hypovanadate to 3 mol. of augitic substance:—

	SiO_2	Al_2O_3	FeO	CaO	MgO	X^*
Lawrowite	53.65	2.25	2.48	23.05	16.00	2.57 = 100
Vanadiolite	15.61	1.10	1.40	34.43	2.61	44.85 = 100

(R. Hermann, *J. pr. Chem.* [2], i. 442).

LAXMANNITE. A mineral occurring at Beresowsk in Siberia. Hardness = 3. Sp. gr. = 5.77. Colour, olive-green. Two analyses by Nordenskiöld (*J. pr. Chem.* cv. 335) gave—

PbO	CuO	Fe^2O^3	Cr^2O^3	P^2O^5	H^2O
61.26	12.43	1.09	15.26	8.05	1.31 = 99.40
61.06	10.85	1.28	16.76	8.75	0.90 = 99.60

whence Nordenskiöld deduces the formula—

He supposes that the P^2O^5 and CrO^3 in this mineral are isomorphous, and thence deduces the general formula—

R. Hermann (*ibid.* [2], i. 447) deduces from Nordenskiöld's analysis the formula—

He moreover regards laxmannite as identical with vauquelinite (i. 934), assuming that Berzelius overlooked the phosphoric acid in the latter.

LEAD. *Occurrence.*—On Antimonite and Antimonate of Lead occurring at Constantine in Algeria, see NADONITE.

On native Molybdates and Vanadates of Lead, Eosite, Dechonite, Descloizite, &c., see MOLYBDATES and VANADATES.

Metallurgy. The extraction of lead from galena in reverberatory furnaces at 'Nouvelle Montagne' is described by V. Bouly (*Ann. Min.* [6], xvii. 159; *Jahresb. f. Chem.* 1870, 1076).

Lead Fume.—C. P. Williams (*Chem. News*, xxiii. 236) has analysed the fumes condensed in the flues of furnaces in which lead ores containing zinc are smelted: I. So-called 'Bartlett Lead-white.' II. Zinc-white from the ore of Sinking Valley in Pennsylvania. III. From Wisconsin ore worked for the preparation of zinc-white at Birmingham in Pennsylvania.

	I.	II.	III.

Williams proposes to condense such fumes in chambers through which water falls in the form of rain (compare iii. 523–526).

* Hypovanadic oxide, $\text{V}^2\text{O}^4 \cdot 2\text{V}^2\text{O}^4$.

Historical notices of the process of desilvering lead with zinc have been given by Gruner (*Berg. u. Hüttenm. Zeitung*, 1870, 190) and by Balling (*Dingl. pol. J.* cxviii. 52).

Estimation. F. H. Storer (*Bull. Soc. Chim.* [2], xiv. 213), estimates the amount of lead in galena and other compounds by decomposing the compound with hydrochloric acid in presence of zinc, whereby hydrogen sulphide and metallic lead are produced. The same decomposition may be effected by hot oxalic acid, acetic acid, and dilute sulphuric acid. Dilute nitric acid, on the other hand, even at ordinary temperatures, forms free sulphur and nitrate of lead. Decomposition with hot hydrochloric acid is the best process for estimating the lead and sulphur, especially for the variety of galena occurring in America, which contains no heavy metal except lead. 2 or 3 grams of the finely-pounded ore are placed in a beaker, together with a zinc regulus 1 inch in diameter and $\frac{1}{4}$ inch thick, and treated with 100 to 150 c.c. of dilute hydrochloric acid (1 vol. acid to 4 vol. water), the liquid being heated to 40°–50°, and the vessel is covered with a watch-glass and set aside for 15 to 20 minutes. After the liquid has become clear and no more hydrogen sulphide is evolved, the solution is poured upon a moderately large filter of smooth paper on which rests a piece of zinc; the lead thereby precipitated is washed with water, and introduced into a tared porcelain crucible, the zinc being cleansed with a glass rod or a piece of caoutchouc. The lead is then dried at a moderate heat in a stream of coal-gas. The amount of sulphur in the galena is estimated by arresting the escaping hydrogen sulphide in the usual way. If the galena is mixed with insoluble matrix, the lead after weighing is to be dissolved in dilute nitric acid, and the residue weighed. The same method of analysis may be applied to the sulphate, chromate, nitrate, carbonate, and other compounds of lead. Attempts to estimate the lead and sulphur in galena by means of nitric acid and zinc did not give satisfactory results.

Mascazzini (*Dingl. pol. J.* cxvii. 46) describes a new method of assaying lead ores based upon the conversion of the lead into sulphate by heating with ammonium sulphate. Lead ores which are all but free from other metals may be reduced directly by means of nascent hydrogen (the zinc should be finely pulverised) and subsequent fusion into a button of lead. Ores containing blende or pyrites must first be converted into sulphates by means of ammonium sulphate. The quantity of salt required varies with the percentage of metallic sulphides present. Two parts by weight of the dry sulphate usually suffice for the conversion of the richest ores into sulphates. The mixture of ore and ammonium salt is heated in a porcelain crucible covered with a small inverted dish. As soon as the boiling up has ceased, the temperature can be increased to strong red heat, without risk of losing any substance from spitting, till the ferric and cupric sulphates undergo decomposition. The mass when cold is readily dissolved out with hot water acidulated with a little sulphuric and hydrochloric acid. The latter prevents the silver from passing into solution, especially if the liquid be diluted and allowed to stand for some time. The insoluble portion, consisting of lead sulphate and silver chloride, is removed by decantation and filtration, and is well washed with hot water, dried, removed to a flask, and treated with powdered zinc and hydrochloric acid as long as any reduction takes place. Two parts by weight of zinc are generally sufficient to reduce one part of pure galena, provided both the metallic zinc and lead sulphate be in the state of a fine powder and intimately mixed. Since even the best kinds of zinc contain a little lead, it is necessary to determine the amount of lead so present, and to make allowance for it. The spongy mass of reduced metals is washed with water freed from air, or with water acidulated with a little dilute sulphuric acid; it is next transferred to a flat basin, pressed with a flattened glass rod, and thoroughly washed. The mass is then introduced into a crucible, dried at a gentle heat, and mixed with $1\frac{1}{2}$ to twice its weight of a reducing flux, covered with a thin layer of the same, or a little dry sodium chloride, and fused by raising the temperature gradually to a red heat.

A flux proposed by Plattner, consisting of 13 parts by weight of potassium carbonate, 10 parts by weight of dry sodium carbonate, 5 parts of fused borax, and 5 parts of dried starch effects the fusion readily, and yields a clean metallic button.

The same process is applicable to the analysis of white lead, minium, and litharge, of lead ores containing gold and silver, and by somewhat modifying the fluxes, also to the estimation of antimony, tin, and copper. Should the gold or silver ores be deficient in lead, a quantity of litharge or lead salt is added, sufficient to yield a proper regulus.

Separation of Lead from Zinc.—The separation of these metals in galena and blende may be effected by heating the finely powdered mineral with excess of iodine to 200° in a sealed tube for several hours, then breaking the tube, pulverising the contents, boiling the powder with distilled water till the excess of iodine has disappeared, then leaving it to cool and filtering. Zinc and iron are thereby dissolved as iodides,

while the lead remains on the filter as iodide together with sulphur and matrix. The lead iodide may be extracted from this mixture by hot water (Filhol a. Mellies, *Ann. Chim. Phys.* [4], xxii. 64).

Analysis of Soft Lead.—The following method is given by Fresenius (*Zeitschr. anal. Chem.* viii. 148; *Zeitschr. f. Chem.* 1870, 55; *Jahresb. f. Chem.* 1870, 906): 1. The lead having been scraped clean with a knife, two pieces weighing 200 grams each are treated with dilute nitric acid, which dissolves the lead completely, excepting when antimony is present, in which case the solution must be filtered and the undissolved oxide mixed with the subsequent antimony precipitations. The solution of one portion is diluted to 1500 c.c. and mixed with 1 c.c. of hydrochloric acid, sp. gr. 1.12, previously diluted with about 50 c.c. of water. This quantity is too small to produce a precipitate of lead chloride; silver, if present, is deposited as chloride after two or three days standing, and after the liquid has been siphoned off, may be collected on a filter, washed, and weighed. The solution of the second portion of lead is mixed in a 2-litre flask with about 115 grams of pure strong sulphuric acid, and diluted up to the mark with water. As soon as the liquid above the precipitate has become clear, 1750 c.c. are measured off and evaporated till fumes of sulphuric acid are abundantly given off; the residue after cooling is mixed with 60 c.c. water; and the solution is filtered from the separated lead sulphate. This precipitate is to be dissolved in hydrochloric acid, the solution precipitated with hydrogen sulphide, the precipitate digested with potassium sulphide, and the resulting solution tested for antimony by acidulation with hydrochloric acid. The sulphuric solution diluted and warmed is treated with hydrogen sulphide; the liquid, after standing for twelve hours, is filtered off at a gentle heat; the precipitated sulphides are digested with potassium sulphide; the resulting solution acidulated with hydrochloric acid; and the sulphides of antimony and arsenic thereby precipitated are added to those previously obtained.

The precipitate insoluble in potassium sulphide is treated with dilute sulphuric acid, and the solution is evaporated with addition of sulphuric acid, filtered from the separated lead sulphate, neutralised with potash, and mixed with sodium carbonate and a little potassium cyanide. On gently heating the liquid, bismuth oxide is precipitated, which, after washing, may be dissolved in acid, precipitated with ammonium carbonate, and weighed.

The solution containing the potassium cyanide is tested with a few drops of potassium sulphide for silver and cadmium. If a precipitate is formed, it must be dissolved in nitric acid, the silver precipitated by hydrochloric acid, and the cadmium, after concentration of the filtrate, with sodium carbonate. The solution freed from these two metals is to be acidulated and evaporated to expel hydrocyanic acid, and treated with hydrogen sulphide to precipitate copper; the precipitated sulphide is weighed; and the estimation (if the quantity is very small) checked by titration with potassium iodide, after solution in nitric acid and evaporation with sulphuric acid.

The precipitates of antimonious and arsenious sulphides are washed, dried and treated with carbon sulphide, then oxidised with fuming nitric acid, mixed with sodium carbonate and nitrate, dried and fused. The fused mass, after softening and trituration with water, is washed with a mixture of water and alcohol; the filtrate, after concentration, is heated with dilute sulphuric acid till all the nitric acid is expelled, and hydrogen sulphide is passed into it at 70°. The precipitate is exhausted with the smallest possible quantity of ammonium carbonate, the solution acidulated, a little sulphuretted hydrogen passed into it, and the resulting precipitate of arsenious sulphide dried at 100° and weighed. The result may be verified by Kessler's method of titration with chromic acid and ferrous sulphate (*Pogg. Ann.* xcv. 204). The precipitate is treated with a hydrochloric solution of mercuric chloride, whereby the arsenic is dissolved as arsenious acid: $2\text{As}^{\text{S}} + 9\text{HgCl}_2 + 6\text{H}^{\text{O}} = 2\text{As}^{\text{O}} + 3(2\text{HgS}.\text{HgCl}_2) + 12\text{HCl}$; the resulting solution is mixed with a titrated solution of potassium chromate till a permanent yellow-green is produced; a titrated solution of ferrous sulphate is then added till a drop taken out gives a blue precipitate with dilute potassium ferricyanide; and finally chromic acid solution is very gradually added till the blue precipitate has disappeared, the solutions being of course so dilute that the green colour of the chromic oxide shall not interfere with the distinctness of the blue precipitation. On deducting the quantity of chromic acid solution equivalent to the ferrous salt added, from the total quantity of chromic acid solution used, the difference gives the amount of chromic acid expended in oxidising the arsenious acid.

The sodium antimonate, together with the antimonious sulphide left undissolved by the ammonium carbonate, is to be dissolved in hydrochloric acid; the antimony reprecipitated by hydrogen sulphide; and the precipitate dried in a stream of carbon dioxide. The result may be checked in the same manner as in the case of the arsenic precipitate.

The filtrate from the copper sulphide, after concentration, is made just alkaline with ammonia, mixed with ammonium sulphide, and set aside in a closed vessel for 24 hours. To obtain the last traces of nickel, the filtered solution is evaporated, after addition of a little acetic acid. The precipitate formed by the ammonium sulphide is treated several times with a small quantity of a mixture of 6 pts. sulphuretted hydrogen water and 1 pt. hydrochloric acid of sp. gr. 1.12, to dissolve zinc and iron. The sulphides of nickel and cobalt are dissolved in nitromuriatic acid, after the filter has been incinerated; and the solution, after evaporation, is mixed with ammonia to slight alkaline reaction, and filtered after addition of a small quantity of ammonium carbonate. The filtrate is boiled in a platinum crucible with potash as long as ammonia continues to escape; and the separated nickel oxide, after being weighed, is examined with the blow-pipe for cobalt.

The solution of zinc and iron is oxidised by nitric acid, the iron precipitated by ammonia, redissolved, reprecipitated, and weighed. For verification, the ignited oxide may be fused with acid potassium sulphate, reduced with zinc, and titrated with permanganate solution. The zinc is precipitated with ammonium sulphide, separated by dilute acetic acid from any manganese that may be present, and weighed. The result may be checked by titration with potassium ferrieyanide and permanganate. From the acetic solution after evaporation, the manganese may be precipitated by caustic potash.

In calculating the results of the analysis, account must be taken of the space occupied in the measuring vessel by the sulphate of lead. By repeated experiments Fresenius has found that for 200 grams of lead this space is equal to that of 45 grams of water at 16°. The quantities of metal determined in 1750 c.c. of solution must therefore be referred to the quantity of solution corresponding with 200 grams of lead, that is to say, 1955 c.c., or, as may be assumed for simplification, to 179 grams of lead employed.

By test experiments, Fresenius has shown that, in the determination of quantities of metal amounting to only a few milligrams, good volumetric methods are affected with errors of only 0.00005 to 0.0002 gram, whereas gravimetric methods requiring ignition of precipitates involve errors of 0.0002 to 0.0003 gram, and those which require the collection of precipitates on dried and weighed filters are liable to errors of 0.0003 to 0.0007 gram.

The table on p. 731 exhibits the quantities of foreign metals contained in a number of soft leads of recent production. Analyses 15-21 are by Fresenius, made by the method above described; the rest are by Hampe (*Preuss. Zeitschrift für Berg-, Hütten-, und Salinenwesen*, xviii. 195; *Chem. Centr.* 1871, 281), made by a similar method.

Alloys of Lead (A. Baur, *Deut. Chem. Ges. Ber.* iii. 691; iv. 449). An alloy of lead and platinum, PtPb, is obtained by fusing 3 parts of lead and 1 part of platinum, and exposing the very brittle pulverised mass, under a bell-jar, to the action of carbonic acid, oxygen, and acetic acid vapours. After three weeks the white lead formed is dissolved in acetic acid, the residue left to form more white lead, then again treated with acetic acid, and so on till no further action takes place; the alloy is then separated from finely divided platinum by levigation. As thus prepared it forms a crystalline powder, having a shining surface and steel-grey colour, easily decomposed by boiling with mineral acids, but not acted upon by dilute acetic acid. When heated it fuses quickly to a crystalline, very brittle, reddish mass, resembling bismuth. It may be obtained at once in this state by fusing platinum with a slight excess of lead under a covering of borax-glass. Chemical combination takes place readily, and is accompanied by vivid flashes of light. The crucible should be allowed to cool slowly (by being placed in hot ashes). The alloy may be freed from excess of lead by treatment with acetic acid and exposure to air as above. Its density is 15.736, the calculated density being—supposing no contraction to take place—14.89. An alloy containing two atoms of lead to one of platinum, is obtained by employing excess of lead. The alloy PtPb₂ differs but little from PtPb in its outward appearance.

An alloy of lead and palladium is obtained by fusing granulated lead in a porcelain crucible, with somewhat more than one part by weight of palladium foil. Combination takes place readily and is marked by flashes of light. The product is a beautiful, crystalline, brittle, greyish-white mass, which is freed from excess of lead by acting upon it with acetic and carbonic acids. It is attacked freely, sugar of lead and white lead being formed; and on powdering it very finely and exposing it repeatedly to the action of these acids, it was found that palladium even dissolved in acetic acid, and that the remaining alloy was of constant composition. This alloy, which has the composition Pd²Pb, forms a steel-grey, crystalline powder, difficultly fusible, and having a specific gravity of 11.225, theory requiring 11.65. When it was used as a negative electrode in a battery of six Bunsen elements, no occlusion of hydrogen could be traced.

No alloys of lead and gold, or of lead and silver, could be obtained by fusing together the respective metals.

An *amalgam of lead* is obtained by melting 2 parts of lead in a crucible, and gradually adding 1 part of mercury. The resulting amalgam is then acted upon with acetic and carbonic acids whilst exposed to air, as long as any sugar of lead and white lead is formed. It contains 40.86 of lead and 59.12 of mercury, the formula Pb^2Hg^2 requiring 40.82 of Pb and 59.17 of Hg, and forms a compact, crystalline, granular white mass, of specific gravity 12.49 at 17°. The calculated density of an amalgam of Pb^2Hg^2 is 12.6085 (sp. gr. of Hg = 13.557). Hence it follows that no contraction has taken place. This is quite in harmony with the observations made by Crookewitt (*Ann. Ch. Pharm.* lxxiii. 290) on amalgams of equal atoms of lead and mercury, but runs counter to the observations made by Kupffer on lead amalgams.

Lead Chloride, PbCl^2 . The solubility of this compound in water and in aqueous hydrochloric acid was determined in 1868 by J. C. Bell (*1st Suppl.* 776; *Chem. Soc. J.* [2], xxi. 350), who found that pure water at 17.7° dissolves 0.046 part of it, or 1 part in 120; with the addition of 1 p.c. hydrochloric acid, only 0.347, while with 14 p.c. of the acid, only 0.000 is dissolved, which is the minimum quantity. After the liquid becomes more acidified, the solubility of the salt increases, so that at 72 p.c. of acid it is more soluble than in water, and in the pure acid (sp. gr. 1.162) as much as 2.900 is dissolved. The reaction is rather different when sodium chloride is used as a solvent. Field (*Chem. Soc. J.* [2], xi. 575), whose experiments also show that the solubility of lead chloride in pure water is 1 part in 120, finds that, on the addition of sodium chloride to the extent of 5 p.c., the solubility of the lead chloride decreases very considerably, and only 1 in 437 remains in solution. When, however, the lead salt is digested with a concentrated solution of sodium chloride, it is found to be rather less soluble than in water, viz., 1 in 129. This fact may be strikingly exemplified by the addition of solution of sodium chloride to an aqueous solution of lead chloride, when crystals of the latter are deposited, and *vice versa*, when water is added to a solution of lead chloride in concentrated sodium chloride.

It is well known that when lead sulphate is treated with hydrochloric acid, lead chloride is formed and free sulphuric acid remains in solution, and Field's experiments show that even a cold saturated solution of sodium chloride immediately decomposes lead sulphate. And it almost appears that at first there is not only an actual decomposition, but a solution, as 1 gram of lead sulphate dissolves perfectly in 100 grams of solution of sodium chloride, and after some hours deposits crystals of lead chloride. Sulphuric acid, or a soluble sulphate, gives no precipitate with lead chloride dissolved in sodium chloride.

The different forms of crystals of lead chloride observed by Mr. Bell, some being in fine needles and others in feathery plates, may be obtained in great beauty by the following method:—A solution of aniline hydrochloride forms lead chloride with difficulty; indeed, both solutions must be rather concentrated before any reaction is perceptible. On leaving the liquid to stand some time, fine needle-shaped crystals are deposited, and if to the mother-liquor a few drops of sodium chloride be added, a beautiful mass of iridescent scales is produced, differing entirely in physical structure from the former. When potassium iodide is added to a solution of lead chloride in sodium chloride, the precipitate formed is not amorphous, but has the brilliant spangly appearance which it presents when deposited from its solution in hot water.

When sodium chloride is added to either acetate or nitrate of lead, if the solutions be sufficiently concentrated, it is well known that a white precipitate is formed consisting of lead chloride. But if acetic acid be immediately added to the precipitate produced in the acetate solution, the whole is entirely dissolved for the moment, but crystals of lead chloride speedily begin to form; the precipitate in the lead nitrate solution remains unchanged on the addition of acetic acid. And further, if to the clear solution, after the precipitation of lead nitrate by sodium chloride, any acetate be added, even in the cold, a cloudiness is immediately formed which gradually becomes a precipitate. This is particularly the case with copper acetate, which, if agitated with the solution above referred to, yields in a few hours a copious deposit, perfectly soluble in acetic acid. The same reaction is produced by the formates (Field).

Lead Oxides. The monoxide, PbO , is completely reduced by carbon monoxide at the temperature of melting zinc (I. L. Bell, *Chem. News*, xliii. 258). It is not acted on by phosphorus trichloride at 160°, but when it is moistened with the trichloride and heated directly over a lamp-flame, a violent action takes place attended with flame and ignition, chloride and phosphite of lead being formed, and a large quantity of lead separated in the metallic state:

The dioxide acts on heated phosphorus trichloride with ignition, according to the equation:

(Michaelis, *J. pr. Chem.* [2], iv. 449).

Red Lead.—The usual process of manufacturing red lead by exposing massicot in trays in the same furnace that serves for the production of the massicot is tedious, and often gives an extremely small yield. G. Mercier (*Ann. Ch. Pharm.* clx. 252) observes that this inadequate result is due to the changes of temperature to which, in such a furnace, it is necessarily exposed. The principal point to be attended to, next to access of sufficient air, is constancy of the right temperature: for the temperature at which massicot takes up oxygen, and that at which red lead loses it, lie very near each other. The most favourable temperature for the formation of red lead approaches that of a dull red heat, without, however, reaching it.

The greatest beauty in the red lead corresponds with the greatest increase in weight in the massicot: this is about 2 p.c. But after the maximum weight is reached, the brilliancy of the red lead can still increase or diminish through a change in its molecular condition.

Mercier has constructed a furnace for use on the large scale, best adapted for the manufacture of red lead. It is essentially a large muffle, round which the fire plays in a great number of small channels. By means of easily worked dampers in certain of these channels, the heat can be regulated at pleasure in that part of the furnace. By this furnace in full action and continuously worked, about 4 tons of red lead may be produced in 24 hours.

LEADHILLITE. This sulphato-carbonate of lead, $\text{PbSO}_4 \cdot 3\text{PbCO}_3$, originally found at Lanark in Scotland, appears from the observations of E. Bertrand (*Bull. Soc. Chim.* [2], xix. 17) to occur also at Iglesias in Sardinia. Some fragments of a mineral from this locality exhibit in polarised light, coloured rings which show that the mineral belongs to the trimetric system; the optic axes are more divergent for the red than for the blue rays. The apparent inclination of the axes in air is about $20^\circ 30'$ for natural light. The crystals are negative, the acute bisectrix coinciding with the axis of greater elasticity. All the Sardinian specimens exhibit a twin-formation of about 120° , like those from Leadhills. The hardness of the Sardinian mineral is between 2 and 3, rather nearer to 3; that of the Scotch mineral is 2.5. The density of the Sardinian mineral is 6.60 at 14° , which is rather higher than that of the Scotch variety, viz. 6.3 to 6.5, the difference being apparently due to alteration in the former, inasmuch as some parts of the Sardinian crystals are more or less opaque, contain water, and decrepitate when heated, whereas the perfectly transparent portions—which were selected for analysis—contain no water and do not decrepitate.

Another sulphato-carbonate of lead from Iglesias, described by Laspeyres under the name of maxite, is regarded by Bertrand as identical with leadhillite; but, according to Laspeyres, the two species are distinct (see MAXITE).

LEGUMIN. See PROTEIDS.

LEMON-OIL. See OILS VOLATILE.

LEMON-TREE. Analyses of the fruit and leaves of the lemon grown in Sicily have been made by A. Cossa (*Gazzetta chimica italiana*, ii. 365). The results are given in the following table:

	Leaves	Rind	Parenchyma	Seeds	Juice
Potash	10.15	34.42	12.99	41.89	54.66
Soda	1.78	2.07	1.50	1.88	1.42
Lime	61.83	38.87	43.98	16.75	15.19
Magnesia	11.06	11.33	11.78	4.62	4.65
Sulphuric anhydride	4.85	3.44	3.60	3.39	4.94
Phosphoric anhydride	4.67	8.88	22.26	20.18	15.63
Silica	3.40	0.66	1.60	1.13	1.77
Undetermined matter and loss	2.17	0.83	2.20	1.26	1.64
	100	100	100	100	100
Ash in 100 parts of dry substance	12.86	6.982	2.130	2.821	

The leaves in the natural state contain 56·61 p.c. water, 38·08 organic, and 5·36 mineral substance; the juice contains 86·22 p.c. water, 12·32 organic, and 1·46 mineral substance. A lemon weighs on the average 75·3 grams, and contains in 100 parts, 15·66 rind, 4·51 parenchyma, 1·06 seeds, and 78·77 juice.

The amount of potash in the ashes of the rind, seeds, and juice of the fruit, is large, viz. 41·89 p.c.; as likewise is the percentage of phosphoric anhydride in the ashes of the parenchyma and seeds.

LEPIDENE, $C^{10}H^{16}O$ (see 1st Suppl. 780). *Orylepidene*, $C^{10}H^{16}O^2$, which is readily formed by treating a solution of lepidene in acetic acid with nitric acid or chromic acid, is easily further acted upon by chromic acid, *dioxylepidene*, $C^{10}H^{16}O^3$, being formed, which crystallises from alcohol in large rhombic, nearly quadratic plates. By the further action of chromic acid, dioxylepidene yields benzoic acid and benzil, but reducing agents do not act upon it. When treated with a weak alcoholic solution of potash, it yields benzoic acid and deoxybenzoin, from which it appears that its rational formula is $C^{11}H^{16}(C^7H^5O)^2O$ (Zinin, *Zeitschr. f. Chem.* vii. 483).

LERP-MANNA (Flückiger, *Arch. Pharm.* [2], cxlvi. 543). This substance occurs on the leaves of *Eucalyptus dumosa*, and consists of white threads clotted together by a syrup proceeding from the insect (*Psylla Eucalypti*) which spins those threads. It contains, in round numbers, of water 14 parts, threadlike portion 33 parts, sugar 53 parts. The threads possess many of the most characteristic properties of starch, from which, however, they are sharply distinguished by their form. When lerp is washed with water, the sugar dissolves and the threads swell but slightly, but dissolve to a slight extent, so that the solution is coloured blue by iodine. The threads freed from sugar by washing consist of a substance called *Lerp-amylum*.

Lerp-amylum is very slightly soluble in cold water, not perceptibly more so in water at 100°, but entirely soluble to a thin transparent liquid when heated to 135° in sealed tubes with 30 parts of water; this solution on cooling deposits the original substance in flocks, without forming a jelly at any time. The separation is almost complete.

If the material employed in this experiment were originally free from sugar, the liquid left after the separation of the flocks will also be free from sugar. The flocks deposited from solution are insoluble in boiling water; therefore lerp-amylum suffers no chemical change on being heated to 150° with water. Heated in the air-bath to 190° while dry, it turns brown, and is afterwards merely reddened by solutions of iodine; at the same time it becomes partly soluble in hot water: hence it appears that lerp-amylum undergoes a change similar to that which occurs when starch is converted into dextrin. By oxidation with nitric acid, it yields oxalic acid but no mucic acid; it is neutral to vegetable colours, and is not precipitated by lead acetate, and is therefore not to be confounded with the gums, &c.

It gave by analysis 43·7 and 43·07 carbon, 6·6 and 6·4 hydrogen, agreeing with the formula $C^{14}H^{10}O^8$ (44·4 C and 6·2 H). Like starch, lerp-amylum rotates the plane of polarisation to the right; and on digestion with dilute sulphuric acid, &c., forms a crystallisable carbo-hydrate which agrees in its properties with dextrin. It is insoluble in ammonia cuprate, and is homogeneous.

Though the behaviour of lerp-amylum to iodine and to water, and its insolubility in cuprammonia distinguish it from cellulose, it is to be borne in mind that there are forms or conditions of cellulose which are blued by iodine and dissolve in water.

LEUCANILINE, $C^{10}H^{11}N$. O. Follenius (*Monit. scient.* [3], i. 678) prepares this base by boiling a solution of rosaniline with zinc-powder till it is completely decolorised. The filtered solution, on cooling, deposits crystals of leucaniline, which may be purified by solution in alcohol, and precipitation with water. Colourless leucaniline, digested in acetic acid, immediately yields a red solution (? from formation of rosanilino), which, on evaporation, gives off acetic acid and leaves a brown mass, turning green when moistened with hydrochloric acid, and then dissolving in water with red colour.

Leucaniline oxalate is obtained on mixing the alcoholic solutions of aniline and oxalic acid, in the form of a precipitate which dissolves sparingly in cold, easily in warm water, but crystallises with difficulty and turns red after a while. By dry distillation it yields an oil which is soluble in water and has an odour recalling those of cressote and bitter-almond oil.

LEUCAURIN. See AURIN (p. 119).

LEUCINE, $C^6H^{11}NO^2$. *Amidocaproic Acid.*—G. Hüfner (*J. pr. Chem.* [2], i. 6) has compared natural leucine (prepared from horn-shavings by sulphuric acid, or from fibrin by pancreatic digestion) with leucine prepared by his own process from fermentation caproic acid (heating the bromocaproic acid obtained therefrom with aqueous ammonia, 1st *Suppl.* 782), and with that prepared from valeral-ammonia. The two former appeared, as regards their solubility in water (3.7 to 3.9 p.c. at 20°), and their subliming point (170°) perfectly identical, whereas the leucine obtained by the third process dissolved at 12° in 117.5 parts water (leucine from caproic acid under similar conditions required for solution only 48.8 parts). With regard, however, to their copper-compounds and their nitrates, and to their reaction with manganese peroxide and sulphuric acid, the three leucines were found to be perfectly similar. On the ground of these observations Hüfner regards their identity as established.

The preparation of leucine from valeral-ammonia by the action of hydrocyanic and hydrochloric acids is not easy. The valeral-ammonia must be quite pure and crystalline, and all excess of hydrocyanic acid must be avoided. Hüfner first prepares the compound $C^6H^{11}N^2.HCl$, obtained by Strecker and by Köllner (1st *Suppl.* 782) and decomposes it by boiling with hydrochloric acid. To prepare the hydrochloride just mentioned, it is sufficient to dissolve 2 parts of valeral-ammonia in 1 part of aqueous hydrocyanic acid, leave the solution for a night at the temperature of the room, and then mix it with excess of hydrochloric acid.

Leucine from Vegetable Proteids.—Ritthausen a. Kreuzler (*J. pr. Chem.* [2], iii. 307; *Chem. Soc. J.* [2], ix. 719), have examined the leucine obtained by boiling these proteids with dilute sulphuric acid, or as a by-product in the preparation of aspartic and glutamic acids. When separated from the other products of the reaction, it is always very impure. For purification it was exhausted with boiling spirit of sp. gr. 0.89 to 0.90, frequently recrystallised from that liquid, then dissolved in boiling water, with addition of as much barium carbonate as the liquid would take up, and recrystallised from water till the quantity of barium salts remaining in the liquid had become quite inappreciable. After decoloration by animal charcoal, it formed thin shining laminae. But even in this state, it still retained a little sulphur, which could be removed only by boiling with potash and lead oxide.

As all the vegetable proteids examined by Ritthausen a. Kreuzler yielded leucine, it may be assumed that all these bodies occurring in plants are capable of furnishing it. The quantity produced varies, however, according to the particular proteid employed, gluten-proteids and conglutin yielding considerably less than legumin. The quantity of purified leucine obtained varied from 4 to 12 p.c.

Leucine when heated with *soda-lime* does not give off all its nitrogen as ammonia, unless it has been previously mixed with sugar; the same was found to be the case with the copper-compound of leucine.

According to Gössmann and others, an aqueous solution of leucine is not precipitated by *mercurio nitrate*, whereas, according to R. Hoffmann, it gives a white flocculent precipitate (iii. 582). Ritthausen a. Kreuzler find that this precipitation occurs only with impure leucine still retaining aspartic or glutamic acid.

Copper-compounds.—Gössmann (*loc. cit.*) by evaporating the blue solution produced by boiling leucine with cupric oxide obtained the compound $2C^6H^{11}NO^2.CuO$ in crystalline grains. Ritthausen a. Kreuzler, by boiling a very dilute solution of leucine with cupric hydrate, obtained the compound $3C^6H^{11}NO^2.2CuO$ in light violet-brown scales, sparingly soluble in water. The light blue compound which Köhler obtained by boiling leucine with cupric acetate (1st *Suppl.* 782) has, according to Ritthausen a. Kreuzler, the composition $7C^6H^{11}NO^2.4CuO$.

LEUCINITRIL, $C^6H^{11}NO = C^6H^{12}O^3$ (leucic acid) + $NH^3 - 2H^2O$. This body, also called *leucimide*, is related to leucic acid in the same manner as acetonitril to acetic acid. It was first obtained by Köhler by dehydration of leucine (1st *Suppl.* 782), and has been more particularly examined by Thudichum (*Chem. Soc. J.* [2], vii. 409), who prepared it by Köhler's method; also from the decomposition-products obtained by the action of sulphuric acid on proteids. These products, after evaporation, were left for some time in contact with the air, and then treated for several weeks with ether or alcohol. These solutions, when left to evaporate, yielded the nitril, which was purified by crystallisation from hot alcohol, and decoloration with animal charcoal. The product thus obtained is, however, very small, and Thudichum, therefore, gives the preference to Köhler's method.

Leucinitril forms white, faintly lustrous, microscopic, rhombic needles which easily melt and sublime. It is insoluble in cold, slightly soluble in boiling water, soluble

also in alcohol, more easily in hot alcohol, less soluble in ether. Concentrated aqueous ammonia and potash have no action upon it, even at the boiling heat; hot hydrochloric acid dissolves a trace; it dissolves in strong acetic or nitric acid, and separates unaltered on addition of alkali or on evaporation. An alcoholic solution of leucinitril mixed with tincture of iodine gives off a small quantity of hydriodic acid, and on addition of potash and a large quantity of water, deposits white crystals.

In the preparation of leucinitril by Thudichum's method, there is often obtained, as secondary product, a substance rich in sulphur, which forms nacreous crystalline laminae more soluble in ether than leucinitril, and giving off hydrogen sulphide when boiled with a solution of lead oxide in potash. Thudichum names this substance *thioterin*. It is not formed when an ethereal or alcoholic solution of leucinitril is treated with hydrogen sulphide.

LEUCITE. Out-casts of Leucite from Vesuvius have been described by G. vom Rath (*Pogg. Ann.* cxlvii. 263). This mineral, the most important and characteristic of all those which occur on Vesuvius and in its lavas, occupies to a certain extent an exceptional place among minerals. It exhibits no varieties, and there are no species isomorphous with it. Of all rock-forming minerals it is the most limited in the mode of its occurrence. Felspar, which, in a chemical point of view, is most nearly allied to leucite, occurs in rocks of all ages, and in beds of every species, but leucite is never found in veins, very rarely in druses of lava or of ejected masses, never in pseudomorphs. Its occurrence in lava might perhaps seem to remove all doubt as to its mode of formation and its crystallisation from a fused mass. Nevertheless the various minerals which constitute lava cannot all have separated from the mass during solidification. It is possible, and even probable, that leucite may have crystallised from lava, but the crystallisation must have taken place, not during the flow of solidification of the lava on the surface, but in the unknown depths below. On Somma, leucite not only forms the lavas, but likewise appears in out-casts, sometimes in limestone blocks, sometimes in sanidine aggregates. The following are descriptions of some remarkable specimens of both these classes of leucitic out-casts.

(a.) A lump of limestone about 10 cm. thick, interspersed with grains of calcspar and very small octohedrons of spinelle and periclase, containing moreover numerous roundish cavities from 3 mm. to 3 cm. in diameter, in which occur rounded grains of leucite, some firmly fixed in the cavities, others loose, so that they rattle when the stone is shaken. The leucite in the interior of these grains has the ordinary constitution, and is intergrown with black augite; externally they are covered with a white very prickly crust, consisting of silky, fibrous prisms 1 mm. long, firmly attached to the grains and arranged in nearly parallel rows. This white mineral, when freed by acetic acid from calcium carbonate (amounting to 15–18 p.c. of the whole), gives by analysis 41.1 p.c. silica, 34.5 alumina, 5.6 lime, 0.7 magnesia, and 18.1 loss (alkalis), whence it appears to be *davyne*.

The calcareous matrix consists of 60.7 p.c. soluble and 39.3 insoluble in acetic acid. The soluble portion is a magnesian limestone containing 86.5 p.c. CaCO_3 and 13.5 MgCO_3 , therefore not a true dolomite. A similar composition was found by Marchand in a fine-grained block of limestone from the Fosso di Pollena.

The insoluble portion of the calcareous matrix appears under the microscope perfectly crystalline, and as a mixture of colourless grains, probably quartz-sand, greenish octohedrons of periclase, black octohedrons of ceilanite, and a very small quantity of magnetic iron ore. It gave by analysis 0.5 p.c. FeO^* , 38.6 SiO_2 , 10.7 Al_2O_3 , 43.1 MgO , 8.3 FeO (=101.2). The alumina may be regarded as combined with the magnesia and ferrous oxide, forming ceilanite; the excess of magnesia with the rest of the ferrous oxide forms periclase, while the silica is probably present in the free state. Not a trace of lime was found in the insoluble portion of the matrix.

(b.) A stone 12 centimeters thick, having the form of a segment, apparently about one-fourth of the original spheroidal block. It consists of a calcareous shell 3 to 4 cm. thick, surrounding a pear-shaped nucleus of leucite of granular structure and abundantly traversed by black augite. In the interior is a cavity lined with fine crystals of leucite and augite. At the boundary between the shell and the nucleus are numerous shining dodecahedrons of reddish-brown garnet, 1–1½ mm. in size, partly imbedded in the leucite mass, which separates easily and smoothly from the calcareous shell, partly resting on the inner side of the latter. The leucite nucleus is immediately surrounded by a radio-fibrous zone 1–1½ cm. broad, the fibres having a light greenish-grey colour. This fibrous mineral, freed by treatment with acetic acid from intermixed calcium carbonate, gave by analysis 38.6 p.c. SiO_2 , 18.4 Al_2O_3 , 4.2 FeO , 2.8 CaO , 24.7 MgO , and 11.3 loss (alkalis); showing that it consists of biotite or magnesia mica. This and the garnet have probably been formed from the leucite and the limestone where they

were in contact, under the influence of a very high temperature, the existence of which is shown by the marks of fusion at the boundary between the shell and the nucleus. To account for the occurrence of leucite in a shell of limestone is by no means easy, for the latter cannot be regarded as the true matrix of the leucite. The leucite nuclei of this and the preceding out-cast must rather be regarded as foreign enclosures in the limestone; but it is difficult to see how the limestone can have enclosed the leucites like a plastic mass.

(c.) A sanidine stone, containing very numerous crystals of leucite, 5 to 28 mm. in size. The matrix consists of a fine-grained mixture of predominant sanidine, black hornblende, brown garnet, and a small quantity of magnetic iron oxide, also separate tabular crystals of sanidine measuring 20 mm. The leucites are white, with conchoidal fracture, very fresh, some unusually pure, others showing admixtures of hornblende. They are not sharp-edged, but rather rounded, and are surrounded with a crust 1-1½ mm. thick of small, beautifully formed crystals of sanidine. These appearances might seem to indicate the commencement of a pseudomorphosis of sanidine after leucite, a change which Rammelsberg observed in its completeness in an out-cast very similar to the one under consideration. Closer observation shows, however, that this can hardly be the case. On breaking a leucite nodule from the stone, the sanidine envelope remains behind in the form of a druse lined with the most beautiful crystals of sanidine, firmly attached to the ground-mass, and consisting indeed of purer crystals growing out of it. The separated nodule of leucite is also covered with slender crystals of sanidine firmly implanted on it, and the surface of the leucite itself is developed into innumerable small but well-defined crystals, arranged in parallel rows. Now, when one mineral has been formed from another, or when the process of transformation is in progress, one of the minerals is sure to be found in parts presenting the appearance of the other, and intermediate stages of this transformation are likewise met with. In the present case, however, the closest examination with the microscope shows nothing of the kind. On the contrary, the surface of the leucite nodule is seen to be covered with crystals of leucite and sanidine placed side by side, and both in perfect freshness. Moreover, the stone is perfectly closed, no crack or channel being visible in which alteration of composition might be expected to occur.

For these reasons vom Rath thinks it more probable that when the large rounded crystals began to form, their chemical composition was somewhat different from the typical composition of leucite; perhaps the following: 55.96 p.c. SiO_2 , 23.0 Al_2O_3 , 21.04 K_2O , which is that of a mixture of $\frac{1}{3}$ sanidine and $\frac{2}{3}$ leucite, and that this mixture afterwards split up into the two minerals, which, indeed, occur on the leucite nodules in about this proportion. The leucite, so remarkably distinguished by its shell of sanidine, exhibits nearly the normal composition:

	SiO_2	Al_2O_3	CaO	K_2O	Na_2O
Analysis . . .	55.58	23.38	0.26	19.53	1.60 = 100.25
Calculation					
$\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$ }	55.0	23.5	—	21.6	— = 100

Leucite has been found in microscopic unaltered crystals in the tufas of the Schlossberg of Ackharrn in the Kaiserstuhl range (F. Sandberger, *Jahrbuch f. Mineralogie*, 1870, 207).

In leucite from Andernach, J. L. Smith (*Sill. Am. J.* [2], xlix. 335) found 54.75 p.c. SiO_2 , 23.03 Al_2O_3 , 1.55 Fe_2O_3 , and 20.06 alkali, reckoned as potash. The quantities of alkali in other leucites were found to be: from Vesuvius, 21.85; from Berghetta, 20.69; from Frascati, 20.38, exclusive of undetermined quantities (up to 0.9 p.c.) of rubidia and caesia.

Crystalline System of Leucite. This mineral has hitherto been regarded as belonging to the monometric system and having the form of the icosi-tetrahedron (ii.125); but G. vom Rath (*Jahrb. f. Mineralogie*, 1873, 113), from the examination of the leucite crystals implanted in the druses of the Vesuvian out-casts above described, has come to the conclusion that the mineral really belongs to the dimetric or quadratic system.

The faces of these implanted crystals are characterised by a peculiar striation, the lines running parallel either to the shorter (so-called hexahedral) edges, or to the symmetric diagonals of the trapezoidal faces. These lines often begin in the middle of a face and are not continued to an edge; but when one of them reaches an edge, it does not usually stop there, but is prolonged into the adjoining face; the line and its prolongation being situated in a plane, which, assuming the form of leucite to be the regular icositetrahedron, is parallel to the truncation-face of the symmetrical summit of

the crystal, or, in other words, to the face of a rhombic dodecahedron. Thus, for example, in the right upper octant (fig. 19) the principal striae lie in the dodecahedral face which truncates the left upper symmetric summit. The plane of the striae which run over i^2 in the diagonal direction, over o^2 and i^4 , parallel to the combination-edge of this latter face, corresponds with the truncation-face of the right upper symmetric summit. The two long striae which, running over the combination-edge $i^4 : i^2$, have a similar position on the two faces, viz. parallel to the edges $i^2 : o^2$ and $i^2 : o^4$, correspond with the dodecahedral face which truncates the front upper symmetric summit. The shorter groups of lines on i^2 and i^4 (parallel to the edges $o^1 : i^2$ and $o^2 : i^4$) are similarly situated with regard to the back upper summit. In like manner it is possible to determine the dodecahedral face in which every stria passing over an edge is situated.

On viewing the crystals by lamplight, it is easily seen that the striation is not merely superficial, but is due to interposed twin-lamellae. Sometimes indeed the striae have a very perceptible breadth, and their surface shines in a position different from that in which the general face of the crystal appears lustrous, the bands remaining dark while the general surface is bright, and *vice versa*. If, for example, the face o^1 be viewed in such a position that it shines, the striae are then dark; but on turning the crystal for about 5° round an axis parallel to these striae, i.e. to the edge $o^1 : i^1$, the twin-lamellae shine while the face itself becomes dark. In short, the striation of these implanted leucites exhibits the closest possible analogy to that of triclinic feldspar, which is known to arise from the interposition of twin-lamellae.

Fig. 19.

Fig. 20.

From the appearances above described, it may be inferred with certainty that these striated leucites do not belong to the regular or monometric system; for in that system a twin-formation parallel to a dodecahedral face cannot occur. If indeed an icositetrahedron be cut parallel to the face of the dodecahedron and turned round 180° , no projecting or re-entering angles will be formed, but the whole will return into its former position.

The conclusion thus deduced is confirmed by exact measurements of the angles of the leucite crystals, from which it appears that edges which ought to be identical if the crystals were monometric, really differ by about 4 degrees.

Leucite belongs in fact to the quadric or dimetric system, its form, hitherto regarded as a regular icositetrahedron, or leucitohedron, being a combination of a quadric octohedron with a di-octohedron (fig. 20).

Octohedron, $o = a, a, c$, or P

Di-octohedron, $i = \frac{1}{2}a, \frac{1}{2}a, c$, or $4P2$.

These faces exhibit a remarkable equality of development. The following also sometimes occur subordinate:

First acute octohedron, $u = \frac{1}{2}a, \infty a, c$, or $2P\infty$

First quadric prism, $m = a, a, \infty c$, or ∞P .

The ratio of the lateral axes to the vertical axis, deduced from the measurement of the lateral edge of the di-octohedron, is—

$$a : c = 1.8988 : 1 \text{ or } 1 : 0.05637.$$

The following are the principal angles:—

Terminal edge of the octohedron	= $130^{\circ} 3'$
Lateral edge of the octohedron	= $73^{\circ} 19' 40''$
Primary terminal edge of the di-octohedron (situated under the octohedral edge)	= $131^{\circ} 23'$
Secondary terminal edge (situated under the octohedral face)	= $148^{\circ} 9' 30''$
Basal angle of the di-octohedron (situated at the ends of the lateral axes)	= $126^{\circ} 52' 15''$
Basal angle of the di-octohedron (situated between the lateral axes)	= $143^{\circ} 7' 35''$

The plane angles of this base are the same as those of the three sections through the octohedral edges of the icositetrahedron 202.

The law of twin-formation of leucite is that 'The twin-plane is a face of the first acute octohedron;' and by this plane the crystals are united. The twin-plane is inclined to the vertical axes at an angle of $43^{\circ} 31'$; to one of the lateral axes at $46^{\circ} 28' 15''$. Leucite, hitherto supposed to be incapable of forming twins, is in reality very much inclined to twin-formation, exhibiting very regular combinations of two or more individual crystals, and also polysynthetic crystals in which, as above described, the principal crystal is intersected by laminae parallel to the faces of the first acute octohedron.

FIG. 21.

The simplest of these twin-formations is represented in fig. 21.

Imbedded leucites do not admit of exact angular measurement, but they frequently have obtuse projecting and re-entering angles, and exhibit the polysynthetic structure in a very high degree. There can, therefore, be little doubt that they are also quadratic, like the implanted crystals.

The chemical analysis of leucite crystals from the same druse as those whose angular measurement has been above given, exhibits the following composition—

SiO ^a	Al ^a O ^a	CuO	K ^a O	Na ^a O
55.21	23.70	0.43	10.83	1.21 = 100.38

agreeing almost exactly with the leucite formula, $K^aO \cdot Al^aO^a \cdot 4SiO^a$, which requires 54.92 SiO, 23.52 Al^aO^a, and 21.56 K^aO. The proportion of soda in these striated crystals is not greater than in crystals of leucite previously examined, and regarded as monometric (Rammelsberg found 6.43 p.c. Na^aO in a Vesuvian leucite): consequently the quadratic form cannot be regarded as a peculiarity of these crystals, due to the presence of soda.

The optical characters of leucite are more in accordance with the quadratic than with the hitherto assumed monometric form. Des Cloizeaux (*Nouvelles recherches sur les propriétés optiques des cristaux*, 1867, pp. 3-5) observes that leucite, when examined by polarised light, does not behave like a monometric crystal, the appearances varying according to the particular plate examined, and the direction in which it has been cut from the crystal. He also remarks that the striae seen in polarised light are parallel to the planes of a dodecahedron. These striae, due to interposed twin-lamellae, had been previously observed by Biot, who founded upon them his theory of lamellar polarisation.

Leucite may therefore take its place amongst the series of quadratic minerals which are so characteristic of Vesuvius, viz., zircon, humboldtilite, meyonite, mizoonite, sarcosolite and vesuvian, to the last of which it approximates very closely. The primary form of vesuvian has, according to v. Zepharovich, an angle of $129^{\circ} 20'$ in its lateral edge, and amongst its numerous combinations there occurs the di-octohedron 4P2, which is otherwise not frequently observed. If the primary form of vesuvian were associated with this di-octohedron, a form would be produced almost exactly like the regular icositetrahedron, as in the case of leucite (vom Rath).

LEUCOLINE. Ballo (*Dingt. polyt. J. cii. 377*) has obtained from crude naphthalene an oily liquid containing leucoline. A quantity of the crude naphthalene, which had never been treated with acids or alkalis, was boiled on the water-bath, and the brown solution obtained was precipitated with ammonia. A specimen precipitate was formed, which on drying at a higher temperature or in a vacuum over sulphuric acid, always fused to a dark thick fluid, possessing in an eminent degree the characteristic odour of impure naphthalene. Potassium bichromate produced a bulky precipi-

tates, which dried up to brown hard masses, but the precipitation was not complete. The oily liquid obtained as above was distilled, a light brownish-yellow coloured distillate coming over; it was then further purified by fractional distillation, the portion coming over at 240° being collected. The distillate was not fully soluble in hydrochloric acid. By shaking with dilute hydrochloric acid, pouring off from the indifferent oils, and then adding ammonia to the solution, the oily body was precipitated in a milky form, gradually collecting in drops at the bottom of the vessel. This oily layer was completely soluble in hydrochloric acid. Dried in a vacuum, it was quite clear, but became somewhat dark-coloured. To this body Ballo gives the name of *leucoline oil*. It appeared to be a mixture of several bases, but did not yield any precipitate of constant composition by fractional precipitation with ammonia; neither did it form any crystalline salts. The sulphate is precipitated from the ethereal solution of the oil, after addition of a few drops of dilute sulphuric acid, in the form of a yellowish-brown oil, and in the strongly acid aqueous solution of the sulphate, potassium bichromate produces a bulky yellow precipitate. Red litmus paper is not turned blue by the oil; it produces grease stains on blotting paper. These properties render it probable that the oil contains leucoline. Platinic chloride yields in a solution of leucoline oil in dilute hydrochloric acid a yellow precipitate; and in the filtrate, after standing some days, further portions crystallise out in long feathery groups of orange-yellow needles. These dried in a vacuum over sulphuric acid, and then at 100° , gave by analysis 28.03 p.c. platinum, agreeing nearly with the platinichloride of lepidine $2(C^{10}H^9N.HCl).PtCl^4$, which requires 28.3 p.c. platinum. The first formed precipitate was only partially soluble in alcohol; the undissolved portion contained 29.2 p.c. and the recrystallised portion 29.7 p.c. platinum. The formula of leucoline platinio-chloride, $2(C^{10}H^9N.HCl).PtCl^4$, requires 29.3 p.c. platinum.

Leucoline oil appears therefore to be a mixture of leucoline and lepidine. Treated with amyl iodide and potash-ley, it gives a violet colouring matter, apparently identical with that obtained from cinchonine-chinoline (i. 873; 1st Suppl. 431).

This last result appears to contradict the statement of C. Groville Williams that coal-tar leucoline gives no colour when treated with amyl iodide and potash. Williams, however (*Chem. Soc. J.* [2], x. 657), has repeated his former experiments with the same result as before, viz., that chinoline gives at once and without difficulty a brilliant and characteristic blue colour, whereas leucoline gives only a faint, dirty, purplish coloration, having no resemblance whatever to chinoline-blue. He therefore infers that coal-tar sometimes contains chinoline as well as leucoline, a conclusion which is strengthened by the fact that so-called leucoline from coal-tar has been found by Hofmann to give with chromic acid the yellow crystalline precipitate characteristic of chinoline, whereas Williams's experiments show that perfectly pure leucoline gives only a yellow oily precipitate.

LEUCOPHANE. This mineral (iii. 584) is trimetric, and according to v. Lang (*Jahrbuch für Mineralogie*, 1872, 426) has the axial ratio. $a : b : c = 0.9657 : 1 : 0.697$. The tabular crystal examined exhibited the faces OP , ∞P , $2P_{\infty}$, $\frac{1}{2}P_{\infty}$, P , $2P$, P_2 , P_2 . Cleavage parallel to OP .

LEUCOROSOLIC ACID. See ROSOLIC ACID.

LEVULOSE. See SUGARS.

LICHENS. According to W. Knop (*Chem. Centr.* 1872, 172), the ashes of lichens contain alumina. He considers this substance to be dissolved out of the dust which settles on the lichen and firmly adheres to its surface after wet weather, by the oxalic acid which is known to be a frequent constituent of lichens, this acid being one of the best solvents of alumina. He also thinks it probable that the oxalic acid in lichens is produced during the growth of the plant from what he names the 'lichen acids;' for treatment of these acids with caustic alkalis produces a carbonate or an oxalate.

Referring to the researches of Schwendener, from which lichens appear to be, not distinct plants, but combinations of fungi with algae, the gonidia of the lichen consisting of algae that have become enclosed in the hyphae (mycelium) of a fungus which then grows into the thallus of the lichen, Knop points out that the lichen-acids are found exclusively in the cortical layers of the lichen, that is, in the fungus, and not in the alga (gonidium).

Respecting the nutrition of the two elements of a lichen, he considers that, on the one hand, the alga (gonidium) which in many lichens is completely enclosed within the fungus, obtains its nutrient matters through the fungus, by which they are absorbed in damp weather from the barks of trees or the stones on which the lichen grows, and on the other, that the fungus, which cannot be converted into a lichen without the presence of an alga, and cannot of itself fix carbonic anhydride, has its food elaborated for it by the alga.

Lastly, he suggests that the detection of a particular lichen-acid in the *soridia* of lichens may aid in determining the lichen to which they belong.

LIGHT. Refraction and Dispersion.—Gladstone (*Chem. Soc. J.* [2], viii, 101, 147) has collected together the results published in his previous papers on the subject (see iii, 624-631, and 1st *Suppl.* 783-785), and shown, with respect to a large number of hydrocarbons, that the values of the refraction-equivalents calculated according to the method already described agree very closely with those determined by observation. Exceptions to this agreement are, however, exhibited by the hydrocarbons of the aromatic group, by two series of nitrogenised bases, viz., the pyridine and chinoline series, and by certain oxidised essential oils, whose observed refraction-equivalents are considerably higher than those calculated from the values of the elements (1st *Suppl.* 785). Gladstone is inclined to attribute this deviation to the circumstance that the phenylic nucleus C^6H^5 exerts as a whole upon the rays of light a predominating influence, which is not destroyed when the hydrogen in the nucleus is replaced by chlorine, nitric oxide, oxygen, and sulphur. The deviations from the normal refraction-equivalent exhibit a regularity depending on the composition, which for the typical hydrocarbons may be represented as follows:—

Hydrocarbons	Typical formula	Refraction-equivalent
Paraffins	C^nH^{2n+2}	Normal
Olefines	C^nH^{2n}	"
Terpenes	C^nH^{2n-4}	" + 3
Benzene and its homologues	C^nH^{2n-6}	" + 6
Naphthalene	C^nH^{2n-12}	" + 14
Anthracene	C^nH^{2n-18}	" + 17

Similar relations are exhibited by a series of oxidised compounds which differ from one another only in their amount of hydrogen:—

Substance	Formula	Refraction-equivalent
Peppermint Camphor	$C^{10}H^{20}O$	Normal
Dihydrate of Cajeput	$C^{14}H^{28}O$	"
Wormwood oil	$C^{14}H^{26}O$	" + 1
Carvol	$C^{14}H^{24}O$	" + 6
Anethol	$C^{14}H^{22}O$	" + 13

The first of the two following tables gives the refractive indices, for the lines A, D, H, of a number of compounds not previously examined, whose refraction-equivalents have the normal values. The second gives the refractive indices of several compounds whose observed refractive-equivalent is greater than that determined by calculation.

TABLE I.—Normal Refractive Indices.

Refraction and Dispersion of Selenium.—This substance exhibits very great refractive and dispersive power. The dispersive power of the rays A to C, that is to say, the magnitude $\frac{n_c - n_A}{n_A - 1}$ is $6\frac{1}{2}$ times, and $n_c - n_A$ $1\frac{1}{2}$ times as great as in carbon bisulphide. The refractive indices of the following Fraunhofer lines have been determined:

n	A	a	B	C	c	D
n	2.654	2.692	2.730	2.787	2.857	2.78.

The first four numbers are very exact (at least to 5 units of the third decimal place); the last two are less exact, inasmuch as beyond the line D, no more light passes through a film of selenium 0.003 mm. thick (J. L. Sirks, *Pogg. Ann.* cxliii. 429).

For Croulebois' measurements of the Refraction and Dispersion of Gases and Vapours, see *Compt. rend.* lxvii. 692; *Ann. Ch. Phys.* [4], xx. 136; *Jahresb. f. Chem.* 1868. 122; 1870, 170.

For the same physicist's determinations of the refractive power of Water, Methylie, Ethylic, and Amylic Alcohols, Ethylic Ether, Carbon Bisulphide, Turpentine-oil and Lemon-oil, see *Ann. Ch. Phys.* [4], xxii. 139; *Jahresb.* 1871, 153.

Refraction and Dispersion of Opaque Bodies.—A method of determining the refractive indices and dispersive powers of bodies which, like metallic oxides and chlorides, are opaque in the mass but transparent in very thin films, has been devised by W. Wernicke (*Pogg. Ann.* cxxxix. 132). Such films may be formed in great perfection on clean plates of the metal by electrolytic action, and their thickness determined by weighing. They exhibit the interference colours of thin plates, and on viewing them through a spectroscope, spectra are seen with well-defined alternate bright and dark bands, from the number and position of which the wave-lengths of the several Fraunhofer lines can be determined. By this method the following results have been obtained:—

Substance	Sp. gr.	Refractive Indices				
		B	C	D	E	F
Cuprous oxide, Cu ² O	5.975	2.534	2.558	2.705	2.816	2.963
Hydrate of Lead dioxide	6.169	1.802	2.010	2.229	—	—
Hydrate of Manganese dioxide	2.542	—	1.801	1.862	1.944	—

The refraction and dispersion of cuprous oxide are the greatest hitherto determined with certainty in any substance.

From a series of observations extending to numerous other bodies, Wernicke draws the following general conclusions:—In all bodies of great refractive and dispersive power the absorption increases as the wave-length diminishes, the increase being continuous from a particular part of the spectrum different for each body. In transmitted

light, therefore, these bodies, in layers of sufficient thickness, always appear yellowish-red or red.

The refraction and dispersion of silver chloride, bromide, and iodide have been determined by Wernicke (*Pogg. Ann.* cxliii. 560) in two ways:—

1. By the method above described. A film of metallic silver was deposited on a glass plate by means of ammoniacal solution of silver nitrate mixed with caustic soda and $\frac{1}{4}$ th of its volume of a reducing liquid prepared by mixing 60 grams of sulphuric acid, 40 alcohol, 35 water, and 50 manganese dioxide; distilling off about 50 c.c. into a vessel containing 60 grams of water; then adding 100 c.c. alcohol, and 10 grams of cane-sugar inverted with nitric acid; and diluting with water to 100 c.c. When the brilliant silver film thus obtained is exposed to iodine-vapour, or when pieces of iodine are laid upon it, the silver is immediately converted into iodide, which exhibits splendid interference colours. To convert the silver speculum into bromide or chloride, the chlorine or bromine-vapour, dry and free from air, must be made to act upon it as quickly as possible, as, if the action goes on long, the transparency of the films is impaired, probably in consequence of the formation of oxychloride or oxybromide.

2. The refraction and dispersion were determined by direct measurement by means of small prisms made by casting the fused salts between plates of parallel glass at the desired angle. Prisms of fused silver iodide exhibited, when cooled to 138° , a sudden alteration of colour and transparency, leading to the conclusion that, at high temperatures, part of the iodine is separated from its combination with the silver, and is absorbed by the remaining substance in the liquid state: for the spectrum, like that of solid and liquid iodine, contains no blue or violet light. In the normal state, below 138° , silver iodide gives a spectrum less bright but twice as long, and particularly developed in the blue-violet portion.

The following are the results of the observations:—

		Refractive Index for:				
		C	D	F	G	H γ
Silver chloride	1 method	—	2.071	2.101	2.135	—
	2	2.0462	2.0611	2.0958	—	2.1309
Silver iodide	1	—	2.202	2.267	2.409	—
	2	2.1531	2.1816	2.2787	2.405	—
Silver bromide	1	—	2.261	2.303	2.360	—
	2	2.2331	2.2533	2.3140	—	—

The results obtained by the second method are as exact as those of the first for the iodide of silver, less exact for the chloride and bromide. According to Des Cloizeaux (*Jahresh. f. Chem.* 1867, 44), the refractive index of yellow light for the ordinary ray in a hexagonal crystal of silver iodide = 2.23; in the amorphous iodide, according to Fizeaux (*Compt. rend.* lii. 274) it is 2.246. With regard to the absorption which, in the spectrum of bromide and iodide of silver, begins even between G and H γ , and in that of the chloride, behind H γ , the three salts follow the law above given. As the temperature rises the refraction of the three bodies diminishes.

Anomalous Dispersion.—Leroux showed, in 1862 (*Compt. rend.* lv. 126), that a hollow prism filled with iodine-vapour transmits only a group of red and a group of blue rays, and that the red rays are refracted more strongly than the blue, this effect being quite independent of the particular arrangements and apparatus used. The iodine-vapour likewise transmits the ultra-violet rays. Its dispersive power varies inversely with the temperature. To this previously isolated observation another was added by C. Christiansen (*Pogg. Ann.* cxli. 479), namely, that aniline-red or fuchsine in an alcoholic solution containing 18.8 p.c. of the colouring matter, exhibits very remarkable refraction-phenomena, the indices of refraction for the several Fraunhofer lines being:

B	C	D	F	G	H
1.450	1.502	1.561	1.512	1.285	1.312

increasing from B to a little beyond D, then decreasing rapidly to G, and from that point again increasing.

Christiansen (*Pogg. Ann.* cxliii. 250) further determined the differences between the refractive indices of five Fraunhofer lines and the line H, whose absolute refractive index was also directly measured. The latter measurements are much more uncertain than those of the differences, in which, nevertheless, the errors may amount to four units in the second place of figures. By observation in aqueous solutions of the refracting angles of 1° to 41° , the following values were obtained for the solutions containing 18.8, 17, 8, and 2.5 p.c. fuchsine in alcohol:—

Lines	18.8		17.		8		2.5	
	$n - n_H$	n	$n - n_H$	n	$n - n_H$	n	$n - n_H$	n
B.	0.138	1.450	0.118	1.426	—	—	0.011	1.354
C.	0.190	1.502	0.149	1.493	0.084	1.456	—	—
D.	0.240	1.561	0.204	1.548	0.130	1.502	0.046	1.419
E.	0.000	1.312	0.000	1.344	0.000	1.372	0.000	1.373
F.	—0.027	1.285	—0.022	1.322	—0.018	1.354	0.006	1.367
H.	—	1.312	—	1.344	—	1.372	—	1.373

The connection between anomalous dispersion and other optical properties of the bodies which exhibit it was first pointed out by A. Kundt (*Pogg. Ann.* cxlii. 163). According to Cauchy's theory of metallic reflection, based upon experiments by Jamin, the refractive index of metals varies with the angle of incidence, and in most metals the law of dispersion is the opposite of that which holds good for transparent bodies. To put this theoretical deduction to the test of experiment is extremely difficult, and in most cases impossible, on account of the opacity of metals. Kundt, therefore, directed his attention to media standing between metals and transparent bodies, namely the so-called *bodies with surface-colours*, which are transparent for certain rays, but behave to others more or less like metals, and reflect light with metallic lustre. The optical properties of these colouring matters, most of which are strongly tinted, may be summarised, as to all essential particulars, in the statement that the light reflected by them is complementary to that which they transmit, and that the reflected rays are elliptically polarised as in metallic reflection. Hence it appears probable that those bodies exhibit the most general case of dispersion; that is to say, that in them the index of refraction for the ordinary series of rays of the spectrum, diminishing by a wave-length from one end to the other, may increase and decrease in any manner whatever, and even become once or several times less than unity. Christjansson's investigation of fuchsine afforded the first verification of this supposition, which has now been shown by Kundt to hold good for numerous media.

The following bodies, which, in the solid state, have a distinct surface-colour, exhibit in concentrated solution an anomalous dispersion; that is to say, a spectrum in which the order of the colours does not agree with that in the diffraction-spectrum or in the dispersion-spectrum of ordinary bodies: all specimens of aniline-blue and aniline-violet, aniline-green (iodine-green or Hofmann's green), indigo (dissolved in fuming sulphuric acid), indigo-carmino, carthamin (doubtful), murexid (dissolved in potash), cyanine, potassium permanganate, carmine.

All these bodies refract red more strongly than blue light, and in those amongst them in which green is the predominant surface-colour and may still be distinctly recognised in the spectrum, this ray is the least refracted. The substance which exhibits the phenomenon with the greatest clearness is cyanine. Potassium permanganate and carmine exhibit it only when made into a paste by the introduction of solid matter. Kundt further remarks (*Pogg. Ann.* cxliii. 149) that probably all bodies which exhibit anomalous dispersion, and certainly fuchsine, aniline-blue, aniline-violet, aniline-green, murexid, cyanine, and potassium permanganate, are also, in the crystalline state, strongly dichroic; that is to say, a ray of white light entering a crystal of one of these media is resolved by refraction into two rays of different colours.

An objection to the theory above developed has been raised by V. von Lang (*Pogg. Ann.* cxliii. 269) on the ground that the observed appearances are produced in the imperfectly achromatised eye by refraction of the light through the edge of the very acute prisms used in the experiments. Kundt, however (*ibid.* 259), overrules this objection by the description of his method of observation with a telescope, which excludes the possibility of such an influence, and by observations on rays which had passed through the prism at a considerable distance from the edge. Further experiments established the existence of anomalous dispersion in all the substances above mentioned, even in clear solutions of those which had previously been examined only in the pasty condition. The anomaly increases with the concentration. In very concentrated solutions the anomalous spectrum is often very long. The Fraunhofer lines in this spectrum are, for the most part, obliterated by the overlapping of the colours; but they soon appear when one of the colours is intercepted by viewing the spectrum through an absorbent medium. In this way it is seen that individual colours are often extraordinarily elongated, as red in fuchsine and cyanine, green in the latter substance, &c.

Bodies have, for the rays which are strongly reflected by them, and therefore enter into them with comparatively little intensity, and, indeed, for these rays alone, a somewhat considerable coefficient of absorption. In a series of bodies which strongly reflect the middle rays of the spectrum and, at the same time, exert a strong absorp-

tive power on these rays, the refraction increases with extraordinary rapidity in passing from the side of the greater wave-lengths (in air) towards the absorption-band; and in passing from the side of the shorter wave-lengths (in air) to the absorption-band it diminishes with extraordinary rapidity.

In media which exhibit several sharply defined and dark absorption-bands, a refraction anomaly is observed at the edges of each of these bands. Proceeding from the red end of the spectrum, the index of refraction increases strongly on approaching an absorption-band, and diminishes perceptibly behind it. A number of bodies which absorb the spectrum from the blue end onwards exhibit a remarkable increase in the refractive index from the red to the yellow.

Anomalous dispersion has further been shown to exist in solutions of Magdala-red, corallin, alizarin dissolved in potash, orsellin, litmus, iodine in a mixture of chlorine-form and carbon sulphide, logwood (in aqueous or ammoniacal extract), Brazil-wood (ammoniacal extract), blood (red aqueous extract), hæmatin, chlorophyll. Among solid bodies, ammonio-chromic oxalate showed a slight indication of anomaly, and in magnesium platinocyanide, which is doubly refractive, one of the rays exhibited a dark absorption-band in the middle of the spectrum, and indications of anomalous refraction; while, in the other, the absorption affected the whole of the blue and green and extended even into the yellow; this ray accordingly exhibited a great increase of refraction from the red to the yellow.

Anomalous dispersion is likewise exhibited by some bodies which have but a faint surface-colour, such as borax-glass coloured deep blue by cobalt, also potassio-cobaltic and ammonio-cobaltic oxalate (Kundt).

J. L. Soret (*Pogg. Ann.* cxliii. 325) has also made experiments on anomalous dispersion, in which the influence of the solvent was eliminated by immersing the filled hollow prism in a trough with parallel glass sides containing the same solvent. Operating in this manner it is no longer necessary to use light of so great intensity, or to make the light traverse the prism close to the edge. With a moderately strong solution of fuchsin in a prism having a refracting angle of 30° , the violet was scarcely deflected, the red $15'$, the orange $23'$; in a much weaker solution the violet was likewise not perceptibly deflected, the red $6'$, the orange $16'$. Aniline-violet showed only a blue and a carmine-red band, which overlapped each other unless the slit of the spectroscope was very narrow. In sunlight a trace of green was also visible towards the end of the spectrum, on the side of the blue band. The deflection of the blue was $1'$, of the red $4'$. Potassium permanganate showed a deflection of $6'$ for violet, $9'$ for red, and $12'$ for yellow light. These numbers show to what extent the addition of anomalously dispersive substances diminishes the dispersive power of the solvent without producing much alteration in the mean index of refraction. By successive increase of concentration the dispersive power is first reduced to nothing and then becomes negative.

A theory of dispersion and its anomalies, and their connection with absorption, founded on the consideration of the vibrations produced in the particles of bodies by the vibrations of the ether and their reaction on the latter, has been given by W. Sellmeier (*Pogg. Ann.* cxliii. 272; cxlv. 309, 520; cxlvii. 386, 525).

Fluorescence.—1. *Fluorescence of Rarefied Gases after the passage of the Electric Spark.*—According to E. Sarasin (*Ann. Chem. Phys.* [4], xix. 180), oxygen is the only elementary gas which exhibits fluorescence after electric sparks have been passed through it, and among compound gases the only ones which exhibit the phenomenon are those which contain oxygen. Morren, on the other hand (*Compt. rend.* lxxiii. 1033, 1260), maintains that the production of fluorescence requires the simultaneous presence of oxygen and nitrogen either free or combined, and moreover that of an acid. De la Rive (*ibid.* 1237) considers that it still remains a question whether pure oxygen fluoresces well, or whether the admixture of a small quantity of nitrogen is necessary to the production of the phenomenon.

Alvergniat (*Chem. News*, xix. 126) observes that Geissler's tubes become luminous when simply rubbed with the dry hand on a piece of silk. The fluorescence, however, is faint, but increases if the tube contains substances which become fluorescent under electric influence.

F. P. Le Roux (*Compt. rend.* lxxiii. 1104) infers from numerous experiments that the luminosity thus produced is due to electrostatic induction within the rarefied gas. A Geissler's tube becomes luminous in the neighbourhood of a thin plate of ebonite, which is rubbed on the side opposite to the tube. On approaching an electrified body somewhat quickly to a dry glass vessel containing a gas sufficiently rarefied to make it conduct (hydrogen, nitrogen, monoxide, &c.), a very brilliant luminosity is frequently developed; the same effect is produced on removing the electrified body.

regards the mode of action exhibited in these experiments as capable of affording an explanation of certain meteorological phenomena such as the aurora borealis, and 'heat-lightning.'

2. *Fluorescence of Mixtures of Alcohols and Sulphuric Acid.*—A mixture of strong sulphuric acid and absolute ethyl alcohol in equal volumes exhibits, when warmed for ten minutes, a strong greenish-yellow fluorescence, which becomes somewhat stronger on further heating. If the liquid be heated till a large quantity of sulphurous oxide is evolved, and the black pasty mass be then treated with alcohol, the extract still exhibits the same greenish-yellow fluorescence in a lower degree. A mixture of methyl alcohol with strong sulphuric acid becomes yellow-brown when heated and exhibits a strong fluorescence, even if greatly diluted with common alcohol; the upper layer consisting of methyl alcohol remains colourless. Sulphuric acid similarly treated with amyl alcohol becomes first yellow, then orange, and finally crimson with greenish-yellow fluorescence, which becomes more distinct after dilution with common alcohol (F. Goppelsröder, *Zeitschr. anal. Chem.* 1870, 178).

3. *Illumination of Transparent Bodies.*—A. Lallemand (*Ann. Chim. Phys.* [4], xxii. 200) has made observations on the illumination of transparent bodies, observed in directions at right angles to the illuminating ray. The intensity and colour of this illumination differ greatly in different bodies, and if the incident light is polarised, the intensity in each body attains a maximum in the plane of polarisation, and a minimum at right angles to it. Collodion is one of the bodies most capable of illumination quartz (rock-crystal), rock-salt and calc spar are among the least capable. The coefficient of illumination depends upon the chemical nature, molecular constitution, and refracting power of the body. The petroleum hydrocarbons become illuminated the more strongly as their density and index of refraction are greater. In non-fluorescent bodies the lateral light is always completely polarised, and in the direction perpendicular to the plane of polarisation its intensity = 0. Only a very few bodies, however, are found to be quite free from fluorescence, most bodies, even crown and flint glass, exhibiting a coloured fluorescence. This fluorescence is either *isochromatic*, that is, of the same colour as the exciting ray, and in this case may be produced by the corresponding homogeneous ray separated from the spectrum in the ordinary way; or it is *hypochromatic*, and is attended with diminution of the refrangibility; this kind of fluorescence, however, is produced only by the ultraviolet rays. In the case of chlorophyll, the general fact that the loss by absorption of the light which passes through a body arises directly from the number of rays expended in the production of the lateral illumination and the fluorescence, is particularly evident for the red rays of the chlorophyll spectrum absorbed between B and C, which predominate in its fluorescence spectrum. Quinine sulphate, uranium glass, and potassium chromate, and solution of sulphur in carbon sulphide do not extinguish the fluorescent light of chlorophyll; but chlorophyll, on the other hand, completely extinguishes the fluorescence of quinine, and for the most part that of uranium glass, and prevents the conversion of soluble sulphur into insoluble, which is produced in that solution by the more refrangible half of the spectrum (from F onwards).

'At right angles to the plane of polarisation, nearly all isochromatically fluorescent bodies exhibit a light not perceptibly different from white light. The ratio of its intensity to the maximum intensity of the lateral light (parallel to the plane of polarisation) was found to be: in collodion = 0.07, ethyl alcohol = 0.16, amyl alcohol = 0.34, carbon sulphide = 0.60. These ratios are greatly altered by the slightest impurity in the substance, and might serve—as Lallemand's apparatus is very simple—as indications of the purity of the several substances.

On Fluorescence in general, see Hagenbach (*Pogg. Ann.* cxlvi. 65–89, 232–256; 375–406; 508–536; *abstr. Chem. Soc. J.* [2] x. 1058).

On the Fluorescence of Solutions, see H. Morton (*Sill. Am. J.* [3], ii. 198, 355; *Chem. Soc. J.* [2], ix. 392; x. 27).

On the action of Rays of different Refrangibility on Phosphorescent (Fluorescent) Bodies, see E. Becquerel (*Compt. rend.* lxi. 994; *Jahresb. f. Chem.* 1864, 167).

Absorption.

1. *Absorption of Light by Iodine.*—Iodine vapour, which transmits the blue and red rays of the spectrum, to which property it owes its fine violet colour, absorbs the whole of the red rays as its thickness increases, transmitting only the blue. A solution of iodine in carbon sulphide exhibits the same dichroism when the quantity dissolved is increased; the alcoholic solution, on the contrary, is always red (Andrews, *Chem. News*, xiv. 75).

2. *Absorption of Light by Chlorophyll.*—According to L. Schönn (*Zeitschr. anal. Chem.* 1871, 327) the spectrum of the alcoholic extract of green leaves exhibits only

three absorption-bands, whereas Hagenbach (*Pogg. Ann.* cxli. 245; *Jahresb.* 1871, 171) observed six. Schönn, however, remarks that the absorption-band in the red transmits a little light in the middle, that is to say, it really consists of two bands. In the passage of light through fresh leaves, only the red band was seen at first, but as the leaves dried and faded, the entire spectrum of the alcoholic solution became visible, whence it appears that the solvent does not alter the optical properties of the chlorophyll.

The gold-yellow filtrate of the alcoholic extract treated with soda-ley shows two absorption-bands, one coinciding with the middle of the band in the red, one with the middle of the space between the bands of the orange and red in the unaltered chlorophyll solution.

The blue colouring-matter extracted by alcohol from hyacinths and violets exhibits three absorption-bands all situated a little to the right of those of leaf-green. The solution coloured by acids transmits only red light in a rather thick layer, but in a thinner layer the spectrum brightens from the violet end onwards, and there remains, to the right of the sodium lines, a broad absorption-band which gradually becomes lighter as the solution is more diluted.

The lower side of most green leaves exhibits, when viewed through a hand-spectroscope, a continuous spectrum from B to F, without the absorption-bands peculiar to chlorophyll. The brightness is somewhat less than that of the corresponding part of a spectrum of white paper, but the colours are distributed in nearly the same proportion (J. J. Müller, *Pogg. Ann.* cxlii. 615).

On the Absorption-spectrum of Chlorophyll and its Modifications, see further, pp. 325-330.

Colours of Bodies. 1. *Colours of Metals.*—The rays of light reflected from a coloured body are always more or less diluted with white light, because the light which illuminates the surface of the object is never completely decomposed, a portion of it being always directly reflected. The colour of a polished metallic surface is ordinarily invisible, because the tint due to the feeble decomposition of the light is overpowered by the more powerful reflected ray.

The method heretofore adopted for rendering the colour of metals visible, consists in repeatedly reflecting a beam of white light from the metallic surface under examination. At each incidence the white light is partially decomposed, and if the number of incidences be sufficiently multiplied, the whole of the white light will disappear, and only the pure coloured rays be visible. The actual experiment, however, is not very successful, inasmuch as a large portion of the coloured rays is lost by gradual dispersion. A better method consists in bringing into operation the well-known law that when white light is decomposed, the reflected coloured ray is complementary to the transmitted or absorbed ray.

For this purpose a transparent solvent of the metals is required which shall have no chemical action upon them. In the case of the alkali-metals, anhydrous liquid ammonia is found to answer successfully. When placed in this menstruum, these metals gradually dissolve, producing a solution which appears blue by transmitted light. From this circumstance it would appear that the natural colour of the alkali-metals by reflected light is copper-red; and, in fact, on gradually adding the solvent to the metal, the silver-white colour first gives place to copper-red, and then, as the solution becomes more dilute, to the blue colour of the transmitted light. A similar change of colour is exhibited by aniline-blue when treated with alcohol (C. A. Seeley, *Chem. News*, xxiv. 223).

2. *Change of Colour produced by Heat.*—Observations by E. J. Houston (*ibid.* 177, 188) have led to the following general rule: When the natural colour of a body heated in the pulverulent state, without the occurrence of any chemical change (loss of hygroscopic or crystallisation-water included), alters with rise of temperature, and goes through the same changes in the reverse order on cooling, till the original colour is restored, the addition of heat invariably alters the colour towards the red, and the abstraction of heat alters it towards the more refrangible end of the spectrum. Especially sensitive are the following substances, arranged according to the position of their colours in the spectrum:—

Red: *Cuprio Ferrocyanide*: colour, mahogany-brown, changed to blackish-brown by heat, the original colour returning slowly on cooling. *Antimonious sulphide* (kermes): brownish-red, becoming darker red-brown. *Anhydrous ferrous ferric oxide*: brownish-red, becoming dark red, brown, black-brown, and finally black at a temperature not much below redness. *Cuprous iodide*: dark red, becoming black at a very moderate heat, afterwards brownish-red, brown, black-brown, and finally almost black, the original colour returning very quickly on cooling. *Mercurous chloride* (cinabar): vermilion-red, becoming brownish-red on heating. *Minium*: red, becoming

coming dark red. *Acid potassium chromate*; red, becoming dark red; best observed on heating a small crystal.

Orange: *Arsenic Bisulphide* (realgar); orange-red in the pulverulent state, becoming red, dark red, and brown; the original colour returns quickly. *Mercuric oxide*: orange-yellow powder, becoming red, dark red, and brownish-red. *Lead iodide*: orange, becoming darker orange, orange-red, and red. *Ferric oxalate*; light orange, becoming darker (in this case only a moderate heat can be applied, as decomposition takes place at higher temperatures).

Yellow: *Neutral Lead Chromate*; yellow-orange, becoming orange-yellow, orange and orange-red. *Stannic sulphide* (mosaic gold); brownish orange-yellow, becoming dark red, nearly black; very sensitive. *Arsenious sulphide* (orpiment); orange-yellow, becoming deeper orange-yellow, yellow [? orange], orange-red, red.

Green: *Argentous iodide*; greenish-yellow, very sensitive; becoming first orange-yellow, then deep orange. *Mercurous iodide*; yellowish-green, still more sensitive than the last; becomes orange-green, reddish-orange, red, and brownish-red in very quick succession.

Many other bodies exhibit similar changes, although less distinctly. No blue, indigo, or violet bodies, have yet been found which, in the solid state, exhibit change of colour before decomposition. Such an alteration has, however, been observed in two white bodies. *Zinc oxide* assumes, when heated, first a scarcely perceptible bluish-white tint, then becomes green and yellowish-green, and does not quite regain its original whiteness on cooling. *Stannic oxide*, when heated, first becomes pale green, then decidedly yellowish-green, and goes through the entire scale of colours to orange and reddish-orange, but returns, on cooling, only to greenish-white.

In solution, bodies are more sensitive to heat than in the solid state. The following have been examined in aqueous solution:—

Red: *Rosaniline*; decidedly red, becomes distinctly darker at the boiling-heat. *Decoction of logwood*; deep red, becoming darker. *Cobaltous chloride*; pale red, becoming darker flesh-red. *Ferric sulphate*; light red, becoming red-brown.

Orange: *Chromic acid*; reddish-orange, becoming redder. *Acid ammonium chromate*; orange-red, becoming pure red. *Ferroso-ferric oxide*; in weak solution orange-red, very sensitive; becomes red and red-brown. *Acid potassium chromate*; orange-red, becoming red.

Yellow: *Ferric nitrate*; brown-yellow, becoming red-brown.

Green: *Potassium ferrocyanide*; yellowish-green, becoming yellow. *Neutral potassium chromate*; yellowish-green, becoming yellow. *Nickel nitrate*; pale green, becoming greenish-yellow. *Nickel sulphate*; green, becoming yellow-green.

Blue: *Cupric chloride*; blue-green, in weak solution becomes decidedly greenish-yellow; very sensitive, the colour returning quickly on cooling. *Cupric sulphate*; decidedly blue, becomes distinctly green at the boiling heat, and quickly recovers its original colour when the source of heat is removed.

Violet: *Ammoniacal Nickel oxide*; violet-blue, becoming light blue. *Litmus solution*; violet, becoming indigo-blue.

The changes of colour produced by fall of temperature were found to be, without exception, directed towards the violet end of the spectrum. *Cinnabar* acquires a bright red colour; *stannic sulphide* changes from brownish orange-yellow to lighter brown-yellow; *mercuric trisulphate* from yellow to greenish-yellow; *lead iodide* from orange to light orange; *lead chromate* from yellow-orange to greenish-yellow. Other bodies exhibited no change of colour, the means adopted for lowering their temperature being, in fact, manifestly inefficient. Aqueous solutions could not, for obvious reasons, be observed at very low temperatures. Distinct results were exhibited only by solutions of—*Cupric sulphate*, pure blue, becoming darker blue on cooling; *potassium ferrocyanide*, nearly pure yellow in saturated solution, becoming slightly greenish; *cupric chloride* changes from bluish-green to blue-green; *ferric chloride*, orange-yellow, becomes yellower; *ferric nitrate*, orange-yellow, behaves like the preceding; *Cupric chloride*, in ethereal solution, cooled by evaporation of carbon sulphide, changed its colour from yellowish-green to pure green.

3. *Complementary Colours*.—A. W. Hofmann (*Dest. Chem. Ges. Ber.* iv. 660) has made observations on the complementary colours exhibited by various aniline dyes in transmitted and reflected light. *Rosaniline* salts in solution exhibit, by transmitted light, a deep purple-red colour; their larger crystals reflect a splendid cantharides green. According to experiments by Dove, these two colours are identical with the complementary colours of a lamina of gypsum, which exhibits, in polarised light, a

difference of path equal to $\frac{1}{4}$ of a wave-length. A concentrated alcoholic solution of *iodine-green*, evaporated in a glass basin, leaves a homogeneous transparent varnish which transmits a splendid green light, but exhibits by reflected light a highly characteristic rod coppery lustre which comes out very distinctly on friction; these, according to Dove, are the two colours of a gypsum lamina having a difference of path equal to $\frac{1}{2}$ of a wave-length. On warming the glass dish, the green changes to violet, and the reflected light becomes brass-yellow, corresponding, according to Dove, with a gypsum lamina, having a difference of path equal to $\frac{1}{2}$ or $\frac{3}{4}$ of a wave-length.

Circular Polarisation.—1. *Relations between Circular Polarisation, Crystalline Form and Molecular Structure.*—Rammelsberg (*Deut. Chem. Ges. Ber.* ii. 31) observes that bodies which exhibit circular polarisation may be divided into three classes: (1) Those which are optically active only in the crystalline, not in the amorphous or the fused state: quartz, sodium chlorate, and sodium bromate, Schlippe's salt. (2) Those which are active only in the amorphous or liquid form, not when crystallised: the two tartaric acids and their salts, the malates, asparagin, various sugars, camphor. (3) Bodies which are active in both states: the only body of this class at present known is strychnine sulphate.

The crystals of circularly polarising bodies are in all cases enantiomorphous, i.e. they exhibit right and left non-superposable forms, resulting from hemihedry. Hence it may be inferred that crystal-molecules are not identical with the individual molecules of bodies themselves, but that a crystal-molecule is a group of individual molecules. In bodies which, in the crystallised form, exhibit the opposition of right and left, the crystal-molecules are linked together in opposite directions (like a right and left handed spiral, screw, winding staircase, snail-shell, or leaf-arrangement). In bodies of the first kind, the individual molecules do not exhibit this opposition of arrangement. In bodies of the third class, on the contrary, this opposition affects the individual molecules themselves, which are arranged in one direction or the other. In bodies of the second class, the molecules constituting a crystal-molecule are arranged in a direction opposite to that of the crystal-molecules, so that in the crystal, the effects of the oppositely arranged individual molecules and crystal-molecules neutralise one another; but when the arrangement of these latter is destroyed by liquefaction or solution, the action of the individual molecules becomes apparent.

On the relation between Circular Polarisation and Crystalline Form, see also P. Groth (*Pogg. Ann.* cxxxvii. 433); V. v. Lang (*ibid.* 447).

2. *Circular Polarisation in Dithionates or Hyposulphates.*—(C. Pope, *Pogg. Ann.* cxxxix. 224). Among the dithionates which crystallise in the hexagonal system, the greatest rotatory power is exhibited by the optically positive crystals of the lead salt with 4 mol. water, and the anhydrous potassium salt, both of which may be obtained in crystals sufficiently large and transparent to admit of the determination of the angle of rotation for the Fraunhofer lines C, D, E, F. The rotation of the plane of polarisation for rays which have traversed the crystal parallel to the principal axis is directed to the right as often as to the left, and is of the same magnitude in both cases. For plates of 1 mm. in thickness the following values were obtained:

	C	Angle of rotation for the line:			
		D	E	F	
Lead Dithionate	4.003°	5.531°	7.252°	8.881°	
Potassium Dithionate	6.182	8.835	10.51	12.33	

The observations on the optically negative dithionates of calcium and strontium presented greater difficulty. The calcium salt with 4 mol. water gave a mean rotation of 2.091; the strontium salt with 4 mol. water gave 1.642. In the double dithionates of lead and strontium, which also crystallise with 4 mol. water, no rotation could be detected; but this negative result was perhaps due to the smallness of the crystals examined. Neither of the four salts above-mentioned exhibited any hemihedral faces which might have afforded indications of the direction of the rotation in the crystal. On the lead salt, however, such faces could be artificially produced by cutting off the proper summits, and leaving the salt to crystallise further. Neither of the salts exhibited circular polarisation when dissolved; neither did the double salt formed of 2 mol. potassium dithionate and 1 mol. sodium chloride, which crystallises in dimetric forms approaching very nearly to the monometric ($\alpha : c = 0.9356$), exhibit the least sign of circular polarisation, even in the thickest crystals.

3. *Circular Polarisation in Benzole and in Camphore.*—Desolaisaux found (*Compt. rend.* lxxiii. 308) that the crystals of benzole, besides their strong double refraction, possess the power of circular polarisation in the direction of their crystallographic axis, and that a plate of this substance 1.15 mm. thick is equal in rotatory power to a quartz plate of 1 mm.; and he has further observed (*ibid.* lxx. 1200) that no such

hedral faces can be detected even on crystals of benzile prepared in the most various ways, and that among the crystals which separate from the solutions, some turn the plane of polarisation to the right, others to the left. When a new solution was formed of dextrogyrate crystals, the first crystals which separated from it were for the most part also dextrogyrate, but those which separated at a later stage were again a mixture of the two kinds. The solution was optically indifferent.

Several kinds of camphor, on the other hand, exhibit circular polarisation in the state of solution, but not when crystallised. Besides common camphor, Descloizeaux has found five other species which possess this property. The following table exhibits the angles of rotation, α , of these several camphors in alcoholic solution [$\frac{1}{2}$ saturated], at 17° C. in a column 20 centimeters long:

Patschouli camphor, $C^{15}H^{28}O$, hexagonal, and exerting negative uniaxial double refraction .	$\alpha = - 237^{\circ}$ at 17°
Mint-camphor or Menthol, $C^{10}H^{20}O$, hexagonal, negative	$\alpha = - 200^{\circ}$ at 15°
Borneo Camphor, $C^{10}H^{16}O$, monometric . . .	$\alpha = + 33^{\circ} 4'$
Tercecamphene, $C^{10}H^{16}$, monometric . . .	$\alpha = - 63^{\circ}$
Monohydrochloride of Turpentine-oil, $C^{10}H^{16}.HCl$, monometric . . .	$\alpha = - 31^{\circ}$

4. *Circular Polarisation induced by Magnetic Action.*—The rotatory power acquired by a considerable number of liquids under the influence of an electro-magnet has been determined by A. de la Rive (*Phil. Mag.* [4], xl. 393), with the following results:—

1. The specific magnetic rotatory power of a body, *i.e.* the ratio of the rotation produced in it to that which is produced under exactly similar circumstances in distilled water, does not exhibit any definite relation to the other physical properties of the body. Although the denser and more refractive liquids appear for the most part to possess this power in a greater degree than others, there are yet several remarkable exceptions to this rule, amongst which the acids of sulphur are the most conspicuous. Chemical composition, on the other hand, has a decided influence. The entrance of an additional atom of oxygen into a body possessing rotatory power diminishes this power, whereas bromine and iodine increase it greatly, and nitrogen in a lesser degree. This last law is demonstrated especially by observations on certain isomeric compounds. Nevertheless, the atomic grouping, and, therefore, the atomic volume, has also a decided influence.

2. Rise of temperature diminishes the specific rotatory power of all bodies; in the first place, by the expansion and consequent diminution of the number of molecules in a given volume which it produces, and, moreover, by a direct action, independent of expansion, which is especially manifest in slightly expansible bodies, such as water.

3. A mixture of two liquids, formed without the occurrence of chemical action, has a rotatory power which is the mean of those of the constituent liquids. This result does not hold good in the case of mixtures of sulphuric acid and water, if the quantity of one of the two constituents amounts to 0.2 of the mixture. The exception is probably due to chemical combination, which always diminishes the rotatory power. This result may afford a means of distinguishing mere solution from chemical combination.

4. A more exact study of rotatory power promises to throw light on the internal constitution of bodies, inasmuch as the phenomenon depends, not only on the nature of the molecules, but likewise on their arrangement. Solutions and isomeric compounds in particular are likely to furnish important results.

The following are some of the numerical results:—

	Density	Specific rotatory power
Alcohol	0.804	0.876
Carbon bisulphide	1.270	3.16
Sulphuric acid (concentrated)	1.842	0.800
H^2SO^4 , chemically pure	1.832	0.750

Further, the specific rotatory power of Ethyl Oxide is 0.838; of Ethyl Bromide, 1.200; of Ethyl Iodide, 2.233; of Liquid Sulphur Dioxide, 1.242; of the same in saturated aqueous solution, 1.100; of Copiba-oil, 1.320; of Turpentine-oil, 1.102; of Creasote, 2.259.

LIGHT, CHEMICAL ACTION OF. *Distribution of Chemical Energy in the Spectrum.*—Concerning the distribution throughout the spectrum of the intensity in the chemically active rays, Dr. J. W. Draper (*Phil. Mag.* [4], xlv. 422) has professed views opposed to those generally held, according to which a maximum intensity of such rays exists between the lines G and H, and a gradual diminution takes place

on each side of this region. Draper, on the other hand, asserts that, so far from chemical influences being restricted to the more refrangible rays, every part of the spectrum, both visible and invisible, can give rise to chemical changes, or modify the molecular arrangement of bodies; and the ray capable of producing chemical change in any particular substance is that one which the substance has the power of absorbing. The experiments cited by Draper in proof of his conclusions do not appear to be new ones, whilst the fact that different photo-chemically sensitive substances are not affected alike when exposed to the solar spectrum has long been known, and it is also generally admitted that a certain action, though a gradually diminishing one, is noticeable in the case of almost every chemically active substance for a long distance both into the invisible and into the yellow and red rays. The maximum of chemical action, as observed with bromide of silver, differs in position from that with the iodide and chloride, and all these again differ from the maximum (apparently in the yellow) observed in the decomposition of carbonic acid in presence of the green colouring matter of plants.

Thus, for instance, C. Schultz-Sellack (*Deut. Chem. Ges. Ber.* iv. 210) has shown that whilst a collodion-film sensitised with chloride of silver is sensitive for the portion of the spectrum lying half-way between H and G, an iodide-film is sensitive to a point beyond G, and a bromide-collodion to a point close upon F; and Sellack (like Draper) concludes that the haloid silver salts are decomposed by those rays upon which they are capable of exerting a powerful absorbent effect.

Professor H. Vogel, of Berlin (*Deut. Chem. Ges. Ber.* vi. 1302; *Pogg. Ann.* 150, 453; *Phil. Mag.* [4], xlvii. 273) has recently shown that not only is the maximum of photographic action dependent upon the absorbent power of the particular substance for different rays, but that the admixture of certain coloured but chemically inactive substances with the sensitive compound has the effect of altogether altering the position of the maximum of chemical action. Thus, for instance, when a yellowish-red colouring matter, such as aurin, was added in small quantities to a brominized collodion, the plates prepared with this and sensitized in the ordinary way exhibited, when exposed to the solar spectrum and developed, two distinct maxima of action; one (being that observed with an ordinary bromide plate) in the indigo, shading off in intensity on each side, and becoming weak near F; the other (being a new phenomenon) nearly as intense as the first, but occurring in the yellow. Thus it appears possible to prepare a bromide of silver plate which is affected as much by the yellow—usually considered as chemically inactive—rays, as it is with those in the violet, usually supposed to be chemically the most active rays. By adding to the collodion a substance (one of the aniline-greens) which absorbs the red rays between D and C, a bromide-film can be prepared upon which the red rays near C are capable of producing an effect. The sensitiveness of this film was found to diminish from violet to yellow, and then to increase again, showing a distinct maximum at the point where the absorption-band appears in the spectrum of the aniline-green.

Dr. H. Draper (*Phil. Mag.* [4], xvi. 419), in a paper on Diffraction Spectrum Photography, states that he has likewise succeeded in photographing the lines of the visible spectrum from *b* downward, and that the picture comprises not only the regions included within the lines F D, C B, and A, but also the ultra-red rays with their three distinct groups. Draper has not, as yet, made known the process by which he has obtained these singular and important results.

E. Budde (*Phil. Mag.* [4], xlii. 290, 204) has described an experiment in which an increase of volume was observed when chlorine was exposed to the chemically active rays, and a corresponding contraction when no longer under the influence of light. A Leslie's differential thermometer was filled with chlorine, and oil of vitriol previously saturated with chlorine substituted for the index fluid. The bulbs were then placed so that either of them could be illuminated by any portion of the solar spectrum, while the variation in the position of the index was observed by a telescope. A small expansion of the gas occurred when the bulb was exposed to the red and yellow rays, but a maximum displacement of 6-7 millimeters took place in the blue and ultra-violet rays. Control experiments showed that this change of volume was not due to change of temperature. A thermometer filled with chlorine was kept in a water-bath and exposed to direct sunlight. By alternately shading the one and the other of the bulbs, a displacement of the index amounting to several centimeters was obtained. Budde explains this expansion by supposing that the light actually decomposes chlorine-molecules into chlorine-atoms. The writer of this article thinks it right to observe that he has repeated Budde's experiments, but that he has failed to obtain the slightest alteration in volume in the insulated as against the non-insulated portion.

With respect to the measurement of the chemical action of light, little has been done beyond the establishment of a self-acting method applicable to observations. Roscoe has recently described (*Phil. Trans.* 1874, Part II.; *Pogg. Ann.* xl. 244; *abstr.*

Proc. Roy. Soc. xxii. 158) an instrument by which the varying intensity of the chemically active rays, as affecting chloride of silver paper of constant sensitiveness, can be made self-recording. The method described (iii. 686) in the Bakerian Lecture for 1865, although it has been the means of bringing into notice many important facts concerning the distribution of the sun's chemical activity throughout the atmosphere, as well as in different situations on the earth's surface, has not as yet been introduced as a portion of the regular work of meteorological observatories, owing to the fact that, in order to obtain a satisfactory curve of daily chemical intensity, at least hourly observations need to be made, and this involves the expenditure of more time and labour than it has been found possible to give. The present method, whilst preserving untouched the principles and accuracy of the former method, reduces the personal attention needed for carrying out the measurements to a minimum, and thus renders its adoption in observatories possible.

According to this plan, a constant sensitive paper is exposed by a self-acting arrangement for accurately known times, at given intervals throughout the day. The insolation apparatus stocked with sensitive paper is placed in position either early in the morning of the day during which the measurements have to be made, or on the previous night, and by means of an electric communication with a properly arranged clock, the sensitive paper is exposed every hour during the day, so that, in the evening, the observer has only to read off, in the ordinary manner, the hourly intensities which have been recorded on the paper during the day.

This self-recording arrangement, though apparently simple, involves points which have rendered its successful completion a somewhat difficult matter, owing, in the first place, to the great variations which occur in the chemical intensity of total daylight in different places, at different times of the day, and in different periods of the year; and secondly, owing to the fact that, in order to be able to estimate the chemical intensity, the coloration acquired by the paper must reach, but not much exceed, a given tint. It becomes necessary, therefore, that on each occasion when an observation is needed, the sensitive paper should be exposed mechanically, not once, but for several known but varying intervals of time, quickly succeeding each other; so that whatever may be the intensity of the total daylight (supposed during these intervals to remain constant), some one at least of the several exposed papers will possess the requisite shade. This is accomplished by a duplicate arrangement of a clock and insolation-apparatus, by means of which discs of the constant sensitive paper are exposed each hour for successive known intervals of time, varying from two to thirty seconds. After an interval of an hour, another set of discs are exposed for the same series of intervals, and these series of insolutions are repeated once every hour during the day. The mechanical arrangements for effecting this with accuracy are shown in the following figures. The minute-hand A of the clock (fig. 22.) is connected with the train of wheels B, C, D, in such a manner that the last wheel D makes one revolution in two minutes. On the periphery of the metal wheel are fixed eleven stout platinum needles (numbered 1 to 11 in the figure), each of which projects three millimeters beyond the face of the wheel. As the wheel turns round, each of these needles is successively brought in connection with the elastic metal arm E, the end of which is coated with platinum. The platinum pins are attached to the wheel in such a manner that the contact lasts only for an instant, and is then broken till the next pin comes into position. This takes place eleven times in all. The intervals during which the contact is broken are of various lengths, according to the intervals between the platinum pins. In this country the following times of breaking contact have been found the most convenient:—

Interval	No. 1	2	3	4	5	6	7	8	9	10
Seconds	2	3	4	5	7	10	12	17	20	30

If the instrument is to be used in places where the chemical intensity is much greater or smaller, another interval must be adopted. While the wheel is in contact with the elastic arm E, an electric current from several cells of a powerful battery passes through a second elastic arm F, and through wires which connect the clock with the insolation-apparatus. As soon as contact is broken at E, this current is likewise interrupted. The paper of constant sensitiveness is cut into long narrow strips as in Morse's telegraph-apparatus. The length (about 3 meters) must be sufficient for a day. This paper strip is wound round the roller B (fig. 23) from which it passes over the light metal wheel W, having a diameter of about 16 centimeters. One end of the paper strap is attached to this end. The escapement wheel F (fig. 23) is set in motion by a spring S, and has a common axis with the wheel W. The escapement is connected with a piece of iron K, placed near an electromagnet M, round which a current passes as soon as metallic contact is established with E (fig. 22).

When a current passes round the electro-magnet, the piece of iron K is attracted,

the escapement is set free, and the wheel with the paper is moved through an arc depending on the number of teeth in the escapement-wheel F. As soon as the current is interrupted, the piece of iron is brought back to its original position by the spiral spring S.

When the minute-hand of the clock (fig. 22) comes to a certain point, a pin *p*, fixed upon it, presses on the longer arm of a lever L, which depresses the elastic arm E. The platinum pins of the wheel D now press against the arm E, and the current is established and interrupted in the intervening spaces. The sensitive paper is thereby moved forward, after certain intervals, through a distance which is sufficient to bring a fresh part of it under the circular opening. This small paper disc (4 mm. in diameter) is thereby exposed till the current is re-established, and a fresh disc brought under the opening. It is easy to see that by this means the sensitive paper is exposed during the above-mentioned interval, which may amount to 80 seconds, till the wheel D has made one revolution. The fixed pin *p*, of the minute-wheel, has, during this interval, moved forward so far that it no longer presses against the bent and thick end of the lever L, and consequently the end of the elastic arm E is brought back by the insulated spiral spring S. The arm now remains in this position for an hour, when it is again pressed down and brought into connection with the platinum pins. During this hour a disc of paper is exposed and thereby strongly blackened. If one of these black discs is marked in the course of the day, the hours may be known in which the different expositions have taken place.

The apparatus, when in use, is protected by a light metallic blackened shade, on which is fixed a metallic plate with a circular opening (4 mm. in diameter) carefully rounded on the edges. A steel spring AB (fig. 23), on which the sensitive paper is

FIG. 22.

FIG. 23.

pressed, presses it against the horizontal metal plate, so that the exposed paper disc lies close under the aperture of the plate. To keep the paper and apparatus dry during wet weather, the whole is covered with a glass shade. The loss of light thereby occasioned must be experimentally determined for each instrument.

When the apparatus is taken out in the evening, which must be done in a room lighted by a soda-flame, the black discs are seen which have been exposed for an hour. Between these are ten discs of various shades; that which has been exposed for 2 seconds only is perhaps scarcely visible, while that which has been exposed for 80 seconds is perhaps too dark for the determination of the intensity. One of the discs must have a shade whose intensity can be read off on a graduated strip (see vol. iii. p. 687; figs. 705, 706).

A new method of calibrating the fixed strips of standard tint necessary for these measurements is also described, but for this we must refer to the original paper.

This paper also contains graphic representations by curves of the results of a series of comparisons of the curves of daily chemical intensity obtained (1) with the hand-insulator; (2) with the self-recording instrument. Comparisons of this nature were made during the months of May, June, and July, 1873, by simultaneous hourly determinations in the neighbourhood of Manchester, according to both methods. The tables and curves show the close correspondence of the two sets of observations. The integrals of total chemical intensity deduced from the two sets of observations likewise exhibit as close an agreement as can be expected from the nature of the experiments.

LIGNIN. This name is sometimes used synonymously with cellulose (i. 818), but it is more properly applied to the substance, or mixture of substances, which ferments and encrusts the cellulose framework of many vegetable tissues. This encrusting matter, which may be removed by prolonged digestion with dilute nitric acid, contains more carbon than cellulose, and more hydrogen than oxygen, whereas in pure cellulose the hydrogen and oxygen are in the proportion to form water. Lignin is much less digestible than cellulose, and forms indeed the indigestible part of fodder (Payen, *Compt. rend.* lxxii. 457).

LIGNITE. The composition and heat of combustion of lignites from several localities in France and Germany have been determined by A. Scheurer-Kestner and C. Meunier (*Compt. rend.* lxxiii. 1332), with the following results:

I. Hard lignite from Fadaeu (Bouches-du-Rhône): black compact mass, with dull conchoidal fracture.

II. Rich lignite from Manosque (Basses-Alpes): friable mass, having an unctuous aspect, black colour, and uneven fracture.

III. Hard lignite from Manosque: black compact mass, with shining conchoidal fracture.

IV. Rich lignite from Bohemia: compact mass, with uneven fracture, black and shining.

V. Lignite passing into fossil wood, from Bohemia: aspect dull in the direction of the woody fibres, shining in the transverse direction. The fracture displays a stratification of closely lying layers.

VI. Fossil wood passing into lignite: much resembles the preceding.

The heat of combustion is in all cases less than the sum of the heats of combustion of the elements, carbon and hydrogen. In this respect the lignites are distinguished from coal, which always gives a calorific power greater than that of the carbon and hydrogen. It is impossible, therefore, to judge of the value of a combustible of this kind from its elementary composition.

A lignite from Vescovado in the province of Sienna, Italy, was found by E. Kopp (*Moniteur Scientifique*, 1870, 58) to contain 26.48 p.c. volatile combustible matter, 45.52 non-volatile combustible matter, 21.80 water, and 9.20 ash. By coking in a retort it yielded 51.72 p.c. of coke. It contained 1.86 p.c. sulphur.

Action of Alkalis on Lignite.—Lignite from Traunthal fused with three times its weight of caustic potash yields a crystalline sublimate of pyrocatechin; but this product is not obtained if the lignite has been previously exhausted with ether: hence it appears that the pyrocatechin is formed from the bitumen of the lignite. Pyrocatechin is likewise obtained from other lignites, but only from those which exhibit a distinct ligneous structure. Lignites of the older formations do not yield it, and coal is not acted upon at all by fusion with alkalis (Schinnerer and Morawski, *Deut. Chem. Ges. Ber.* v. 185).

Specific Gravity of Liquids.—An exact and easy method of determining the specific gravity of liquids is given by H. Sprengel (*Chem. Soc. J.* [2], xi. 577). The

FIG. 22.

FIG. 23.

apparatus used consists of an elongated U-tube (fig. 22), the open ends of which terminate in two capillary tubes, which are bent at right angles in opposite directions. The size and weight of the instrument must be adapted to the size and capability of the balance in which it is to be weighed. As the ordinary balances indicate $\frac{1}{10}$ milligram when loaded with 50 grams, the U-tube, when charged with the liquid, should not exceed this weight (1,000 grains = 64,709 grams). An instrument used by Dr. Sprengel had a length of 17.7 cm. (7 inches), and was made of a glass tube, the outer diameter of which was 11 mm. ($\frac{1}{2}$ of an inch). The U-shape is of course adopted for the sake of presenting a large surface, and so rendering the instrument sensitive to changes of temperature. An important point is the different calibre of the two capillary tubes. The shorter one is a good deal narrower (at least towards the end) than the longer

one, the inner diameter of which is about $\frac{1}{4}$ mm. The horizontal part of this wider tube is marked near the bend with a delicate line (*b*). This line and the extremity of the opposite capillary tube (*a*) are the marks which limit the volume of the liquid to be weighed.

The filling of the instrument is easily effected by suction, the little bulb apparatus (as represented in fig. 23) having previously been attached to the narrow capillary tube by means of a perforated stopper, i.e. a bit of an india-rubber tube tightly fitting the conical tubulus of the bulb. On dipping the wider and longer capillary tube into a liquid, suction applied to the open end of the india-rubber tube will produce a partial vacuum in the apparatus, causing the liquid to enter the U-tube. As this partial vacuum maintains itself for some time (on account of the bulb, which acts as an air-chamber), it is not necessary to continue the suction if the end of the india-rubber tube be timely closed by compression between the fingers. When bulb and U-tube have about equal capacity, it is hardly necessary to repeat the exhaustion more than once during the filling. Without such a bulb the filling of the U-tube through these fine capillary tubes is somewhat tiresome. The emptying of the U-tube is effected by reversing the action and so compressing the air.

After the U-tube has been filled, it is detached from the bulb, placed in water of the standard temperature almost up to the bends in the capillary tubes, left there until it has assumed this temperature, and, after a careful adjustment of the volume, it is taken out, dried, and weighed.

Particular care must be taken to ensure the correctness of the standard temperature, as a mistake of 0.1° causes the weight of 10 c.c. of water to be estimated either too high or too low by 0.14 milligram, giving rise to an error in the 5th decimal, or making 100,000 parts 100,001.4 parts.

A peculiar feature of the instrument is the ease and precision with which the measurement of the liquid can be adjusted at the moment it has taken the standard temperature, the liquid expanding and contracting only in the wider capillary tube, viz., in the direction of the least resistance. The narrow capillary tube remains always completely filled. Supposing the liquid reaches beyond the mark *b*, it may be reduced through capillary force by touching the point *a* with a little roll of filter-paper. Supposing, however, that in so doing too much liquid is abstracted, capillary force will redress the fault if the point *a* be touched with a drop of the liquid under examination: for this gentle force acts instantly through the whole mass of the liquid, causing it to move forward again to the mark or beyond it.

As the instrument itself possesses the properties of a delicate thermometer, the time when it has reached the standard temperature of the bath may be learned from the stability of the thread of liquid inside the wider capillary tube. The length of this thread remains constant after the lapse of about five minutes.

In wiping the instrument (after its removal from the bath) care should be taken not to touch the point *a*, as capillarity might extract some of the liquid; otherwise the handling of the instrument requires no especial precaution.

The capillary tubes need not be closed for the purpose of arresting evaporation, at least that of water. It appears from the mean of several determinations that the error arising from this source amounts in one hour to $\frac{1}{100}$ milligram.

If the temperature of the balance-room is high, and the expansion of the liquid considerable, it may be found necessary to put a small cap (bowl-shaped and open at both ends) over the extremity of the wider capillary tube, for the purpose of retaining the liquid which, during the time of weighing, might otherwise be lost, owing to its expansion. Raising the standard temperature of the bath is another way of meeting this inconvenience. When a cap is used, the wider capillary tube need not be longer than the narrow one.

For Marignac's determinations of the specific gravities and expansions of aqueous solutions, see HEAT (pp. 602-604).

Extensive Tables of the Specific Gravities of the Aqueous Solutions of various Salts used in the Arts and Manufactures are given by Benno Franz (*J. pr. Chem.* [2]. v. 274-308).

For Thomson's determinations of the Specific Gravities, Molecular Volumes, and Specific Heats of Solutions, see HEAT (pp. 596-600). For Marignac's determinations of the Specific Heats of Solutions, pp. 600-602.

On Conduction of Heat in Stratified Liquids, p. 640.

Compressibility of Liquids under High Pressures.—The following determinations are by Chaillet (*Compt. rend.* lxxv. 77):—

	Density	Temperature	Compressibility corresponding to one atmosphere	Total pressure applied: Atmospheres
Distilled water deprived of air	1000	+ 8	0.0004451	705
Carbon bisulphide	—	+ 8	0.0000980	607
		+ 9	0.0000676	174
Alcohol	0.858	+ 9	0.0000701	305
		+ 11	0.0000727	680
Petroleum	0.865	+ 11	0.0000828	610
Essence of petroleum	0.720	+ 10.5	0.0000981	630
Ether	—	+ 10	0.0001440	630
Sulphurous acid	—	- 14	0.0003014	606

These numbers are not corrected for the compression of the glass vessel, for the determination of which, under these high pressures, no method is known.

Transpiration of Liquids.—Löwenthal (*Zeitschr. anal. Chem.* x. 298) has made experiments on the capillary transpiration of certain liquids, by means of an apparatus differing only in a few details from that used by Graham (iii. 722). The vessel containing condensed air has a capacity of not less than 1,500 c.c., and two capillary tubes are used, fitted with two stopcocks of exactly equal dimensions, so that two experiments may be carried on simultaneously. Instead of placing the tubes in water at a known temperature, Löwenthal finds it easier to regulate the temperature of the room so that it shall be maintained at a constant point during the experiments. The tubes used are of varying capacity, containing from 2.5 to 57 c.c., some of these having one and some two bulbs. The time which the liquid takes to pass through the capillary tube is noted by a method similar to that employed by Graham.

Löwenthal finds that the fatty oils used in the arts have very different rates of transpiration, and that this is also the case with milk, beer, wine made from fruits, grape-wine, and various other substances. This fact may perhaps be turned to practical account in testing such compounds.

The experiments show further that, for at least some liquids, there exists a relation between their respective diffusion and transpiration rates. Thus, Graham gives the diffusion of HCl solution to NaCl solution as 1 : 0.7, Löwenthal has found their respective rates of transpiration to be as 1 : 0.732. In like manner the diffusion of NaCl to sugar is as 2.33 : 7, their transpiration rates as 2.33 : 5.83.

LITHIOPHORITE (A. Frenzel, *J. pr. Chem.* [2], iv. 353; *Jahresb. f. Mineralogie*, 1872, 219). This mineral, nearly allied to the cupriferous and cobaltiferous ores of manganese, contains 1.5 p.c. lithia. It is found, usually on quartz, in the beds of iron ore of the granite district near Schneeberg, Schwarzenberg, and Johanngeorgenstadt. The felspar of the granite, which is much weathered, contains a trace of lithium, recognisable by the spectroscope. The mica contains more of this metal.

Lithiophorite is amorphous, occurs in compact, botryoidal, and reniform masses, in flat shell-like forms, and in pseudomorphs after calcspar. Hardness = 3; sp. gr. = 3.14–3.36. Colour, bluish-black; streak, brown-black. It gives off water when heated in a tube; does not melt before the blowpipe, but colours the flame with carmine-red.

Two analyses, by C. Winkler, of lithiophorite from Schneeberg, gave:—

	K ² O	Li ² O	BaO	CoO	NiO	CuO	MnO	O	Fe ² O ³	Al ² O ³	H ² O	X*
(1.)	0.73	1.23	2.78	2.42		1.74	55.12	10.28	1.48	10.54	12.64	— = 98.96.
(2.)	1.50	1.42	1.26	0.64	0.30	0.96	40.87	7.77	2.43	15.53	15.42	3.08 = 100.18.

* Sand; also traces of lime, and in (1.) of bismuth oxide.

F. v. Kobell has detected lithia in the asbolans of Sayn, and of the iron mine at Siegen.

LITHIUM. This metal, like potassium and sodium, dissolves in anhydrous liquid ammonia, and is left behind, with its original appearance and colour, on evaporating the liquid (Seeley, p. 60).

On the Spectroscopic Character of various Lithium Minerals, see F. v. Kobell (*J. pr. Chem.* [2], iii. 176; *Chem. Soc. J.* [2], ix. 312).

Separation of Lithium and Sodium.—To separate these metals, v. Kobell (*J. pr. Chem.* [2], v. 112) heats the mixed chlorides to incipient fusion in a weighed platinum crucible; then weighs the mixture, leaves it exposed for 24 hours to an atmosphere not moist enough to act upon the sodium chloride, till the lithium chloride has absorbed water; drenches the partly deliquesced mass with alcohol; decants carefully; repeats the washing and decantation a second time; and weighs the residual sodium chloride. An experiment on weighed quantities of the mixed chlorides showed that the method gives exact results.

Lithium Hydrate.—An aqueous solution of lithia evaporated in a vacuum yielded a slightly hygroscopic hydrate, $\text{LiHO.H}^2\text{O}$ (Muretow, *Deut. Chem. Ges. Ber.* v. 331).

LOBARIC ACID. A resinoid acid obtained from the lichen called *Parmelia saxatilis* by Wallroth, *Loberia adusta* by Hoffmann. It is colourless, crystallises in warty masses made up of thin plate, and in its degree of solubility in different menstrua and in other of its properties, it resembles a crystalline resin. It is not affected by prolonged exposure to ammonia gas, but dissolves in either aqueous or alcoholic ammonia, forming a colourless solution, which turns rose-red on exposure to the air, and dries up to an amorphous violet-brown mass, resembling in tint the thallus of the lichen which yields it. It dissolves in caustic potash with a pure yellow colour, which, on exposure and evaporation, changes like the ammonia-solution to rose-red and brown-violet. When heated it fuses, evolves dense inflammable vapours, and chars. It has the composition expressed by the formula $\text{C}^{17}\text{H}^{10}\text{O}^3$, that of evernic acid being $\text{C}^{17}\text{H}^{10}\text{O}^2$.

The colour of the brown variety of *Parmelia saxatilis* may, perhaps, be attributed to the presence of oxidation-products of the potassium salt of lobaric acid. The colour is only superficial, and is produced by the action of the potash derived from the weathering of the granite upon which the lichen grows (W. Knop, *Chem. Centr.* 1872, 172).

LOKAO. This dye, also called *Chinese green*, was originally imported from China, but has likewise been obtained from the berries of the common buckthorn. In the crude state it is a lake containing 25 p.c. of mineral matter. If left in contact with water for some days it ferments, and is partially reduced. The liquor is filtered, and the residue washed with cold water, and dissolved in warm water, which it colours reddish-violet. This solution, on exposure to air, throws down a blue precipitate, which, though purer than the original lokao, still leaves a considerable ash on ignition. Perfectly pure lokao is obtained by agitating the crude green with solution of ammonia carbonate, filtering, precipitating with alcohol, washing, and drying at 100° . The product is blue (confirming the observation of Persoz, that 'Chinese green, when quite pure, is a blue'), and is a compound of ammonia with the pure colouring matter (*lokaïn*). The analysis of ammonium-lokaïn gives numbers corresponding with the formula $(\text{NH}_4)^2\text{C}^{20}\text{H}^{10}\text{O}^{14}$. Lokaïn may be considered as a weak acid, and represented by the formula $\text{C}^{20}\text{H}^{10}\text{O}^{14}$.

When ammonium-lokaïn is kept at 100° for some hours, it is transformed into an insoluble violet substance, which is also formed when crude lokao is fermented with yeast, but is best obtained by treating ammonium-lokaïn with warm dilute sulphuric acid, when it splits up into glucose (showing that lokaïn is a glucoside), and an insoluble residue (*lokaëtin*), the composition of which may be expressed by the formula $\text{C}^{19}\text{H}^{10}\text{O}^{10}$; and the contact of this substance with a trace of ammonium-carbonate, produces the violet before named (*ammonium-lokaëtin*).

Lokaëtin, when heated with dilute nitric acid at 100° , splits up into oxalic acid and a substance giving an intense yellow coloration with alkali. With concentrated sulphuric acid lokaëtin is changed into a substance giving a deep blue with weak alkali. Its formula is $\text{C}^{18}\text{H}^{12}\text{O}^8$, i.e., lokaëtin minus $2\text{H}^2\text{O}$.

Uses of Lokao, &c., in Dyeing.—(1.) The liquor obtained by digesting crude lokao with water, and filtering, dyes cotton a pale green, but gives to wool and silk only a very pale bluish-grey, similar to the tint of some silks dyed by the Chinese. (2.) The deep violet ammonium-lokaëtin may be fixed upon cotton without a mordant, also upon silk and wool. (3.) Ammonium-lokaëtin, added to a bath of sodium thiosulphate, gives a liquor which dyes cotton a very pure sky-blue, permanent in sunlight, and fast when washed.

LÜNEBURGITE. This name is given by C. Nöllner (*Münch. Acad. Ber.* 1870, i. 291) to a mineral obtained by boring at Lüneburg. It contains—besides 0.7 p.c. BF₃, which goes off at a red heat, and traces of salts from the neighbouring salt bed—the components given under A, agreeing nearly with the formula $(2\text{MgO.H}^2\text{O.P}^2\text{O}^5) + (\text{MgO.B}^2\text{O}^3) + 7\text{H}^2\text{O}$, which requires the numbers B:—

	MgO	FeO ^a	B ² O ³	H ² O	
A (found)	25.3	29.8	12.7	32.2	= 100
B (calc.)	25.10	29.83	14.32	30.25	= 100

The same composition was exhibited by some crystals deposited from the mother-liquors of sen-water, the source of which is not given (Nöllner, *Jahrbuch f. Mineralogie*, 1871, 175).

LUPINE. The general composition of yellow and blue lupine-seed is as under:—

	Yellow lupine	Blue lupine
Water	10.4	13.2
Albuminoids	37.5	22.0
Non-nitrogenous extractive matter	27.3	43.8
Fat	4.4	5.6
Crude fibre	16.4	12.2
Ash	4.0	3.2
	100.0	100.0

As lupine-seed is rich in nutritive matter, and can, moreover, be grown on a poor soil, it would be of great value as feeding material but for the bitter principle (the volatile alkaloid) which it contains. The presence of this substance renders lupine-seed distasteful and injurious to animals, especially to pigs; sheep are but little affected by it. The blue lupine-seed is more objectionable than the yellow. The amount of alkaloid present varies a good deal. The alkaloid may be more or less removed by baking the seed in an oven or kiln; or by steeping in water and washing; or by treatment with dilute hydrochloric acid, washing, and then boiling with a little sodium carbonate (H. Settegast, *Ann. d. Landwirtschaft. Wochenblatt*, June 7, 1871).

Yellow lupine-seed has been further examined by A. Beyer (*Landwirtschaftliche Versuchs-Stationen*, xiv. 161). He finds that a section of the moist seed is strongly acid to litmus-paper, and that the seed contains citric acid. Ritthausen (*J. pr. Chem.* [2], ii. 330) found malic and oxalic acids.

Beyer also found a viscid substance, soluble in alcohol, but did not succeed in obtaining it pure.

The seed contains two fats: a fluid fat extracted by cold ether, and a solid fat obtained by treatment with hot alcohol after the extraction by ether. The percentage composition of the fluid fat, when purified, is 75.7 C., 11.35 H., 0.098 P., 12.862 O.; while that of the solid fat is 72.68 C., 10.84 H., 1.56 P., 14.92 O. The amount of phosphorus in the solid fat (quite free from adhering phosphates) is remarkable. Knop found 1.25 p.c. of phosphorus in a fat from a sugar-pea.

The alkaloids of lupine-seed are best extracted by means of alcohol containing hydrochloric acid; when isolated they are found to be fluid bodies resembling conine. Beyer separates the alkaloids by the different solubility of their platinum salts. The platinum salt, insoluble in alcohol and in cold water, has the formula $C^{11}H^{12}N^2O^2Cl^2.PtCl^4$; the more soluble platinum salt has the formula $C^{20}H^{16}N^2O^2Cl^2.PtCl^4$. The soluble platinum salt corresponds with an alkaloid soluble in water, and *vice versa*.

Siewert has separated the two alkaloids by distillation. The one distilling at 216° corresponds with the insoluble platinum salt; that distilling at 261° with the soluble. Siewert's formulae for the alkaloids are in each case less, by a molecule of water, than those deduced from the above platinum salts.

LUTEIC ACID. A yellow colouring matter prepared from the flowers of *Euphorbia Cyparissias* (p. 495).

LUTIN. This name is given by Thudichum (*Proc. Roy. Soc.* xvii. 263) to the yellow substance obtained by Piccoli and Lieben from the ovary of the cow, and called by them hæmolutein (*1st Suppl.* 497).

LUTECOBALITIC CHLORIDE. See COBALT-BASES, AMMONIACAL (p. 365).

LUTIDINE. This base has been found, together with several of its homologues, in tobacco-smoke (see TOBACCO).

LYCOCTONINE. See ACONITE ALKALOIDS (p. 24).

M

MAGNESITE. Crystals of magnesite from Mariazell in Styria, some colourless, others brownish, exhibit, according to J. Rumpf (*Jahrbuch. f. Mineralogie*, 1870, 356) the form OR, $\infty P2$.

Magnesites (a) from Mahronberg in Styria, sp. gr. 2.091–2.094; (b) from Frankenstein in Silesia, sp. gr. 2.090, have been analysed by H. Schwarz (*Dingl. pol. J. exxviii*, 154), with the following results:—

MgCO ³	CaCO ³	* FeCO ³	Insol.
92.52	3.55	3.79	0.14 = 100
98.47	trace	trace	1.53 = 100

A ferruginous magnesite from the north bank of the Schuylkill river, between Philadelphia and Montgomery county, Pennsylvania, consists, according to Leeds (*Chem. News*, xxii, 173), of:—

MgO	FeO	CaO	CO ²
38.43	10.39	3.20	47.96 = 100.07

MAGNESIUM. *Separation from the Alkali-metals.*—The following method is given by H. Scheerer (*J. pr. Chem.* [2], iii, 4761). Evaporate the hydrochloric acid solution of the metals nearly to dryness in a platinum crucible; add ammonium oxalate; dry, heat gently, then to full redness; treat the residue with water, boil and filter. Magnesium carbonate is then found on the filter, potassium and sodium carbonates in the filtrate. This method is said to yield good results. If, however, the metals are present wholly or partly as sulphates, these salts must first be converted into chlorides by treatment with barium chloride.

Separation from Aluminium.—When a solution containing alumina and magnesia, together with a large quantity of sal-ammoniac, is boiled with excess of ammonia till all the ammonia is driven off, alumina is thrown down almost free from magnesia. If, however, sulphuric acid is present, the quantity of magnesia precipitated, together with alumina, is greater than when that acid is absent. The quantity of magnesia in the precipitate likewise increases when the ammonia is added quickly and in excess, instead of being added in drops and with stirring. In solutions containing sulphuric acid, rapid addition of ammonia leads to the precipitation of 2 mol. magnesia with each molecule of alumina, whereas, when the ammonia is gradually added, the precipitate contains only 1–2 p.c. magnesia (*S. Wrinkles, Chem. News*, xxii, 4).

Oxychlorides.—Sorel found that a mixture of strongly heated *Magnesia usta* with a concentrated solution of magnesium chloride dries up in a few hours to a hard mass, apparently of oxychloride, which resists the action of water (*1st Suppl.* 796). The products thus formed have been more exactly investigated by C. Bender (*Ann. Ch. Pharm.* clix, 341), whose analysis of a sample prepared as above and hardened by six months' exposure to the air, gave numbers which rendered it probable that the product consisted of a mixture of magnesium carbonate, $MgCO_3$, with the compound $MgCl^{1.5}MgO.17H^2O$ (a). By drying over sulphuric acid, it was converted into $MgCl^{1.5}MgO.14H^2O$; by drying at 100° into $MgCl^{1.5}MgO.8H^2O$; and at 150° – 180° into $MgCl^{1.5}MgO.6H^2O$. These facts seem to show that the elements of the chloride and oxide of magnesium have entered into more intimate combination, inasmuch as magnesium hydrate decomposes at 106° . When the above-mentioned sample was treated with water, part of the magnesium chloride dissolved, while (together with magnesium carbonate) the compound $MgCl^{1.9}MgO.24H^2O$ (b) was formed, from which, by heating to 100° and to 150° – 180° , the compounds $MgCl^{1.9}MgO.16H^2O$ and $MgCl^{1.9}MgO.10H^2O$ were produced. By prolonged treatment of the compound b with boiling water, the whole of the magnesium chloride could be removed and the residual substance then contained the compound $2MgO.3H^2O$ (c), from which, by drying at 150° – 180° , the compound $4MgO.5H^2O$ could be obtained.

The compounds a, b, c, γ —if the materials have not been pulverised at the commencement of the process—are compact solid bodies; having the hardness and tenacity of a good sandstone, a brilliant surface, and susceptible of a high polish; their cohesive power is not destroyed by water either cold or hot. In this respect the compound γ resembles the mineral brucite $Mg(OH)_2$, the absence of crystallisation being probably due to its rapid mode of formation.

For the proximate constitution of these compounds, C. Bender gives the following formulae:

The compounds dried at 100° and at 150° – 180° are similarly constituted. These formulae, however, are not intended to represent the phases of the successive decomposition by cold and hot water, as they would indicate that the compound $\text{MgCl}^2 \cdot \text{MgO}$ passes in each case into solution, which is not the case.

The crystalline deposit which frequently occurs in the solutions of magnesium salts mixed with sal-ammoniac (known in the laboratory as 'magnesia mixture') consists, according to J. Davis (*Chem. News*, xxv. 258), of the hydrated oxychloride $\text{MgCl}^2 \cdot 5\text{MgO} + 13\text{H}^2\text{O}$ or $\text{Mg}^2\text{Cl}^2\text{O} \cdot \text{H}^2\text{O} + 4(\text{MgO} \cdot 3\text{H}^2\text{O})$. By washing the crystals with a large quantity of water, the whole of the chlorine may be removed, and the oxychloride converted into a hydrated oxide.

MAGNETISM. Coulomb's law of the force with which two magnetic poles tend to move towards or away from each other, makes it possible to express the strength of magnetic poles, and the intensity of magnetic forces in general, by reference to the fundamental units employed for the measurement of forces in mechanics. The law itself, which is that the *mutual force* (attraction or repulsion) *acting between two magnetic poles is proportional directly to the product of their strengths and inversely to the square of the distance between them*, leads at once to the following as the definition of a magnetic pole of unit strength: *the unit magnetic pole is such that the force acting between it and another equal pole at the unit distance is unity*. But the effects produced in any actual case by a given magnet do not depend simply on the strength of its poles: for these, being necessarily equal and opposite, neutralise each other's external action the more nearly the smaller the distance which separates them, and it will be shown further on that the resultant force exerted by the two poles of a complete magnet upon each pole of a second magnet is directly proportionate to the distance between the poles of the first magnet as well as to their strength. Hence the true measure of the power of a complete magnet is obtained by multiplying together the strength of its poles and the distance between them. To this product the name *magnetic moment* has been given. In the case of a straight piece of steel, of great length in comparison with its width (such as a piece of thin steel wire), which is uniformly magnetised in the direction of its length, the poles coincide sensibly with the extreme points, so that it would be possible to determine the distance between them by direct measurement. It would also be possible to ascertain approximately the strength of the poles of such a magnet by means of the torsion-balance (MAGNETISM, iii. 758), and so the magnetic moment of the magnet could be calculated from its two factors. But in general, neither the position of the poles of a magnet nor their strength can be determined with anything like accuracy by a direct measurement. It was shown by Coulomb (iii. 760) how the moments of different magnets can be compared, but his method does not give an absolute measure of magnetic moments, since the quantity measured, namely, the moment of the couple required to deflect a magnet through a given angle from the magnetic meridian, depends not only on the properties of the magnet under examination, but also on the intensity of the horizontal component of the earth's magnetic force (iii. 781), which varies with time and place. Hence, in order to be able to determine absolutely the magnetic moment of a magnet, we require either to have some method of measurement which is not affected by the earth's magnetic force, or we must be able to ascertain the intensity of this force. The way in which this can be done was first pointed out by Gauss, in 1832. The phenomena which he employed, as the basis of his system of measurement, were (1) the oscillation of a magnet suspended so as to be free to vibrate in a horizontal plane, in obedience to the magnetic forces exerted upon it by the earth; and (2) the deflection of a declination compass from the magnetic meridian caused by the same magnet, when placed at a known distance from it, with its axis perpendicular to the meridian. From observations of these two phenomena, measures can be obtained respectively of the product of the earth's magnetic intensity into the magnetic moment of the magnet to be examined, and of the ratio of the same quantities; so that a combination of the two sets of observations gives a value of each quantity separately. The general principles of the method are more precisely indicated in what follows.

1. *Determination of the product of the horizontal component of the earth's magnetic intensity into the magnetic moment of an artificial magnet.*

If a magnet is suspended in a horizontal plane by a fibre without sensible torsional rigidity, or on a point without sensible friction, it will be in equilibrium when its axis is in the magnetic meridian; but if displaced very slightly from this position, it will perform isochronous oscillations backwards and forwards from one side of it to the other. The rate of oscillation under such circumstances will depend upon the mass

and dimensions of the magnet, and upon the moment of the couple, which tends to restore the magnet to its position of equilibrium when it is turned from it through an angle of 90° , that is to say, when it is placed at right angles to the magnetic meridian. The moment of this couple is evidently given by multiplying one of the equal but opposite parallel forces, whose points of application are the poles of the magnet, by the distance between their lines of action—that is, by the distance between the poles. Again, these forces themselves depend conjointly upon the magnetic intensity of the earth at the time and place of experiment, and upon the strength of the poles of the magnet; that is, if F denote the force applied at either pole, H the horizontal component of the earth's force, and m the strength of the poles of the magnet, we have—

$$F = Hm;$$

and the moment of the couple due to the forces $+F$ and $-F$, acting at the arm l , is given by—

$$Fl = Hml = HM,$$

where l denotes the distance between the poles and M the magnetic moment of the magnet. The time in which the magnet will make one whole oscillation of very small amplitude may then be represented by—

$$t = 2\pi \sqrt{\frac{i}{HM}},$$

in which i stands for the 'moment of inertia' of the magnet, or the mass which, placed at unit distance from the axis of suspension, would offer the same resistance to change of angular velocity about this axis that the magnet does.

If the magnet be a rectangular prism of weight w , and be suspended with two of its faces, whose diagonals measure $2a$, horizontal, we have—

$$i = \frac{a^2 w}{3g}.$$

The observations belonging to this part of the process consequently resolve themselves into a determination of the time of oscillation of the magnet and of its moment of inertia. When these are known, the value of the product to be measured is given by the equation—

$$MH = 4\pi^2 \frac{i}{t^2} \quad . \quad . \quad . \quad (1).$$

2. Determination of the ratio of the magnetic moment of an artificial magnet to the horizontal component of the earth's magnetic intensity.

In order to explain the principle of this part of the process, it is convenient to consider, first, the action of an indefinitely small magnet upon an isolated magnetic pole

FIG. 24.

in a known position relatively to it. Let AB be an indefinitely small magnet and let there be at the point O a magnetic pole of the strength m' . Then if m represents the strength of the pole A , and r the distance AO , the force acting between A and O will be

$$\frac{mm'}{r^2}.$$

Let O be taken as the origin of rectangular co-ordinates, the axis of abscissae being taken parallel to AB . Then the force exerted between A and O may be resolved into components X' and Y' acting along the axes, which, if x and y be the co-ordinates of the point A , will have respectively the following values, namely—

$$X' = \frac{mm'}{r^2} \frac{x}{r} = \frac{mm'x}{r^3}.$$

$$Y' = \frac{mm'}{r^2} \frac{y}{r} = \frac{mm'y}{r^3}.$$

Similarly, the components of the force acting between B and O will be represented by—

$$X'' = -\frac{mm'(x+dx)}{(r+dr)^3}$$

$$Y'' = -\frac{mm'y}{(r+dr)^3},$$

where dx is the increment of x in passing from A to B and dr the corresponding increment of r . But since $r^2 = x^2 + y^2$ and $(r+dr)^2 = (x+dx)^2 + y^2$, and since also dx and dr are indefinitely small, we get $dr = \frac{x}{r} dx$; hence—

$$X'' = -\frac{mm'(x+dx)}{r^3 + 3rxdx} = -\frac{mm'(x+dx)}{r^3} + \frac{3mm'xdx}{r^4},$$

$$Y'' = -\frac{mm'y}{r^3 + 3rxdx} = -\frac{mm'y}{r^3} + \frac{3mm'xydx}{r^4}.$$

For the resultant forces acting along the two axes we have consequently—

$$X = X' + X'' = -\frac{mm'dx}{r^3} \left(1 - 3 \frac{x^2}{r^2}\right),$$

and

$$Y = Y' + Y'' = \frac{3mm'dx}{r^3} \cdot \frac{x}{r} \cdot \frac{y}{r}.$$

Putting θ for the angle AOx, or for what is sensibly the same, namely, COx, we have $\frac{x}{r} = \cos \theta$ and $\frac{y}{r} = \sin \theta$.

Also mdx is the magnetic moment of the magnet AB, so that, if this be denoted by M , the above values become—

$$X = -\frac{Mm'}{r^3} (1 - 3 \cos^2 \theta),$$

$$Y = \frac{3Mm'}{r^3} \sin \theta \cos \theta.$$

The total force exerted by the magnet AB upon the pole at O is the resultant of these two; it may be represented by—

$$F = \sqrt{X^2 + Y^2} = \frac{Mm'}{r^3} \sqrt{1 + 3 \cos^2 \theta},$$

and it acts in such a direction that, if ϕ be the angle which it makes with the axis of x ,—

$$\tan \phi = \frac{Y}{X} = -\frac{3 \sin \theta \cos \theta}{1 - 3 \cos^2 \theta}.$$

From these values it is evident that the component Y vanishes whenever θ is equal either to 0° or to any whole number of right angles. For $\theta = 0^\circ$ or 180° , we have—

$$F_1 = 2 \frac{Mm'}{r^3}, \quad \phi = 0^\circ.$$

For $\theta = 90^\circ$ or 270° , we have—

$$F_2 = \frac{Mm'}{r^3}, \quad \phi = 0^\circ.$$

The first of these special cases corresponds with the position A_1B_1 of the magnet, and the second with the position A_2B_2 .

If now, instead of a single magnetic pole, there is at O a magnet whose length l is an indefinitely small fraction of the distance r , its two poles will be acted on by equal, but opposite, parallel forces, constituting a couple. When the axis of the magnet at O is parallel to Oy, the moment of the couple tending to place it parallel to Ox is—

$$G_1 = 2 \frac{MM'}{r^3}, \quad \text{for the position } A_1B_1 (\theta = 0^\circ),$$

$$G_2 = \frac{MM'}{r^3}, \quad \text{for the position } A_2B_2 (\theta = 90^\circ);$$

where $M' = m'l$ is the magnetic moment of the magnet at O.

If, however, the magnet at O is deflected through any angle, say α , from the direction Oy, the moments of the couples tending to increase the deflection will be obtained by multiplying these values by $\cos \alpha$. Further, if Oy be the direction of the earth's magnetic meridian, the magnet at O, when deflected through the angle α , will be subject to a couple tending to bring it back to the meridian, the moment of which is represented by $M'H \sin \alpha$, where H stands for the horizontal component of the earth's magnetism. Consequently, a magnet at O acted upon by the earth, will place itself so that, for every position of the magnet AB, the two couples which act upon it, namely, the couple tending to set it parallel to Ox, and the couple tending to set it parallel to Oy, shall be of equal but opposite moments. For the two special positions of the deflecting magnet already mentioned, the conditions of equilibrium will therefore be represented by the equations—

$$2 \frac{MM'}{r^2} \cos \alpha_1 = M'H \sin \alpha_1 \quad (\text{for the position } A_1B_1),$$

$$\frac{MM'}{r^2} \cos \alpha_2 = M'H \sin \alpha_2 \quad (\text{for the position } A_2B_2).$$

Denoting these two positions, for the sake of shortness, as the *first position* and *second position* respectively, we obtain the two following values of the ratio of M to H, namely:—

$$\frac{1}{2} r^2 \tan \alpha_1 = \frac{M}{H} \quad (\text{for the first position}),$$

$$r^2 \tan \alpha_2 = \frac{M}{H} \quad (\text{for the second position}).$$

These expressions are rigorously true only when the magnets employed are indefinitely small; but they are *nearly* true when the length of the magnets is only a small fraction of r , the distance between them. The larger they are proportionately to r , the less nearly is the value of the product $r^2 \tan \alpha$ constant; but even when the length of the magnets is as much as a quarter of the distance between them, this product can be represented with considerable accuracy by a formula of two terms, of the following form:—

$$r^2 \tan \alpha = A + \frac{B}{r^2}.$$

Here A is evidently the value towards which $r^2 \tan \alpha$ approximates as r becomes greater; that is $A = \frac{M}{H}$ or $= 2 \frac{M}{H}$, according as the deflecting magnet is placed in the second or in the first position. It cannot be deduced from any single observation of the deflection of the magnet at O, since the quantity B, which occurs in the same equation, is also unknown. But by observing the deflections corresponding with two different distances of the deflecting magnet, two equations are obtained from which B can be eliminated, and hence the value of A or of the ratio $\frac{M}{H}$ can be found. Thus, suppose α and α' to be the deflections observed when the deflecting magnet is placed in the first position at the distances r and r' respectively; the two observations give the equations:—

$$\left. \begin{aligned} r^2 \tan \alpha &= A + \frac{B}{r^2} \\ r'^2 \tan \alpha' &= A + \frac{B}{r'^2} \end{aligned} \right\}$$

whence we obtain—

$$\frac{M}{H} = \frac{1}{2} A = \frac{1}{2} \frac{r^2 \tan \alpha - r'^2 \tan \alpha'}{r^2 - r'^2} \quad (2). \dagger$$

By combining the value of the ratio $\frac{M}{H}$ thus found with the value of the correspond-

* Or $\tan \alpha = \frac{A}{r^2} + \frac{B}{r^4}$: the fact that when the sign of r is changed, the *sign* of the deflection, but not its magnitude, is changed also, shows that only *odd* powers of r can appear in the right-hand member of this equation.

† In practice, the value of α , corresponding with each value of r , would be deduced from *four* observations, namely: (1) with the deflecting magnet *east* of the suspended magnet, and with its north pole *east*; (2) deflecting magnet *east*, north pole *west*; (3) deflecting magnet *west*, north pole *west*; (4) deflecting magnet *west*, north pole *east*. In the second position of the deflecting magnet, four corresponding observations would be made; namely, two with this magnet to the north, and two with it to the south of the suspended magnet.

ing product MH given by equation (1) (p. 761), we obtain the following value for M , the magnetic moment of the magnet employed:—

$$M = \frac{2\pi}{i} \sqrt{\frac{i}{2} \cdot \frac{r^2 \tan \alpha_1 - r'^2 \tan \alpha_1'}{r^2 - r'^2}};$$

where the magnitudes i , r , and i' , which appear on the second side of the equation, are all expressible in terms of the fundamental mechanical units of *time*, *space*, and *mass*. The result thus obtained is called the *absolute* value of M , not in order to signify that it is necessarily very exact, but in contradistinction to the *comparative* value obtained when it is measured by any process which merely enables us to compare one magnet with another, but does not tell us what the actual moment of either of them is.

It is obvious, further, that the same two equations, (1) and (2), afford also a value of H , or the horizontal component of the earth's magnetic intensity, namely:—

$$H = \frac{2\pi}{i} \sqrt{\frac{2i(r^2 - r'^2)}{r^2 \tan \alpha_1 - r'^2 \tan \alpha_1'}}.$$

The value of H thus found denotes the force with which a magnetic pole of unit strength would be urged towards the magnetic north or south respectively, or the moment of the couple which would tend to displace a magnet of unit-magnetic moment if it were placed with its axis perpendicular to the magnetic meridian.

(For much of the above see Bertin, *Ann. Ch. Phys.* [4], xix. 483, April, 1870.)

G. C. F.

MAIZE. The following table shows the composition of green maize cut for fodder about the time of blossoming; the numbers are the mean of eight analyses. Also the composition of maize-corn, mean of ten analyses of the ripe straw and leaves, and of the empty cobs; the last two are from Knop's *Agricultur-Chemie*, 717:—

	Water	Albumi- noids	Fat	Fibre	Soluble carbo- hydrates	Ash
Green maize	85.22	1.68	.53	4.41	7.06	1.10
Maize grain	12.14	10.06	5.01	4.04	67.10	1.65
Straw and leaves . . .	14.00	3.00	1.10	40.00	37.90	4.00
Empty cobs	14.00	1.40	1.40	37.80	42.60	2.80

Maize-corn is remarkable for the large amount of fat it contains (reaching in some analyses to 9 p.c.) and for its small amount of ash. An analysis of maize-corn by Pillitz's improved method of analysing grain (p. 577) gave: Starch, 62.69; dextrin, .76; sugar, 1.38; fibre, 4.19; soluble albuminoids, 1.87; insoluble albuminoids, 8.63; fat, 4.36; extractive matter, 1.43; soluble ash, 1.15; insoluble ash, .33; water, 13.89 p.c. For earlier analyses see *CHEMICALS*, vol. i. Malted maize contains, according to C. Graham, three times as much soluble albuminoids as malted barley, and is therefore used with advantage when much sugar is used in brewing.

The following is the mean of eight analyses of the ash of maize-corn, with single analyses by Way and Ogston (*Jour. Roy. Agri. Soc.* xi. 497) of the ash of the straw and leaves and of the empty cob:—

	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	Cl	SiO ²	CO ²
Maize grain	27.8	3.9	2.5	15.0	.8	46.8	1.5	trace	1.6	none
Straw and leaves . . .	35.3	1.2	10.5	5.5	2.3	8.1	5.2	1.4	28.0	2.9
Empty cob	47.1	1.2	3.4	4.1	.2	4.4	1.9	5.1	26.4	7.5

The embryo of the seed has a very different composition from the endosperm. Haberlandt (*Jahrb. Agri. Chem.* 1866, 107) separated the embryo from six varieties of maize; it amounted, on an average, to 11.68 p.c. of the seed. The embryo and endosperm, dried at 60°, contained per cent.:—

	Fat	Albuminoids
Embryo	30.90	22.77
Endosperm	1.32	13.34

The whole of the fat seems to exist in the embryo, from which, indeed, oil may be

obtained by treatment with hot water and pressure. The albuminoids of the embryo are soluble, those of the endosperm insoluble.

By extracting maize-flour with spirit of 80–85 p.c. at a temperature of 40°–50°, Ritthausen obtains about 5 p.c. of an albuminoid which he calls maize-fibrin, having the percentage composition—carbon, 54.60; hydrogen, 7.51; nitrogen, 15.58; sulphur, .69; and oxygen, 21.53. It is similar in properties to wheat-fibrin, but is not soluble in dilute acetic acid; the maize-fibrin contains also 1 p.c. less nitrogen. By treatment with $\frac{1}{2}$ p.c. caustic potash, after the exhaustion with spirit, an albuminoid similar to conglutin is obtained, having the composition: carbon, 51.41; hydrogen, 7.19; nitrogen, 17.72; oxygen and sulphur, 23.68 (*Jour. f. prakt. Chem.* cvi. 471). Garbam's Zein is apparently a mixture of fibrin and casein.

The fat of maize resembles olive-oil; its percentage composition, according to König (*Landw. Versuchs-Stationen*, xiii. 241), is: carbon, 75.79; hydrogen, 11.43; oxygen, 12.78. According to Allemann it contains oleic, stearic, and palmitic acid.

R. W.

MALDONITE. This name is applied by G. Ulrich (*Sill. Am. J.* [2], 1. 272) to a native alloy of bismuth and gold occurring in the gold-bearing granito-veins at Nuggety Riff, Malden, Victoria, in small malleable spangles of flesh-red colour, changing to copper-red and black on exposure to the air. Cleavage parallel to $\infty 0\infty$. Hardness, 1.5 to 2.

MALEIC ACID, $C^4H^4O^4$. This acid is formed when silver succinate mixed with sand is heated to a temperature somewhat above 108°: $C^4H^4Ag^2O^4 = Ag^2 + C^4H^4O^4$. A small quantity of succinic acid is at the same time regenerated and a carbonaceous residue is left. (E. Bourgoïn, *Compt. rend.* lxxii. 52).

To explain the isomerism of maleic and fumaric acids, both of which are converted into succinic acid by addition of hydrogen, it must be assumed either that they are polymerides, or that one of them contains carbon-atoms with free combining units: thus

To decide this question, Hübner a. Schreiber (*Zeitschr. f. Chem.* [2], vii. 712) have determined the vapour-densities of ethyl fumarate and maleic anhydride, both of which can easily be obtained pure, and volatilise without decomposition. That of ethyl fumarate (determined in aniline vapour) was found to be 85.2 to 85.6 ($H=1$); the calculated value for the formula $C^4H^4(C^2H^3)^2O^4$ being 86; that of maleic anhydride was found to be 47 to 49.13, the calculated value for $C^4H^4O^4$ being 49. Hence it follows that fumaric and maleic acid have the same molecular weight.

MALIC ACID, $C^4H^4O^4$. According to Béchamp (*Compt. rend.* lxx. 999) calcium malate fermented with microzyme-chalk (1st Suppl. 614) yields alcohol, acetic, propionic and butyric acids, and free hydrogen.

On *Adipomalic acid, $C^6H^{10}O^4$* , see p. 29.

On the *Nitrins of Malic Ethers*, see NITRINS.

MALT. Malt is prepared by soaking barley in water for about 50 hours. The barley is then thrown on a floor, and allowed to germinate, with frequent turning, until the plumule has reached two-thirds the length of the grain; the radicle is earlier developed and attains a greater length. The malt is then dried in a kiln, and finally screened to remove the radicle and plumule, which constitute malt-dust. 100 parts of barley yield about 80 of kiln-dried malt, and 2 or 3 parts of malt-dust. In the process of soaking about $\frac{1}{2}$ p.c. of the dry matter of the barley is removed, the loss being chiefly nitrogenous and cinereal matter. In germination a considerable amount of organic matter is lost by oxidation. The total loss in the production of screened malt will be about 10 p.c. of the dry matter of the barley; but if the malt-dust is included in the product, the loss will be about 8 p.c. The loss is of course greater the further germination is allowed to advance. Malt of the same degree of dryness contains less ash, and generally rather less nitrogen than the barley from which it was made, the loss falling most heavily upon these constituents; if, however, the malt-dust is included in the product, the loss chiefly falls on the non-nitrogenous organic matter.

The alteration in general composition during malting is shown in the following table, which gives the percentage composition of the perfectly dry grain in various stages of the process, also the percentage of water in the natural condition. The experiments quoted are taken from the Report of Mr. Lawes to the Board of Trade, 'On the relative Values of Unmalted and Malted Barley as Food for Stock,' 1866.

	Barley	Barley after steeping	4½ days on the floor	8 days on the floor	12½ days on the floor	14½ days on the floor	Screwed Malt	Malt- dust
Sugar . . .	2.66	1.56	8.16	10.10	11.67	12.14	11.01	11.35
Starch, dex- trine, and fat	80.42	81.12	74.72	72.16	70.73	70.09	72.03	43.68
Albuminoids	9.83	9.83	9.89	10.14	10.27	10.39	9.95	26.90
Fibre . . .	4.69	5.22	1.96	5.18	4.98	5.03	4.84	9.67
Ash . . .	2.50	2.27	2.27	2.23	2.35	2.35	2.17	8.40
Water in frosh	17.64	42.70	41.87	41.65	40.71	40.44	6.66	11.73

The determination of sugar in malt is attended with considerable uncertainty; in the above analysis the powdered malt was stirred with cold water for several hours, and the sugar in the solution determined by fermentation and by copper. O'Sullivan informs the writer that alcohol of 91 p.c. extracts 10-12 p.c. of solid matter from malt. This extract chiefly consists of carbo-hydrates, but contains (by the copper test) only about 1.5 of sugar reckoned as dextrose; the sugar is, however, neither dextrose nor maltose, and its nature is not yet established. The cold water extract of malt amounts to 18-30 p.c.; it contains, according to O'Sullivan, both dextrin and maltose, the latter being formed by the action of soluble nitrogenous matter or the gelatinised starch of the malt produced during kiln-drying; ungelatinised starch is not converted into sugar in the cold by extract of malt; the amount of gelatinised starch in malt varies much according to the treatment of the kiln. C. Graham states (*Jour. Soc. Arts*, xxii. 251) that absolute alcohol extracts no sugar from malt, and alcohol of 80 p.c. very little. With alcohol of 80 p.c. 5.68 p.c. of sugar was in our experiment extracted, and nearly the same amount of sugar was removed by 15 minutes extraction with cold water; 30 minutes extraction with cold water gave 7.14 p.c. of sugar. As the sugar was determined by copper, the latter weights should probably be increased (*vide infra*).

Malt contains about 4-7 p.c. of water. In the process of malting the starch has been partially destroyed and converted successively into soluble starch, dextrin, and sugar. Maltin, the soluble albuminoid which effects these changes, has been already described (*1st Suppl.* 801); all soluble albuminoids possess this property to a greater or less extent. When extract of malt acts upon starch-paste the same changes occur, achrodextrin (the dextrin not coloured by iodine) being produced, on which the further action of malt is but slow (Brücke, *Wien. Acad. Ber.* lxx. [3], 126), and the final product is a sugar called maltose (iii. 799). Maltose has been recently shown by O'Sullivan (*Jour. Chem. Soc.* 1872, 579), to be isomeric with cane-sugar; it reduces only 65 p.c. as much cupric oxide as the same weight of glucose; the latter fact explains the opinions hitherto held (founded on experiments with cupric oxide) that two of glucose and one of dextrin were the final products of the action of malt on starch. O'Sullivan confirms the statement of Dubrunfaut that the rotatory power of maltose is nearly three times as great as that of dextrose, being +150. Maltose is readily soluble in 31 p.c. alcohol.

From the great solvent action of malt on starch, it has been suggested that malt would assist the digestion of animals; the trials conducted by Mr. Lawes, referred to above, have shown, however, that with healthy animals the addition of malt to their vegetable food produces a less increase of weight than the addition of the quantity of barley to which the malt is equivalent. From an economical point of view malting is therefore undesirable for feeding purposes.

Malt-dust is used for cattle-feeding; it will vary in composition according to the amount of growth attained; it is remarkably rich in nitrogen and ash constituents. The ash is often contaminated with sand, but the pure ash is not less than 6 p.c. The following is the mean of 11 analyses of malt-dust:

	Water	Albumi- noids	Fat	Fibre	Soluble carbo- hydrates	Ash
Malt-dust . . .	9.52	23.65	2.19	12.51	44.87	7.38

The mean of two analyses of the ash of malt-dust by J. O. Lerner (*Jahrb. Agri. Chem.* 1866, 433) is as follows:

K ₂ O	Na ₂ O	CaO	MgO	Al ₂ O ₃	Fe ₂ O ₃	P ₂ O ₅	SO ₂	Cl	SiO ₂	CO ₂	Ash p. c.
28.77	2.65	3.54	3.44	.75	1.08	29.92	2.91	7.41	18.36	.91	6.55

Lerner (*see above*) states that he has detected in malt-dust, citric, malic, lactic, propionic, acetic, formic, succinic, oxalic, and tannic acid; also cholesterin and asparagin. R. W.

MANDELIC ACID, C⁸H⁸O³. This acid, which has the constitution of phenyl-glycolic acid, C⁶H⁵—CH $\begin{matrix} \text{OH} \\ \text{COOH} \end{matrix}$, is formed synthetically by boiling the compound of benzoic aldehyde and acid sodium sulphite for several hours with potassium cyanide and alcohol, whereby the nitril of mandelic acid is produced—

then distilling off the alcohol, and decomposing the residual brown mass by boiling with water and hydrochloric acid. The acid liquid is evaporated to dryness, the residue is redissolved in water, and the solution saturated with barium carbonate. On evaporating the resulting solution of barium mandelate to dryness, washing the residue with a mixture of alcohol and ether till it becomes white, and decomposing it with dilute sulphuric acid, a solution is obtained from which mandelic acid may be extracted by ether; it may then be purified by recrystallisation from water (O. Müller, *Deut. Chem. Ges. Ber.* iv. 980).

MANGANESE ORES. The Manganese ores of Virginia imbedded in the Potsdam sandstone yield by analysis, after being superficially separated from intimately admixed quartz and micaceous ochre:

Mn ₂ O ₃	MnO	Fe ₂ O ₃	Al ₂ O ₃	CaO	MgO	SO ₂	P ₂ O ₅	SiO ₂	H ₂ O
65.20	4.75	6.20	3.93	1.43	0.41	0.30	0.42	14.20	3.02 = 99.86.

The micaceous ochre contains:

Fe ₂ O ₃	Mn ₂ O ₃	Co ₂ O ₃	P ₂ O ₅	H ₂ O	Mica
31.20	1.28	0.23	0.13	5.75	61.18 = 99.77.

The mica contains 34.48 p.c. silica, 20.65 alumina, 2.99 magnesia, and 3.6 potash (J. E. Mills, *American Chemist* [2], ii. 49).

On *Manganese in Iron and Steel*, see *Iron*, p. 691.

Manganese in Blood.—Manganese exists in ox-blood, in the corpuscles as well as in the serum, both of which also contain iron. The ash of the corpuscles contains larger quantities of those metals than that of the serum. The portion of the serum-ash which is soluble in water contains traces of iron, but no manganese (G. Campani, *Gazzetta chimica italiana*, i. 469).

Metallic Manganese. A. Valenciennes (*Compt. rend.* lxx. 907) prepares this metal by reducing the pure dioxide with charcoal in a crucible lined with magnesia. Manganese thus obtained is very hard and brittle, so that it easily splits under the hammer into fragments, which have the white colour of cast iron, but are quickly oxidised in contact with the air.

The smelting of manganese ores on the manufacturing scale has been studied by Hugo Tamm (*Chem. News*, xxvi. 111), who has succeeded in obtaining refined manganese containing 99.9 p.c. of metal.

The following is an outline of the process:—

Fluxes.—Two fluxes are required. No. 1, or white flux, is prepared by mixing together ground glass 63 parts, quicklime 18½ parts, fluor-spar 18½ parts. It is a fusible flux, and is principally required for the preparation of No. 2, or green flux.

The latter is made by smelting together:—Flux No. 1, 34 parts; lamp-black or soot, 5½ parts; manganese dioxide, of good quality, 60½ parts. The slag obtained in this operation alone is required. It presents a fine green colour from the presence of manganates, and when once prepared may be used over and over again, provided the manganese ore reduced is of tolerably good quality. It requires from time to time the addition of a little white flux to increase its fusibility.

Crucibles.—On account of the high temperature required for the reduction of manganese, some difficulty was experienced in obtaining a crucible which would withstand the action of the molten flux, but it was finally overcome by lining the crucible with a paste made by mixing 3 parts of plumbago and 1 part of loam or fire-clay with a

small quantity of water. This lining, which should not under any circumstances exceed half an inch in thickness, effectually protects the crucible.

Smelting the Ore.—The following proportions are recommended:—

Manganese dioxide, of good quality	1000 parts
Lamp-black or soot, " " "	91 "
Green flux " " "	635 "
Oil in sufficient quantity to wet the mixture.	

The mixture is introduced into a crucible prepared as above directed, and a cover of thick wood placed over it. The wood is carbonised during the smelting, and forms a charcoal cover which protects the mixture from oxidation. A clay cover is subsequently luted over the whole. The crucible is then placed in a wind-furnace, and slowly heated as long as fumes escape; the fire is then urged, and the crucible maintained at a white heat for several hours, the time actually required depending upon the quantity operated on.

When cold, the contents of the crucible are turned out, and the button of metal is detached from the slag, and preserved in a well-closed bottle.

Refining.—The cast manganese obtained by smelting an ore containing 79.5 p.c. of manganese peroxide was found to contain manganese 96.9, iron 1.05, with traces of carbon, silicon, and other metals. It may be refined by re-melting it in a close crucible, with one-eighth of its weight of manganese carbonate.

Refined manganese presented the following composition:—

Manganese	Iron	Silicon	Carbon	
99.91	0.05	0.015	0.025	= 100.36.

Specific Gravity.—J. E. Loughton (*Chem. News*, xxv. 139) finds that metallic manganese of sp. gr. 7.84 prepared by heating the peroxide made up into balls with charcoal and oil, may be rendered denser by repeated reheating with charcoal, its specific gravity being ultimately raised to 7.903; hence he concludes that the low density of certain specimens prepared by the older methods was due to the presence of oxide. He did not succeed in preparing manganese of sp. gr. 8.015, as obtained by Deville.

Detection and Estimation of Manganese. Fresenius (*Zeitschr. anal. Chem.* xi. 113) has examined and compared the various methods used and proposed for the precipitation of manganese from solution. Known quantities of the metal were taken for each experiment, and the weight of the precipitate obtained was checked by determining the quantity left in the mother-liquor and wash-waters.

Guyard's method of throwing down the manganese as dioxide by addition of an excess of potassium permanganate (1st Suppl. 803) gave results considerably too high. W. Gibbs's method of precipitating by oxalic acid in presence of an excess of strong alcohol, and washing with nearly absolute alcohol, gave about 99 p.c. of the manganese present, the rest remaining in solution.

Gibbs's other plan of converting the manganese into phosphate of manganese and ammonium by adding ammonia in excess to the boiling acid solution containing sodium phosphate, and then washing with boiling water, after keeping the whole for about an hour at the boiling point, gave very constant and correct results, especially when cold water was used for washing and the quantity of the wash-water diminished as much as possible by the use of the sucking filter. The phosphate of manganese and ammonium is soluble in 32,092 parts of cold, and in 20,122 parts of boiling water. The precipitate is ignited, and weighed as pyrophosphate.

Precipitation of Manganous Sulphide.—The circumstances affecting the accuracy of this method were examined, with the following results:—1. A great excess of ammonia causes the results to come out a little too low. 2. Even a great excess of ammonium sulphide does no harm. 3. Great excess of sal-ammoniac interferes slightly with the precipitation. 4. Yellow ammonium sulphide is at least as good as colourless. The presence of tartaric acid has no effect. 6. Citric acid almost entirely prevents the precipitation of manganous sulphide.

In estimating the small quantities of manganese left in solution, it is customary to drive off the excess of sal-ammoniac by heat, but Fresenius finds that the latter body carries with it a very considerable quantity of manganese.

Hugo Tamm's method of precipitating with ammonium carbonate gives very exact results, very little affected by the presence of sal-ammoniac even in large quantities.

A. Classen (*ibid.* 370), from an examination of the circumstances attending the precipitation of manganese by ammonium sulphide from solutions containing sal-ammoniac and free ammonia, recommends that the ammonium sulphide used for the precipitation should not contain free ammonia, and that the manganese solution should not contain excess of sal-ammoniac or of ammonia.

J. H. Talbut (*Deut. Chem. Ges. Ber.* iv. 279) recommends the precipitation of man-

ganate by ammonium sulphide from a boiling solution containing sal-ammoniac. The precipitate, which is pulverulent and easy to wash, is dissolved in hydrochloric acid, and the manganese estimated as pyrophosphate.

According to E. Prior (*Zeitschr. anal. Chem.* viii. 428) the precipitate formed in solutions of manganous salts, by the neutral and acid carbonates of the alkali-metals, consists of normal manganous carbonate, not of a basic carbonate. Even after the precipitate formed by sodium carbonate has been partially oxidised by exposure to the air, it still (after deduction of the quantity of manganoso-manganic oxide equivalent to the quantity of chloride evolved on heating it with hydrochloric acid) contains 1 mol. MnO to 1 mol. CO_2 .

For How's observations on the influence of fixed organic acids on the precipitation of manganese by ammonium sulphide, see 1st Suppl. p. 803.

T. M. Chatard (*Chem. News* xxiv. 196) has applied Crum's method of testing for manganese with lead dioxide and nitric acid (iii. 606) to the quantitative estimation of small quantities of manganese. He prepared a solution of ammonium oxalate of such a strength that 1 c.c. was equivalent to 0.0005467 gram of manganese. He then weighed out four portions of dolomite, dissolved them in nitric acid, added a little lead dioxide, and boiled, whereupon the red colour of permanganic acid was developed. The solution was passed through an asbestos filter by means of a filter-pump, and then titrated with the solution of ammonium oxalate:

Grams	Cub. cen.	Gram	p.c.
3.1300 dolomite required	39.0	= 0.0216 Mn	= 0.069
2.781 "	33.2	= 0.0181 "	= 0.065
2.0998 "	24.5	= 0.0134 "	= 0.063
1.8671 "	23.5	= 0.0128 "	= 0.062

The method yields good results only when the quantity of manganese present is very small; to large quantities it is not applicable, because it then becomes impossible to convert the whole of the manganese present into permanganic acid, either by means of sulphuric acid, nitric acid, and lead dioxide, or of sulphuric acid and lead dioxide alone.

On the Estimation of Manganese in Iron and Steel, see *IRON*, p. 690.

Valuation of Manganese Dioxide.—E. F. Teschemacher and J. Denham Smith (*Zeitschr. anal. Chem.* vii. 509) point out that the differences in the results of the valuation of manganese dioxide by different methods arise from the presence of magnetic iron oxide. One of the harder varieties, for example, gave, by Fresenius a. Will's oxalic acid method (iii. 814), 71.5 p.c. MnO_2 , whereas, by titration with a ferrous salt, it gave only 70.5 p.c.; but, after the iron oxide had been removed by a magnet, the first method gave 72.6, and the second 72.25 p.c. The examination of other samples of manganese dioxide showed that the strength of the magnetic properties of this substance always increases with its hardness; and in the same proportion do the differences in the results of the two methods increase.

E. Scheerer and G. Rumpf (*Zeitschr. anal. Chem.* ix. 46) have subjected the several methods in use for the valuation of manganese dioxide to a comparative examination. The dioxide which served for the experiments was an American sample which, when treated by Fresenius a. Will's method, gave 63.49 to 63.63 p.c. MnO_2 . Eight experiments were made by dissolving a weighed quantity of harpsichord-wire in hydrochloric acid in a flask filled with carbonic anhydride, introducing the manganese dioxide in a test-tube, and boiling till the reaction was complete; after which the excess of ferrous salt was estimated by titration with potassium chromate. The results varied between 61.39 and 62.54 p.c. MnO . In the next place weighed quantities of the dioxide were heated in a flask with fuming hydrochloric acid, and the evolved chlorine was passed into milk of lime. Titration by Penot's method with arsenious acid gave, in seven experiments, results lying between 68.16 and 68.30 p.c. Three experiments made according to Bunsen's iodometric method (the liberated iodine being estimated by Mohr's method with sodium thiosulphate), gave 62.73 to 62.76 p.c. MnO_2 . It appears, then, that only the first and last methods give results which agree satisfactorily among themselves, and the last alone gives the true commercial value of the sample.

Scheerer a. Rumpf further observe that, in the process depending on the oxidation of ferrous oxide, undecomposed manganese dioxide is often driven to the surface of the liquid, where it cannot act on the ferrous salt. They further regard the use of ferrous salts as unadvisable, on account of the difficulty of keeping them free from ferric oxide and moisture. With reference to the method of absorbing the chlorine by milk of lime, an attempt was made, but without success, to prevent the formation of calcium chlorate, which begins at 40° , by cooling the liquid with Glauber's salt and hydrochloric acid.

Scheerer a. Rumpf finally recommend Bunsen's iodometric method as the most accurate and simple of all. They think, however, that it is not advisable to use less than

half a gram of dioxide in each experiment; and they accordingly bring the resulting solution of iodine in potassium iodide to 250° c.c., and titrate 50 c.c. of this solution. They further point out that it is indisputably necessary to determine the iodine immediately after the evolution of chlorine, since, after a certain time, the results become altered by decomposition of hydriodic acid. The quantities of iodine found after the lapse of 24 hours represented 2 p.c. MnO_2 more than before.

F. Mohr (*Zeitschr. anal. Chem.* viii. 314) likewise regards the method of distilling the manganese dioxide with hydrochloric acid, receiving the evolved chlorine in solution of potassium iodide, and determining the liberated iodine by titration, as preferable to other methods of estimation, inasmuch as it depends on the evolution of chlorine by the method actually employed in manufacturing operations. He titrates the iodine with a $\frac{1}{10}$ -solution of sodium thiosulphate.

Fresenius (*Zeitschr. anal. Chem.* ix. 63) recommends that, in performing Bunsen's method of iodometric estimation, the peroxide to be valued should be mixed with magnesite, in order to produce a slow evolution of carbon dioxide, and thereby prevent the potassium iodide solution from being driven back into the generating flask.

E. Luck (*Zeitschr. anal. Chem.* xi. 310) has examined the various disturbing influences that may interfere with the results of Fresenius a. Will's method of manganese analysis. In the analysis of manganese dioxide containing ferrous oxide, by the iron method, and other methods in which the dioxide is directly acted on by hydrochloric acid, the practical value of the sample is at once determined; but in the oxalic acid process of Fresenius a. Will the presence of iron in the sample may cause the value given by the analysis to exceed the actual working value by a number proportional to the fractional amount of the ferrous oxide which, from various circumstances, has escaped further oxidation. Results in accordance with those of other methods may, however, be obtained by adding to the liquid 6 to 8 c.c. of a solution of sodium acetate (1 : 9), inasmuch as, in presence even of small quantities of acetic acid, the ferrous oxide is completely oxidised without the carrying forward of acetic acid vapours by the escaping carbon dioxide. In carrying out the process of Fresenius a. Will it is, however, necessary that the temperature be not allowed to rise above 70°, and that the apparatus, during and after the analysis, be protected from direct sunshine; since, on the one hand, the mutual action of sulphuric acid, oxalic acid, ferric oxide, and a manganoous salt, gives rise at 80°-82° to the evolution of a small quantity of carbon dioxide, and, on the other hand, the formation of carbon dioxide, which takes place under certain circumstances, becomes much more considerable under the influence of direct sunshine.

On circumstances affecting the accuracy of Fresenius a. Will's oxalic method, see also J. Pattinson (*Chem. News*, xxi. 267); E. Scheerer (*ibid.* 284; *Jahresb. f. Chem.* 1870, 991, 992).

Alloys of Manganese. Some of these alloys have been examined by F. Fenwick Allen (*Chem. News*, xxii. 194). They cannot well be prepared from metallic manganese, on account of the difficulty of separating the metal from its compounds. To obtain a copper-alloy, a mixture of pure manganic oxide or manganoous carbonate was fused with cupric oxide and charcoal in a plumbago crucible at the highest attainable temperature. The alloy, which was afterwards found disseminated through the mass in granules, fused with moderate facility. An alloy of 75 parts copper and 25 manganese was very hard and brittle while hot, but very elastic and easy to roll when cold. By the addition of zinc, an alloy was obtained resembling the inferior sorts of nickel-silver, and easy to work either hot or cold. The experiments were repeated with similar results in a crucible capable of containing 100 pounds of metal. An alloy containing from 5 to 30 p.c. manganese was more malleable, ductile, and tough than copper. Mixed alloys of manganese with tin, lead, and other metals, are well adapted for the journals of machinery. Such alloys cannot be prepared on the large scale in plumbago-crucibles, as too much manganese passes into the slag, and the wear of the crucible is very considerable. They are best prepared in a Siemens' furnace with reducing flame.

A. R. v. Schrötter (*Wien. Akad. Ber.* [2te. Abth.] lxxiii. 451) states that the method of preparing manganese alloys on the large scale was discovered in 1849 by the late Hofrath R. v. Gersdorff. Schrötter himself also prepared an alloy of manganese and copper by igniting manganoous-manganic oxide with cupric oxide and charcoal, and, in like manner, an alloy of manganese, copper, and zinc.

Respecting the alloys of manganese and iron (ferromanganese, spiegelmaess), and their use in the manufacture of steel, see IRON (p. 699).

Manganoous Chloride, MnCl_2 . According to Knecks (*J. pr. Chem.* [2] v. 105) this salt exhibits remarkable changes of colour when its aqueous solution is evaporated to certain degrees of concentration. On concentrating it at a temperature between

70° and 100°, the solution, which is at first colourless, becomes rose-coloured, afterwards yellow, and finally, before crystallising, a splendid green. A solution of rose-coloured crystals of manganous chloride in 10 to 12 parts of water is colourless, either cold or boiling. On evaporating on the water-bath, a little over 70°, and strongly concentrating, the rose colour is developed and gradually increases in intensity, the maximum tint being attained when the solution contains about 15 p.c. of the salt. On further concentration the rose-tint passes into orange, and at last, when the strength of 20 p.c. is attained, the colour becomes a clear yellow, like that of a solution of potassium chromate. On cooling below 70° the rose-tint is regained. Crystallised manganous chloride, dried at 100°, forms a clear green mass, not hygroscopic like the original salt. This mass dissolves partially in water, with liberation of heat, yielding a red solution. The undissolved portion is a white pulverulent basic salt, soluble in dilute acid (Krecke).

According to K. J. Bayer, on the contrary (*ibid.* 445), perfectly pure manganous chloride does not exhibit these remarkable changes of colour; but if small quantities of ferric chloride or cobaltous chloride be previously added to the manganous solution, the changes of colour make their appearance during evaporation exactly in the manner described by Krecke. In the case of cobalt chloride the colour is so characteristic that it may serve very well for the detection of small quantities of cobalt in a concentrated solution of manganous chloride.

Bayer remarks, also, that pure anhydrous manganous chloride is not green, but an easily fusible red body, which solidifies, on cooling, to a beautiful crystalline mass, having a lustre like that of magnesium chloride.

Oxides. The oxides MnO^2 and Mn^2O^4 are reduced to manganous oxide, MnO , by carbon monoxide at the temperature of melting zinc; MnO^2 suffers the same reduction even at a heat just below redness (L. Boll, *Chem. News*, xxiii. 258).

Pure manganous oxide may be prepared as follows:—A solution of potassium permanganate saturated at 60°, filtered through paper free from lime, is added to a saturated oxalic acid solution, and the liquid is decomposed with acetic acid and boiled. The precipitate is repeatedly washed with water by subsidence and decantation, dried in a platinum basin, ignited and reduced in a stream of pure dry hydrogen. Thus prepared, manganous oxide has a light green colour, the solution in dilute hydrochloric acid being slightly brown (F. Kessler, *J. pr. Chem.* [2], vi. 172).

Pyrolusite, MnO^2 , from Giessen, contains, according to an analysis by E. Stapf (*Arch. Pharm.* [2], cxliii. 194):—

MnO ²	FeO ²	AlO ²	CaO	BaO	MgO	CoO	
94.32	1.98	0.66	1.97	0.43	0.065	trace	= 99.425.

Manganates and Permanganates. The preparation of a number of these salts on the large scale is described by E. Desclabissac (*Dingl. pol. J. cci.* 58). a. 500 lbs. of potash-ley (45° B.) and 100 lbs. potassium chlorate are evaporated down in an iron pot, 182 lbs. of finely pounded manganese dioxide are added, and the mixture is heated till it fuses quietly. The mass, after being stirred till it is cold, is heated to redness in iron pots, and after again cooling is boiled out with water.

b. A solution of 12 parts sodium hydrate (36 parts soda-ley of sp. gr. 1.337 and 34 parts soda-ley of sp. gr. 1.365) is fused with 12 parts potassium chlorate and 18 parts manganese dioxide till the mass begins to crumble. The mixture is then heated to redness in an iron melting-pot, and after cooling exhausted with 200 to 220 parts of hot water.

c. Ten parts of caustic soda and 1 part potassium nitrate are fused together, and 6 parts of strongly heated manganese dioxide are thrown into the quietly fusing mass. The fused mass in the crucible, as soon as it dissolves as completely as possible in water with a deep green colour, is ladled out, and the crucible immediately recharged. The muddy deposit which remains in the pot when the melted mass is dissolved in water, is lixiviated with water, and this water is utilised for dissolving a new melt; or chlorine is passed into the aqueous solution, and the resulting liquid is used as a disinfectant.

d. Tessié du Mothay and Maréchal work up the fused mass of sodium manganate—which they obtain by melting the residues of chlorine preparations with caustic soda in contact with the air—to sodium permanganate, by treating it with magnesium sulphate. The reaction is represented by the equation—

With reference to this process, Desclabissac observes that contact of air is essential to the formation of good oxidation-products, the oxidising salts alone not being sufficient for the purpose. Manganese dioxide and sodium nitrate heated together to redness for a considerable time in the muffle of a stone-ware furnace, and lixiviated with hot water

after cooling, yield a solution which on cooling deposits nearly colourless crystals having the composition $\text{Na}^+\text{MnO}_4^- + 10\text{H}_2\text{O}$. These crystals in dissolving in water are partly decomposed and acquire a green colour.

Decomposition of Potassium Permanganate by Sulphuric Acid.—Spieß (*J. pr. Chem.* [2], i. 421) observes that when pure sulphuric acid is poured upon this salt in the state of powder, violet vapours are evolved which condense in the neck of the flask to a brown-black sublimate, which turns brown when treated with water and yields a solution containing sulphuric acid and manganous oxide, but no potash. Heated with strong sulphuric acid it gives off gas, and yields a dark violet solution, which when diffused in water assumes the colour of a manganous salt. Kolbe (*ibid.* 423) is of opinion that the sublimate obtained by Spieß was probably nothing but permanganic acid containing a little sulphuric acid. He remarks also that Unverdorben (*Pogg. Ann.* vii. 322), by distilling potassium permanganate with sulphuric acid, obtained a red transparent gas which was quickly resolved into manganic oxide and oxygen (*vide* PERMANGANIC ACID, iii. 819).

Action of Reducing Agents.—According to Aschoff (*J. per. Chem.* lxxxi. 20 : *Jahresb.* 1860, 167) a neutral solution of potassium permanganate is coloured green by addition of caustic potash. Mohr, however (*Zeitschr. anal. Chem.* ix. 43), has shown that this effect is produced only when the caustic alkali contains organic matter. A solution of the permanganate mixed with previously fused caustic soda may be heated to boiling without turning green. An alkaline solution of permanganate affords indeed an extremely delicate test for the presence of organic matter and of reducing substances in general. Sugar, gum, paper, starch, and other organic bodies which do not act readily on permanganic acid in acid solution, instantly turn it green in presence of excess of alkali. The alkaline solution of permanganate is also a very delicate test for thiosulphates (see further *Jahresb. f. Chem.* 1870, 333, 995).

Manganous Sulphide. According to F. Muck (*Zeitschr. f. Chem.* vi. 6) flesh-coloured manganous sulphide is not altered by heating to $140^\circ\text{--}150^\circ$ for four or five hours in a sealed tube with water, hydrogen sulphide, and ammonia; yellow ammonium sulphide under the same circumstances completely converts it into green manganese sulphide; potassium polysulphide forms a closely adhering violet precipitate, but leaves the manganous sulphide otherwise unaltered; caustic potash decomposes it, with formation of greyish-white manganous hydrate. Under ordinary pressure, water, ammonia and potassium polysulphide do not act upon manganous sulphide; when treated with a very large quantity of ammonium sulphide it turns green, but it is not acted on by a small quantity of that reagent, and not even when first warmed with a small quantity of it and then mixed with a large excess. Potash-ley decomposes manganous sulphide even in the cold, more quickly on warming, the sulphide not being reproduced; on the other hand, recently prepared manganous hydrate is but slowly converted into manganous sulphide by sodium sulphide, though easily by ammonium sulphides.

A. Wagner (*Dingl. pol. J.* xcxy. 532) has examined the behaviour of hydrogen sulphide towards manganese compounds, and the regenerability of manganese sulphide, with reference to the use of manganese compounds for the purification of coal gas from hydrogen sulphide. A stream of hydrogen sulphide was passed for six hours over air-dried manganous hydrate, whereupon the mass became very hot, and the product was exposed for a week to the action of the air. It was then found to contain 34.4 p.c. Mn^2O^3 , 32.2 MnS, 1.5 MnSO_4 , 23 p.c. sulphur soluble in carbon sulphide, and 8.2 water. Hence it appears that a week is not sufficient for the regeneration of the manganous sulphide. Moist carbon dioxide expels hydrogen sulphide from manganese sulphide; hydrogen sulphide, on the contrary, acts but very slowly on manganous carbonate. Manganese dioxide tolerably free from iron decomposed hydrogen sulphide completely; after the mass had been exposed to the air for a week, it gave off only traces of hydrogen sulphide when treated with hydrochloric acid, and then contained only 6.1 p.c. free sulphur to 33.1 p.c. manganese; only traces of the sulphur had been oxidised to sulphuric acid. Manganese dioxide, which had been treated with hydrogen sulphide, gave off that gas when carbon dioxide was passed over it, and contained, after regeneration, 5.0 p.c. sulphur to 29.9 p.c. Mn.

MANGANESE SPAR, MnCO_3 . (1.) A highly calcareous variety of this mineral, rose-coloured, and of sp. gr. 3.032, occurring with willemite at Minehill, Sussex Co., New Jersey, has been analysed by W. T. Roepper (*Sill. Am. J.* [3], i. 37); (2.) Manganese-spar from Dietz in Nassau, forming a flesh-coloured nodular coating on clay-slate, by Höhn a. Enders (*Arch. Pharm.* [2], cxliii. 198).—

MnCO ²	CaCO ²	FeCO ²	MgCO ²	CoCO ²	Insoluble	
43.64	50.40	0.76	6.69	—	0.08	= 100.47
90.88	1.96	6.85	0.41	0.91	—	= 100

MANGANITE, $H^2(Mn^2)O^4$. On the isomorphism of this mineral with chrysoberyl, diaspore, and gôthite, see p. 572.

MANNITE, $C^6H^{14}O^8$. *Formation*.—Linnemann (*Ann. Ch. Pharm.* cxxiii. 136) found that invert-sugar is converted by nascent hydrogen (water and sodium amalgam) into mannite. Dewar (*Phil. Mag.* [4], xxxix. 345) confirms this statement, but considers that there is no ground for supposing that lavulose is the only kind of sugar that can be converted into mannite by addition of hydrogen. In no case is the conversion of the sugar into mannite complete, a gummy uncrystallisable substance being always formed at the same time. Glucose from honey also yields mannite when treated as above. Milk-sugar does not appear to be converted into dulcitol under similar circumstances.

Optical Rotatory Power.—Mannite has hitherto been classed among substances inactive to polarised light: for though many of its substitution-derivatives rotate the plane of polarisation, this power had not been directly demonstrated for mannite itself. Recently, however, L. Vignon (*Ann. Chim. Phys.* [6], ii. 433; *Compt. rend.* lxxvii. 1191) has established the existence of this power in mannite, by mixing its saturated solution with boric acid or borax, and examining the action of the resulting liquid on polarised light. Boric acid indeed is known, from the researches of Biot and Pasteur, to possess the singular property of augmenting the rotatory power of tartaric and malic acids; and Vignon finds that it likewise increases the optical activity of mannite to such an extent that a dextrorotatory action can be clearly perceived, a mixture of the saturated solutions of mannite and boric acid producing in a Soleil's apparatus, with a tube 200 mm. long, a deviation of about 5 degrees.

On evaporating this solution over the water-bath, a viscid mass is obtained, which when treated with absolute alcohol, gradually changes to a white powder consisting of mannite, again appearing inactive to polarised light, and the boric acid is found in the alcoholic solution, with all its usual properties. It appears, therefore, that the boric acid has not entered into chemical combination with the mannite. On adding crystals of sodium carbonate to the mannite-boric solution, the salt dissolves with effervescence and the dextrorotation increases to 20 degrees. A similar result is obtained on adding borax to a saturated solution of mannite.

These facts show that mannite possesses rotatory power. The boric acid and borax do not combine with it, but merely increase, by an action which is peculiar to them, the dissymetry which pre-existed in the molecules of the mannite. It may, therefore, also be inferred that the rotatory power exhibited by the ethers of mannite, pre-exists in the mannite itself, and is not created by the act of etherification.

Arsenic acid and its salts likewise increase the rotatory power of mannite, the increase being progressive when the mixture is left to itself. Thus a mixture of mannite and arsenic acid which, immediately after solution, gave for the yellow ray in a tube 200 mm. long, $\alpha_D = + 0.3924^\circ$, gave after 24 hours $\alpha_D = + 1.090^\circ$; and a mixture of mannite with potassium diarsenate exhibited the following variations of rotatory power—

Immediately after solution	$\alpha_D = - 5.25^\circ$
After 24 hours	$\alpha_D = - 10.1783^\circ$
" 4 days	$\alpha_D = - 10.82^\circ$
" 6 days	$\alpha_D = - 10.82^\circ$

Pastour (*Compt. rend.* lxxvii. 1192) reports that Bichat, by operating with a tube 4 meters long, has obtained a direct demonstration of the rotatory power of mannite in aqueous solution.

Action of Water on Mannite at Different Temperatures.—Mannite, heated with water in sealed tubes for three hours, undergoes no alteration below 280° ; but at that temperature it is converted into a viscid product which, when purified in the manner to be presently described, has the composition of mannitic ether, $C^{12}H^{22}O^{11}$. The viscid product gradually deposits a small quantity of a crystalline body which pre-existed in the mixture; it is isomeric with mannitan, and is called, for distinction, mannitone.

Mannite, heated with water to 287° , no longer yields mannitone, but only mannitan, mannitic ether, and a small quantity of unaltered mannite.

Lastly, mannite, mannitone, and mannitic ether, heated, together or separately, with water to 295° , are completely transformed into mannitan (Vignon).

Chloro- and Bromo-Derivatives of Mannite (G. Bouchardat, *Compt. rend.* lxxiv. 1187; lxxvi. 1550; *Bull. Soc. Chim.* [2], xix. 199).

Dichloromannite, $C^6H^8(OH)Cl^2$, is prepared by heating 1 part of mannite with 6 parts of strong hydrochloric acid to 100° in a sealed tube for 6–10 hours. The product, dried over quick-lime and oil of vitriol for about a month, yields light yellow scales which, when dissolved in cold water and recrystallised, yield dichloromannite in monoclinic crystals soluble in 22 parts of water at 14° . This compound is laevogyrate, its molecular rotatory power for the yellow ray being -3.7° . The aqueous solution is neutral and tasteless, and is not precipitated by silver nitrate. Dichloromannite is insoluble in absolute alcohol and in ether. It melts at 174° , being at the same time decomposed; at a higher temperature it volatilises completely. Its vapour burns with a green-edged flame. Boiling water, or concentrated solution of alkali, rapidly converts it into monochloromannitan, thus:—

just as dichlorhydrin is converted into epichlorhydrin.

Nitrosulphuric acid converts dichloromannite into dichloro-tetranitromannite, $C^6H^8 \left\{ \begin{matrix} (NO^2)^4 \\ Cl^2 \end{matrix} \right\}$, which is insoluble in water, but soluble in boiling alcohol, separating from that solution, on cooling, in fine needles. This substance is not easily explosive, notwithstanding its composition; it is, in fact, more stable than dichloromannite. It melts at 145° .

Dibromomannite, $C^6H^8 \left\{ \begin{matrix} (OH)^4 \\ Br^2 \end{matrix} \right\}$, is prepared in a similar way to the analogous chlorine-compound, the mannite and hydrobromic acid being heated together for two hours only. Crystals appear after a considerable length of time, and are purified by rapid solution in hot water and cooling. Dibromomannite is tasteless, scentless, insoluble in cold water, alcohol, and ether, but soluble in warm water, and in concentrated hydrobromic acid. It crystallises in small colourless plates, melting, with decomposition, at 178° .

Nitrosulphuric acid converts dibromomannite into dibromo-tetranitromannito, $C^6H^8 \left\{ \begin{matrix} (NO^2)^4 \\ Br^2 \end{matrix} \right\}$, which crystallises in long needles, insoluble in water and in cold alcohol, but soluble in the latter when it is heated.

The compounds above described are isomeric with the dulcitol-ethers (p. 441); they give similar reactions, with one exception, viz., that when treated with alkaline hydrates, the mannitic ethers furnish mannitan, whereas those of the dulcitol series yield dulcitan, which may be recognised by converting it into mucic acid (Bouchardat).

Aceto-mannites (Schützenberger, *Ann. Ch. Pharm.* clx. 74).—Mannite, heated in an open vessel with acetic anhydride containing 10–15 p.c. of acid, dissolves, and the product, on cooling, becomes a mass of indistinctly-shaped crystals which, after separation of syrupy mother-liquor by filtration through asbestos by means of a filter-pump, and washing with alcohol, forms a solid, white, very light substance, apparently homogeneous, scarcely soluble in boiling alcohol, soluble in water and acetic acid, insoluble in ether: it has a faint, sweet and bitter taste, and is feebly dextrorotatory; its composition is that of a monacetyl derivative of di-mannitic anhydride, $C^{12}H^{22}O^{10}$, viz., $C^{12}H^{22}(C^2H^3O)O^{10}$. On saponification, this body yields a faintly sweet substance apparently identical with mannitan.

By the further action of acetic anhydride a thick syrup is obtained which, on treatment with water, gives a precipitate crystallisable from boiling water or alcohol; this is **hexaceto-mannite**, $C^6H^8(C^2H^3O)^6O^6$; it melts at 100° , and becomes crystalline on cooling. It has no action on polarised light. [According to Bouchardat it has a dextrorotatory power, $[\alpha]_D = +18^\circ$.] The syrupy mother liquors of this compound give on evaporation an extremely bitter substance easily soluble in water, acetic acid, and alcohol; it is dextrorotatory, $[\alpha] = 22.6^\circ$; has the composition $C^6H^{16}(C^2H^3O)^6O^6$, and appears to be identical with diacetomannitan (compare *1st Suppl.* 808).

MANNITIC ANHYDRIDES. 1. **Mannitic Ether**, $C^{12}H^{22}O^{11} = \frac{(C^6H^8)^2}{H^2} O^{11}$.

—This compound, the first anhydride of mannite, is formed, as above stated (p. 773), by heating mannite with water to 280° for three hours. On dissolving the product in water, filtering, evaporating to dryness, dissolving the residue in absolute alcohol, filtering, and again evaporating, a viscid substance is obtained which, after a while, deposits crystals. These may be separated from time to time by means of absolute alcohol, which dissolves the viscid substance and leaves the crystals; after about a

month they cease to form. The viscid mass is then redissolved in absolute alcohol; the liquid evaporated; the residue boiled for an instant with water; the resulting solution filtered through animal charcoal and evaporated to dryness; the residue washed with ether, and redissolved in absolute alcohol; the filtered solution once more evaporated to dryness; and the residue dried at 120° till it no longer loses weight.

Mannitic ether thus obtained is a slightly yellowish mass, having the consistence of turpentine, a bitter-sweet taste, very soluble in water and alcohol, insoluble in ether. It is levogyrate; $[\alpha]_D = -5.59^{\circ}$. It does not reduce potassio-cupric solution or ferment with yeast. It is not converted into mannite or mannitan by boiling for six hours with dilute sulphuric acid or baryta-water. It unites with strong sulphuric acid, forming a sulphonic acid identical with that obtained from mannitan. With a mixture of sulphuric and nitric acids it forms a nitro-derivative analogous to nitro-mannitan. Heated with water in a sealed tube for two hours it is completely transformed into mannitan.

All these reactions show that the compound in question is a true ether of mannite.

2. *Mannitan*, $C^6H^{12}O^6 = C^6H^{10}O^6 - H^2O$.—This compound was discovered by Bertholot, who obtained it by boiling mannite with hydrochloric acid, and by the saponification of mannitic ethers (iii. 825). Vignon (*Ann. Chim. Phys.* [5], ii. 458) prepares it by mixing pulverised mannite with half its weight of strong sulphuric acid, gradually heating the mixture, with constant stirring, to 125° , at which temperature it must be kept stationary. After about two hours the mixture is gradually saturated with barium carbonate, without allowing the temperature to fall, as otherwise too much sulphomannitic acid would be formed. After complete neutralisation the mass is left to cool and exhausted with absolute alcohol, the solution is filtered and evaporated over the water-bath, and the residue dried at 120° .

The viscid product thus obtained is mannitan. Its formation is due to direct dehydration of the mannite, not to the previous formation of sulphomannitic acid and its subsequent decomposition into sulphuric acid and mannitan. This is shown by the following facts. If barium sulphomannitate, prepared by heating 1 mol. mannite with 1 mol. sulphuric acid to 100° , saturating with barium carbonate, filtering, and evaporating, be heated to 125° for two or three hours, it quickly acquires an acid reaction, and, if the mass be then saturated with barium carbonate, it yields barium sulphate and mannitan; but if the sulphomannitate be heated to the same temperature, after being mixed with excess of barium carbonate, so that the mixture remains constantly neutral, the sulphuric acid being neutralised as fast as it is set free, no mannitan is formed, the only products obtained being barium sulphate and mannite. It is clear, then, that the production of mannitan in the former case arose from the action of the free sulphuric acid on the mannite resulting from the decomposition of the sulphomannitate. It may therefore be concluded that the formation of mannitan from mannite by the action of sulphuric acid is an act of simple dehydration.

Mannitan is a very viscous substance, having a saccharine, slightly caramellic taste; very soluble in water and in absolute alcohol, insoluble in ether. Its molecular rotatory power is $[\alpha]_D = +36.6^{\circ}$. It does not reduce potassio-cupric tartrate or ferment in contact with yeast. It deliquesces when exposed to the air, but is not converted into mannite even in the course of a month. Neither does it yield any perceptible quantity of mannite when heated for some hours with dilute sulphuric acid or baryta-water. When treated with a mixture of strong sulphuric and fuming nitric acid, it is converted into nitromannitan. Heated with oxalic acid, it reacts like a polyatomic alcohol, producing formic acid and carbon dioxide. It unites with sulphuric acid, forming a conjugate acid, the barium salt of which is uncrystallisable, easily decomposable, especially when heated, and very soluble in water.

Nitromannitan is prepared by gradually adding 1 part of mannitan to a mixture of 10 parts strong sulphuric acid and $\frac{1}{2}$ parts fuming nitric acid, keeping the mixture cool for a quarter of an hour, then pouring it into water, whereupon a copious white precipitate is formed, and a brownish-yellow liquid resembling melted phosphorus gradually falls to the bottom. This liquid is washed with water and digested with ether, which dissolves the nitromannitan, and the solution is evaporated at the ordinary temperature and further concentrated in a vacuum.

Nitromannitan is insoluble in water, but soluble in alcohol and in ether. When dissolved in a mixture of alcohol and ether it has a molecular rotatory power $[\alpha]_D = -52.26^{\circ}$.

When heated it gives off nitrous vapours and an odour like that of ethyl nitrate; then at a higher temperature the mass swells up and quickly takes fire, leaving a carbonaceous residue. It detonates violently under the hammer. Ammonium sulphhydrate easily reconverts it into mannitan having the same rotatory power as the original substance.

The physical characters and detonating properties of nitromannitan render it diffi-

ammonia and nitric acid than rain collected in country places; also that light showers are far more nitrogenous than long-continued heavy rain.

Agricultural statistics plainly show that more nitrogen is obtained from the atmosphere in an ordinary rotation than is on an average supplied by rain. If we take any well-established rotation, on soil not deficient in cinereal plant-food, and compare the amount of nitrogen in the crops with that supplied in the manure, we are forced to this conclusion. Whether this nitrogen is obtained from the air by the crops or by the soil, or if by crops, by which crops, are questions that are as yet very imperfectly answered.

The amount of ammonia in the atmosphere is, according to Ville, about 1 part in 50,000,000. In Boussingault's experiments, plants protected from rain, but allowed free access of air, assimilated only a very small quantity of nitrogen, the trace of ammonia in the air having no practical effect. Sachs, and latterly A. Mayer (*Deut. Chem. Ges. Ber.* vi. 1410), and T. Schlösing (*Compt. rend.* lxxviii. 1700), have grown plants in an atmosphere artificially enriched with ammonia; under these circumstances nitrogen was assimilated by the plant, but even then not to an extent sufficient for normal growth. The direct effect of the combined nitrogen of the atmosphere on the nourishment of crops is probably therefore but small. The question whether plants can assimilate the free nitrogen of the atmosphere has been already referred to (iii. 828).

Various chemists hold that the soil obtains nitrogen from the atmosphere. Ammonia is possibly absorbed in small quantity by the humus, clay, and ferric oxide of the soil. It has also been argued that the oxidation of organic matter in the soil must be attended with the formation of ozone, which, acting on the nitrogen of the air, may produce nitric acid. Boussingault has, however, lately shown (*Compt. rend.* lxxvi. 22) that nitrification in a vegetable soil is attended with a loss and not a gain of nitrogen. Lastly, P. Déhérain has shown (*Bull. Soc. Chim.* [2], xix. 538) that a mixture of glucose and caustic alkali exposed to pure nitrogen for some time may absorb a portion of the gas even in the cold, and the absorption becomes distinct if the temperature is raised; results less marked were obtained with moist sawdust. He thinks that ammonia is first produced, and then forms compounds similar to the *glucose azoté* of P. Thénard; no proof of the formation of ammonia is given. Déhérain concludes that in the lower layers of the soil, where little oxygen is present, the decomposing vegetable matter absorbs nitrogen and thus enriches the soil.

Against these possible accumulations of nitrogen by the soil and plant has to be placed the well-ascertained loss of nitric acid in drainage-water, with other possible sources of loss to be considered presently.

The conditions which affect the agricultural statics of nitrogen are thus both complicated and obscure. One set of facts—namely, the amount of nitrogen obtainable in the form of crops from land receiving no nitrogenous manure—is being gradually ascertained at Rothamsted. Mr. Lawes has kindly furnished the writer with the following figures, which represent approximately the amount of nitrogen, in pounds per acre, contained in crops growing continuously on the same land without nitrogenous manure. In the rotation experiment the crops consist of turnips, barley, beans or clover, and wheat. The whole of the crops are removed from the land.

Nitrogen removed in Crops grown without Nitrogenous Manure.

Nature of Crop and Manure	Average Nitrogen removed in crop per acre per annum
Wheat, 20 years } without manure, and with purely cinereal } Barley " } manure }	lbs. 20-25
Oats, 4 years, without manure, and with purely cinereal manure	18-23
Beans, 21 crops, without manure	about 30
" " with purely cinereal manure	" 45
Meadow-grass, 18 years, without manure	" 36
" " with purely cinereal manure	" 56
Rotation, 20 years, without manure	30-35
" " with superphosphate to turnips only	35-40

The above figures must be taken as simply representing the present state of the experiments. In some cases the crops are slowly falling off, showing that a part of the nitrogen in the crop has been obtained from past accumulations in the soil; in

other cases we have yet to learn whether the crops diminish, before we can safely conclude that the whole amount of nitrogen in the produce is obtained from the atmosphere. The figures show that leguminous crops yield far more nitrogen than graminaceous crops, even when nitrogenous manure has been for many years withheld. The mixed herbage of meadow-grass stands much higher than the cereals as to the amount of nitrogen harvested each year, and where cinereal manures are applied to the meadow the nitrogen annually removed in the crop reaches the maximum point in the table. In the latter case the manure has developed a very considerable growth of clover, which accounts in great measure for the high nitrogen obtained. This most interesting plot as yet shows no signs of falling off in its produce.

The production of clover on meadow-land by cinereal manures containing potash is of considerable interest. In 1856, at the commencement of the grass experiments at Rothamsted, the herbage appeared uniform upon all the plots; various manuring has, however, strikingly changed the character of the herbage. A series of botanical analyses of the hay has been made, the first only of which has been hitherto published (*Jour. Roy. Agri. Soc.* 1863); the following summary of the results for four of the principal plots has been kindly communicated by Messrs. Lawes and Gilbert.

Percentage Botanical Composition of Meadow-Hay variously Manured.

Manuring	1862			1867			1872		
	Gram- inaceæ	Legum- inoseæ	Other orders	Gram- inaceæ	Legum- inoseæ	Other orders	Gram- inaceæ	Legum- inoseæ	Other orders
No manure	71.52	7.15	21.33	62.27	8.07	29.66	66.18	9.58	24.24
Mixed cinereals	64.65	24.70	10.65	59.29	12.60	28.02	48.82	39.77	11.41
Ammonium salts	86.32	.12	13.56	71.85	.34	27.81	84.70	.46	14.84
Mixed cinereals and ammonium salts	88.59	.13	11.28	77.06	.16	22.78	92.19	.02	7.79

The cinereal manure supplies lime, magnesia, soda, phosphoric and sulphuric acids, besides potash; but where the potash only is omitted, the characteristic growth of clover ceases. It is seen that ammonia prevents the growth of clover even when potash is present.

In ordinary agriculture, as is well known, a great part of the constituents of the crops are returned to the land in the form of farmyard-manure, while the remainder is lost by sales of produce. The average loss of ash-constituents, in an ordinary rotation, by the sale of corn and meat, has been already given in detail (see previous article on MANURE, iii. 832-842). To complete the subject we proceed to consider the chemistry of farmyard-manure.

Farmyard-manure consists of the solid and liquid excrements of the stock of the farm, *plus* the straw used as litter. The value of the manure will depend greatly on the character of the animals contributing to it. In the case of a working animal, as a horse or draught-ox, the whole of the nitrogen and ash-constituents contained in the food will appear in the manure. In the case of fattening animals, or of animals producing milk or wool, a part of the nitrogen and ash-constituents of the food will be retained by the animal, and the manure will be of poorer quality. The quantity of nitrogen and ash-constituents contained in the various animal products of a farm, and consequently not recovered in the manure, will be gathered from the following table. The composition of the fat ox, sheep, and pig is deduced from the experiments at Rothamsted, in which whole bodies of animals were submitted to analysis.

Composition of the Animal Exports from a Farm.

	Nitrogen	Phosphoric acid	Potash	Lime	Magnesia
	lbs.	lbs.	lbs.	lbs.	lbs.
Fat ox, 1,000 lbs. fasted live } weight	23.18	16.52	1.84	19.20	.63
Fat sheep, 1,000 lbs. fasted live } weight	19.60	11.20	1.59	12.80	.50
Fat pig, 1,000 lbs. fasted live } weight	17.57	6.92	1.48	6.67	.35
Milk, 1,000 lbs.	6.25	2.03	1.80	1.56	.18
Wool (unwashed), 1000 lbs.	73.00	1.00	40.00	1.00	.70

The character of the food supplied to the farm-stock has, however, the greatest influence in determining the quality of the manure; the more nitrogenous and abundant is the diet, the higher will be the quality of the manure. A third element in determining the character of the manure is the nature and proportion of the litter used.

Supposing the quantity and kind of food and litter consumed on any farm to be known, it is possible to calculate pretty nearly what will be the quantity and composition of the farmyard-manure produced. Lawes and Gilbert have made such a calculation for a farm on the ordinary four-course rotation, assuming that 1 cwt. of oil-cake per acre per annum is consumed by the stock, and that the manure suffers no loss from drainage. The result they arrived at synthetically is given in the next table, with an abstract of the actual analyses of other chemists.

Percentage Composition of ordinary Farmyard-Manure.

	Lawes and Gilbert	Boussingault	Voelcker		E. Wolf	Anderson
	Calculated composition of fresh dung	Average composition	Fresh dung	Rotten dung	Average composition	Mean of 8 samples
Water . . .	70.00	79.30	66.17	75.42	75.00	72.48
Organic matter . .	27.23	14.03	28.24	16.63	18.09	13.94
Ash . . .	2.77	6.67	5.59	8.05	6.91	13.58
Potash53	—	.67	.49	.68	.32
Phosphoric acid . .	.23	—	.31	.45	.32	.31
Nitrogen64	.41	.64	.61	.53	.38

Lawes and Gilbert's calculated composition for fresh dung is lower in total ash than the actual manure, as this always contains an admixture of sand and earth. Boussingault's results relate to a mixed manure from horses, oxen, and pigs, the decomposition of which was moderately advanced. He found water to vary from 77.8 to 80.4 p.c., and the nitrogen in the dry matter from 1.7 to 2.4 p.c. The fresh dung, analysed by Voelcker, was 14 days old; it was the mixed produce of horses, cows, and pigs. The rotten dung was 6 months old, and of similar origin to the preceding. Anderson's results, relating to the manure of Scotch farms, show great variation and low quality. Water ranged from 58.64 to 83.02; organic matter from 7.24 to 21.68; potash from .10 to .60; phosphoric acid from .09 to .62; nitrogen from .19 to .49 p.c.

The composition of farmyard-manure is greatly dependent on the extent to which it has suffered decomposition, and on the losses of soluble matters which follow exposure to rain. Fermentation speedily commences in fresh dung, and a great loss of organic matter soon takes place; but, except under the influence of rain, the loss of nitrogen is but small. If the dung is exposed to the influence of rain and drainage, the loss of nitrogen and of soluble ash-constituents will, on the other hand, be very great.

Voelcker (*Jour. Roy. Agri. Soc.* 1856, 191) has investigated the losses farmyard-manure suffers during keeping. A considerable bulk of the fresh manure mentioned in the preceding table was kept for one year under cover, a similar bulk was kept for the same time in a heap exposed to weather, and a third portion of the manure was spread as in a yard. Under cover the organic matter fell in 6 months to 52 p.c., and in 12 months to 44 p.c. of the original quantity; but the nitrogen at the end of the year was still 90 p.c. of the original; the manure at the close of the experiment contained only 41.6 p.c. of water. The same manure exposed to weather during 6 winter months of little rain, contained 59 p.c. of its original organic matter; but at the end of the 12 months only 33 p.c. remained. The nitrogen was scarcely altered in the first 6 months, but at the end of 12 months, after a wet summer, it had fallen to 71 p.c. of the original amount. The manure spread in a yard suffered a far greater waste; at the end of one year it contained only 21 p.c. of the organic matter, and 41 p.c. of the nitrogen originally present. It is evident from these results that well-fermented dung is a more concentrated manure than fresh dung, since it has lost considerably in bulk, while but little of the nitrogen and none of the ash-constituents have escaped; on the other hand, if the dung is exposed to weather, and the drainage-water lost, the manure rapidly wastes, and the residue is comparatively worthless. The nitrogen lost by dung not exposed to rain disappears as ammonia and as free nitrogen.

In fresh farmyard-manure the nitrogenous compounds are mostly insoluble in water;

in well-fermented dung the proportion both of soluble nitrogen and of soluble organic matter is considerably greater. Farmyard-manure, even after fermentation, contains only a small part of its nitrogen as ammonia. The phosphates and silica in dung are to a great extent soluble.

The experiments at Rothamsted exhibit the quantitative relations of the manure to the crop produced; it is found that in no case is the whole, or nearly the whole, of the manure recovered in the produce. Thus, on the meadow-land, manure has been applied for 9 years, supplying the nitrogen and ash-constituents contained in 1 ton of hay; the average produce of this manure has been 33 cwts. During the same period the produce without manure has averaged 20 cwts.; the manure has thus actually produced only 13 cwts. per annum, and consequently only about 65 p.c. of the manure has been recovered in the crop. In the case of barley and wheat the relation of the nitrogen applied to the nitrogen found in the increase of the crops has been calculated for a period of 20 years, and in the case of oats for 3 years; the mean results are given below. In each case the crop was abundantly supplied with ash-constituents, and the increase due to the nitrogenous manure has been ascertained by subtracting from the produce yielded by the mixed cinereal and nitrogenous manure that given by the cinereal manure alone:—

Nitrogen Recovered in the Increase for 100 supplied as Manure.

Manures applied per acre	Wheat	Barley	Oats
Cinereals and ammonium salts (41 lbs. nitrogen) . .	32.4	48.1	—
" " " (mean 53.3 lbs. nitrogen) . .	—	49.8	—
" " " (82 lbs. nitrogen) . .	32.0	—	51.0
" " " (123 lbs. nitrogen) . .	31.6	—	—
" " " (164 lbs. nitrogen) . .	28.5*	—	—
Cinereals and sodium nitrate (82 lbs. nitrogen) . .	45.3	—	50.4
Cinereals and rape-cake (mean 61.75 lbs. nitrogen) . .	—	36.3	—
Farmyard-manure (about 200 lbs. nitrogen) . .	14.6	10.7	—

It is seen that the nitrogen recovered in the crop is at best only about one-half of that applied in the manure, and that with excessive applications of nitrogen the return is much less. The return is smallest of all in the case of farmyard-manure. This manure does not produce a larger crop than some of the artificial manures mentioned, the amount applied, though large, does not therefore appear to be relatively excessive; the low result is rather due to the fact that the nitrogen of dung exists principally in organic combinations, and becomes available to the plant only by a slow decomposition. In the case of wheat, all the manures, save the sodium nitrate, are applied to the land in the autumn, while in the case of barley and oats the manures are applied in spring-time. The wheat manures thus suffer a loss of winter drainage to which the barley and oat manures are not subject. A great part of the inferior result obtained with wheat is due to this cause, but not the whole of it, as other experiments confirm the statement of the table that barley gives a rather better return for nitrogen applied than wheat. In the rotation experiments the amount of nitrogen recovered in the produce appears to be decidedly larger than with wheat and barley, but details are not yet published.

A crop can never appropriate in one season the whole of the manure applied; for it is impossible that the whole can come in contact with the roots; but in a succession of seasons the whole of the manure should be recovered if none is lost by drainage, by exhalation, or by conversion into inert compounds within the soil. Repeated analyses of drainage-waters have shown that scarcely any phosphoric acid is lost in this direction, all soils containing any ferric oxide or alumina having a powerful retentive power for phosphoric acid. Potash also very seldom appears in drainage-waters, but they are comparatively rich in lime, sulphuric acid, nitric acid, soda, and chlorides. The analyses of the drainage-waters from the wheat-field at Rothamsted (Voelcker, *Jour. Chem. Soc.* 1871, 286, and Frankland, *Jour. Roy. Agr. Soc.* 1878, 387) show that the loss of nitrogen in the form of nitrates may be very considerable. The spring and summer drainage-waters from the plots receiving ammonia contain very little nitric acid, but the winter drainage-waters, following the autumn application of ammonium salts, seldom contain less than 1 part of nitrogen per 100,000, and this in many instances to much larger quantities, the amount being generally proportional to the quantity of ammonia applied. The drainage-water from the plots receiving

* Mean of 15 years only.

sodium nitrate reaches its maximum contents in nitrates shortly after the spring application of the manure, and in the case of heavy rain the amount thus lost is very considerable. From the plot which has received farmyard-manure for many years very little drainage-water is obtained, owing to the increased porosity of the soil, and it contains less nitric acid than the drainage-waters from any of the ammonia plots, the organic matter of the dung evidently checking oxidation. Lawes and Gilbert calculate that every inch of rain that passes beyond the range of the roots entails a loss of 2.20 lbs. of nitrogen per acre, if the drainage-water contains 1 part of nitrogen per 100,000; and from the evidence yielded by their drain-gauge, they conclude that one-third of the annual rainfall may pass below 40 inches, this drainage being chiefly confined to the winter months. It is quite evident then that a soil will lose a considerable amount of nitrogen by drainage. The great absorptive power of soil for ammonia was formerly thought to ensure the conservation of nitrogen when applied in this form, but the readiness with which ammonia is oxidised into nitric acid in an aerated soil destroys the safeguard just mentioned, and ammonium salts, like nitrates, should not be applied to land till the crop can make speedy use of them.

Besides loss of nitrogen in drainage-waters, some is possibly lost by exhalation. Boussingault found that snow which had lain on a garden bed contained much more ammonia than the snow collected from the neighbouring terrace. A soil rich in organic matter may also evolve nitrogen in a free state. T. Schlösing has shown (*Compt. rend.* lxxvii. 203, 353) that a moist vegetable soil containing nitrates, if confined in a small quantity of air, first absorbs all the oxygen, carbonic acid being produced; that the nitrates are then reduced with formation of ammonia; and that finally a quantity of free nitrogen is evolved in excess of the nitrates originally present, the organic nitrogen of the soil evidently therefore suffering loss. Nitrogen is apparently evolved in the free state during the decomposition of organic bodies only when oxygen has been admitted. Lawes, Gilbert, and Pugh obtained considerable quantities of free nitrogen from the decomposition of moistened beans, &c., when oxygen was admitted, but the gases evolved were only carbonic acid and hydrogen when oxygen was excluded.

The nitrogen of manure may also exist in the soil in a form unsuitable for assimilation by the plant and thus cease to be effective. Nitric acid appears to be pre-eminently the form in which nitrogen is most readily assimilated by plants. Whether ammonia is equally available seems open to doubt, some of the German water-culture experiments exhibiting ammonia as far inferior to nitric acid, while in other cases a normal growth was obtained when ammonia was the only source of nitrogen. The experiments of Cameron, Humpe, Wagner, and others have shown that urea, uric acid, hippuric acid, glycocine, and creatine are perfectly available forms of nitrogen to plants, and in the case at least of urea and creatine, they are taken up without decomposition, being easily detected in the living plant. On the other hand, the nitrogenous humus bodies, which form the bulk of the nitrogenous matter in vegetable soils, are clearly unable to supply nitrogen to plants (at least to cereals), a small quantity of a nitrate far surpassing in its effects a large quantity of nitrogenous peaty matter. By oxidation, and especially by treatment with lime, the nitrogen of the humus becomes, however, slowly available.

In the wheat-field at Rothamsted there is considerable evidence that the residues of ammoniacal manuring speedily assume a form unavailable for succeeding crops of wheat. Plots to which very large quantities of ammonium salts have been applied yield scarcely more produce than unmanured soil as soon as fresh additions of ammonia cease; yet analysis of the soil shows that a considerable accumulation of nitrogen has really taken place. It has been shown by P. Thénard and others, that ammonia is capable of combining with glucose and other vegetable substances at a high temperature, forming dark coloured nitrogenous bodies in which ammonia cannot be detected. Knop found that peat soils by long contact with ammonia absorbed considerable quantities, and that after this absorption it could not be again recovered in the form of nitrogen by treatment with sodium hypochlorite. It seems possible that nitrogenous matters of a similar character may be formed in the soil by the action of the ammonia applied as manure on decaying vegetable substances.

With regard to the ash-constituents of manure there can be little doubt that some of them, especially phosphoric acid, assume more or less insoluble forms after mixing with the soil, and cease to be as available for the plant as a fresh application of manure. The Rothamsted experiments, however, plainly show that residues of mineral manures are capable of producing a marked and long-continued effect on succeeding crops, and that in the case of wheat, residues of phosphates and alkalis are far more effective than residues of ammonia. For details of these results see Lawes and Gilbert's statements (*Jour. Roy. Agri. Soc.* 1873, 321).

From the considerable absorptive power of soil for phosphoric acid and potash, the

residues of these manures remain accumulated near the surface. Hermann v. Liebig (*Jour. Chem. Soc.* 1872, 318, 837) has analysed some of the soil of the Rothamsted wheat-field after 22 years' application of manure: he finds the accumulation of phosphoric acid and potash to be chiefly in the first 9 inches of soil, and none has apparently passed below the second 9 inches.

R. W.

MAXITE. This name is given by Laspeyres (*J. pr. Chem.* [2], v. 470) to a hydrated sulphato-carbonate of lead found in the Mala-Calzetta mine, near Iglesias in Sardinia, where it occurs in small quantities in galena, together with anglesite (PbSO_4) and cerussite (PbCO_3), forming curvilinear and crystalline masses, with one distinct cleavage-plane to which the acute bisectrix is perpendicular. The cleavage and the optical properties show that the mineral belongs to the rhombic or trimetric system. Besides the principal cleavage, which yields lamellae with adamantine lustre and Newtonian colour-rings, there appear to be also indistinct directions of cleavage. The mineral is negatively uniaxial, with very small axial angle, and strong refractive power, like all native lead-salts; the optic axes are more divergent for the red than for the blue rays. Fracture, conchoidal or splintery. Hardness, 2.5 to 3; that is, between potash-mica and calcsp. Sp. gr. 6.874. Somewhat brittle; colourless, transparent to translucent. Lustre on the fractured surface, fatty-adamantine like that of cerussite. In physical properties, therefore, maxite closely resembles leadhillite ($3\text{PbCO}_3 \cdot \text{PbSO}_4$), but it is distinguished from that mineral by containing water. At 100° it gives off only traces (0.099 p.c.) of hygroscopic water, the constitutional water requiring a heat of 250° – 300° to expel it. The carbonic acid requires a still higher temperature, and is not completely expelled below a bright red heat. At the outer edge of an ordinary spirit-flame, maxite fuses quickly and quietly, almost as easily as native sulphide of antimony (which, as v. Kobell has shown, is the most easily fusible of all minerals) to a bead of lead sulphate and oxide, which is red while hot, then becomes yellow, and, on cooling, crystalline and nearly white. Before the blowpipe it gives the ordinary reactions of lead, and when fused with sodium carbonate on charcoal, a strong hepatic reaction.

Quantitative analysis gave results agreeing with the empirical formula, $5\text{H}_2\text{O}$, 18PbO , 9CO_2 , 5SO_3 .

	Calculation		Analysis
$5\text{H}_2\text{O}$	90	1.838	1.866
9CO_2	386	8.081	8.082
5SO_3	400	8.163	8.140
18PbO	4014	81.918	81.912
	4890	100.000	100.000

From this may be deduced the rational formula, $5\text{PbSO}_4 \cdot 9\text{PbCO}_3 \cdot (4\text{PbO}, 5\text{H}_2\text{O})$, which is that of a molecular compound of 31 p.c. lead sulphate, 40 p.c. lead carbonate, and 20 p.c. of a lead hydroxide not known in the separate state.

Bertrand (*Bull. Soc. Chim.* [2], xix. 17; *Chem. Soc. J.* [2], xi. 481) regards maxite not as a distinct mineral, but as leadhillite altered by the action of water, and describes a specimen of leadhillite from Iglesias, in which the same alteration has taken place, but to a smaller extent than in the maxite described by Laspeyres (see *LEADHILLITE* (p. 730).

Laspeyres, on the other hand (*Jahrb. f. Mineralogie*, 1873, 292; *Chem. Soc. J.* [2], xi. 1112), points out that the difference of composition between maxite and leadhillite is much too great to allow of their being regarded as identical, as, indeed, may be seen by the following comparison:—

	PbO	CO ²	SO ³	H ² O
Maxite	81.912	8.082	8.140	1.866
Leadhillite (Scotch)	80.800	11.950	7.250	—
Difference	+1.112	—3.868	+0.890	—1.866

These differences become still more apparent on writing the formulae $(18\text{PbO}, 9\text{CO}_2, 5\text{SO}_3 + 5\text{H}_2\text{O})$ and that of leadhillite ($4\text{PbO}, 3\text{CO}_2, 1\text{SO}_3$). The numbers of molecules of lead oxide; they then become—

	PbO	CO ²	SO ³	H ² O
Maxite	36	18	10	5
Leadhillite	36	27	5	—
Difference	0	—9	+5	5

Laspeyres is further of opinion that the so-called leadhillite from Iglesias is maxite.

by Bertrand, is not leadhillite more or less altered by hydration, but a mixture of true leadhillite with *marcasite*.

MELAMPYRUM. The seed of the Purple Cow-wheat (*Melampyrum arvense*) contains a glucoside identical with, or very much like, rhinanthin (1st Suppl. 994). It is obtained by exhausting the seeds with alcohol, freeing the extract from fat, and leaving the alcoholic solution to evaporate over sulphuric acid; by a second crystallisation it is obtained white. When boiled with an acid, it splits up into glucose and an insoluble violet-brown substance (H. Ludwig and H. Müller, *Arch. Pharm.* [2], cxlix. 6).

MELAPHYRE. The melaphyres of the Little Carpathians have been examined by H. Höfer (*Jahrbuch f. Mineralogie*, 1871, 113). They are eruptive rocks of the middle trias period, and may be classified as compact, crystalline, porphyritic and amygdaloidal.

1. *Compact*.—This is the predominating variety of the group, and is distinguished by its varied colour, the darker hues, however, prevailing. The typical colour is black, with a dash of violet; red and reddish-brown are rare, and black passing into green is frequent. By weathering, the latter hue changes to a light yellowish-brown, through the oxidation of ferrous oxide. The green varieties effervesce more with acid than the black, and this is especially the case with freshly-exposed dark green specimens. The green melaphyre takes a black colour and almost metallic lustre by weathering. By aid of a lens, numerous dark green granules, resembling selenonite, are observed in it. Compact melaphyre melts before the blowpipe to a black and very vesicular slag; has a stony conchoidal fracture, and a hardness between 6 and 7. Though hand specimens but slightly affect the magnetic needle, this instrument is entirely untrustworthy in the vicinity of the rocks themselves. The specimens examined were: I. Violet-black melaphyre, from the southern end of the Blumenthal, north of Gronitz; sp. gr. 2.852. II. Blackish-grey melaphyre, with a dash of olive-green, resembling basalt, from the bed of the Schwarzen Waag, near Hoskova; sp. gr. 2.734:

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	Na ² O	CO ²	H ² O	Total
Ia.*	52.75	10.80	20.24	3.84	2.36	0.41	1.54	3.62	1.99	3.10	100.65
Ib.	56.20	11.30	21.18	4.02	2.47	0.43	1.61	3.79	—	—	100.00
IIa.	50.41	21.40	11.07	4.95	3.31	0.94	2.26	3.91	—	3.33	101.58
IIb.	51.31	21.78	11.26	5.04	3.37	0.96	2.30	3.98	—	—	100.00

The oxygen ratios of silica, sesquioxides, and protoxides are in Ib: 29.438, 11.620, 3.009; and in IIb: 27.364, 13.556, and 3.865.

2. *Crystalline*.—This variety is in a state of transition from the compact to the porphyritic variety; bright coloured scales separate themselves from the uniform mass, and when of some size are recognised as felspar; the conchoidal fracture is lost, and becomes irregular. If the crystals of felspar increase in size, the rock is then porphyritic, and the three forms of melaphyre are occasionally met with, side by side, *in situ*. The lithological characters of the crystalline varieties are, as regards colour, as varied as those of the compact melaphyres, to each of which, in fact, a congeneric crystalline kind is to be met with.

The specimen examined was from the Ipoliczathal, near Hoskova. It was green; had a sp. gr. = 2.850, and enclosed very small white brilliant crystals, apparently of felspar, green, often foliated, masses, intimately mixed with the felspar, and occasional black, angular granules. Its composition is:—

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	Na ² O	H ² O	Total
a.	48.60	12.81	10.77	9.43	7.99	0.99	1.66	5.56	3.36	99.26
b.	50.77	13.37	11.23	9.84	8.33	1.03	1.73	5.71	—	100.00

The oxygen ratios of silica, sesquioxides, and protoxides are: 27.076, 8.610, and 5.203.

3. *Porphyritic*.—The dark varieties and those with a violet hue are, with scarcely an exception, the only ones which become entirely porphyritic. This division, there-

* In this and the following tables the percentages given under a are the direct results of analysis, those under b are raised to 100% after deduction of carbonic anhydride and water.

fore, is characterised by a blackish-violet base, enclosing greenish felspar in crystals, on an average 6 lines in length and 1 line in breadth.

The composition of a specimen of the above kind, found south of Lucavina, at the north foot of the Palkniczaberg, is given below (I), as well as that of the light green felspar (andesin) which it encloses (II), and of the dark violet base itself (III).

	SiO ^a	Al ^a O ^a	Fe ^a O ^a	FeO	CaO	MgO	K ^a O	Na ^a O	H ^a O	Total	Sp. gr.
Ia. . .	52.46	19.65	10.86	1.92	5.30	0.65	1.57	2.89	4.81	100.11	2.689
Ib. . .	55.05	20.62	11.40	2.01	5.56	0.68	1.65	3.03	—	100.00	—
IIa. . .	53.26	24.28	—	2.96	6.83	0.56	2.47	4.68	3.08	99.02	2.633

IIIb. . .	53.62	17.25	15.88	2.46	4.70	0.67	1.89	3.63	—	100.00	—

The oxygen ratios of silica, sesquioxides, and protoxides, are: Ib. 29.358, 13.139, and 3.552; IIb. 29.886, 11.943, and 4.681; and IIIb. 28.542, 12.822, and 3.397.

A further example of this variety, from an entirely isolated out-crop in the Bistrathal, near Bries, enclosed green crystals of felspar, and round masses, $1\frac{1}{2}$ lines across, of a green, almost compact mineral, which was found to be dellesite, enclosing small particles of calcite. This rock has a rather even splintery fracture, and is probably in the first stage of decomposition. Its specific gravity is 2.816, and composition:—

SiO ^a	Al ^a O ^a	Fe ^a O ^a	FeO	CaO	MgO	K ^a O	Na ^a O	CO ^a	H ^a O	Total
52.21	12.84	16.35	5.67	3.67	1.13	0.98	1.90	2.01	4.50	101.26
56.10	13.55	17.26	6.00	3.87	1.19	1.03	2.00	—	—	100.00

The oxygen ratios of silica, sesquioxides, and protoxides, are: 29.385, 11.506, and 3.589.

4. *Amygdaloidal*.—The numerous varieties of this group agree in having a dark base. In one from the Nischne Chmelenithal, at Svarin, it was of a dull dirty violet, and enclosed felspar crystals $1\frac{1}{2}$ lines in length, which had lost their distinct cleavage, were without lustre, and effervesced with acid. In some of the more altered crystals small spherules of a dark green mineral are seen; in other instances the entire structure of a crystal has been replaced by this substance. The amygdaloids, then, are clearly due to a metamorphosis of the andesin.

The specific gravity of this altered melaphyre is 2.856, and its composition is given below, under I.

A typical specimen from Schwarzwaag had a dull reddish-brown base, enclosing dellesite, amygdaloids of calcite, and here and there small particles of mesitin. The felspar was completely decomposed. Its specific gravity is 2.727, and composition as under (II):—

	SiO ^a	Al ^a O ^a	Fe ^a O ^a	FeO	CaO	MgO	K ^a O	Na ^a O	CO ^a	H ^a O	Total
Ia. . .	51.80	7.78	20.90	5.34	3.10	0.47	2.25	2.71	1.29	3.77	99.60
Ib. . .	54.85	8.24	22.23	5.65	3.28	0.50	2.38	2.87	—	—	100.00
IIa. . .	42.75	14.04	14.10	2.50	9.10	0.57	2.22	4.29	7.69	3.49	100.75
IIb. . .	47.73	15.67	15.74	2.79	10.16	0.64	2.48	4.79	—	—	100.00

The oxygen ratios of silica, sesquioxides, and protoxides, are: Ib. 29.252, 10.414, and 3.523; and IIb. 25.454, 12.042, and 5.411.

The minerals met with in the larger cavities of the altered melaphyre of this region are: dellesite and green earth, calcite, mesitin, quartz, chalcedony, agate, and jasper, pistacite, heulandite, copper pyrites, and malachite.

MELLITIC ACID, C¹²H⁴O¹². The principal results of Beeyer's elaborate investigation of this acid and its derivatives have been given in the *Ann. Chem. Phys.* (pp. 808-814). The following facts have since been published (*Ann. Chem. Phys.* xlvii. 325-360).

The acid C¹²H⁴O¹² = C⁶H²(COOH)⁴, formerly called hydropyromellitic acid, is

mixture of two isomerides. One of these, for which the original name is retained, is amorphous, while the other, called *isohydropyromellitic acid*, crystallises in agglomerations of needles having the composition $C^{10}H^{10}O^3 \cdot 2H^2O$, and giving off their water of crystallisation at 120° . Its aqueous solution is not precipitated by baryta-water in the cold, but on heating the liquid, a dense crystalline precipitate soluble in acetic acid is formed. Lead acetate produces a flocculent precipitate insoluble in acetic acid.

Both varieties of hydropyromellitic acid, when heated above 200° , yield a distillate of tetrahydrophtalic acid, $C^8H^{10}O^4$ (see PHTHALIC ACID).

When mellitic acid is heated with *glycerin* till the solid mass becomes brownish-black and porous, no pyromellitic acid is formed, but a large quantity of trimesic acid, $C^6H^4O^6$.

Trimellitic acid, $C^6H^2(CO^2H)^3$, when heated, yields the anhydride $C^6H^2 \begin{Bmatrix} CO > O, \\ CO > O, \\ COOH \end{Bmatrix}$

a crystalline mass which melts at 157° – 158° , and dissolves readily in hot water.

Prehnitic anhydride, formed in like manner from prehnitic acid, $C^6H^2(CO^2H)^4$, has the composition $C^6H^2 \begin{Bmatrix} CO > O. \\ CO > O. \\ (COOH)^2 \end{Bmatrix}$

The *methylic ethers* of the several polycarbonic acids of benzene crystallise exceedingly well, and are well adapted for the detection and comparison of these acids. The following have been prepared by the action of methyl iodide on their silver salts.

Methyl isohydropyromellitate crystallises from a hot alcoholic solution in short thick needles, melting at 156° , and distilling without decomposition. *Methyl pyromellitate* is but sparingly soluble in boiling alcohol, and forms large plates melting at 138° .

Methyl trimellitate crystallises from dilute alcohol in long slender needles melting at 63° – 65° .

MELOLONTHIN, $C^8H^{12}N^2SO^3$ (P. Schreiner, *Deut. Chem. Ges. Ber.* iv. 763). A crystallisable substance obtained together with leucine, sarcosine, doubtful traces of xanthine, abundance of water, and calcium oxalate, from cockchafer (Melolontha vulgaris). The aqueous extract of the mashed insects is freed from albuminoids by boiling; the concentrated filtrate is precipitated by basic lead acetate; and the filtered liquid, freed from excess of lead by hydrogen sulphide, is concentrated, whereupon it deposits urates. The mother-liquor evaporated to a syrup and left at rest for some time deposits crystals which exhibit under the microscope well-defined needles, together with the spherical forms of leucine, and the mother-liquor after a few days yields a second crop of the needles. The united products are treated, first with a large quantity of alcohol of 80 p.c., then for a considerable time with alcohol of 70 p.c., whereby the leucine is dissolved and a white flocculent substance consisting of microscopic needles is left behind. These needles also separate from the 70 p.c. alcohol during the filtration.

The substance thus obtained is melolonthin. 30 lbs. of cockchafer yield only 1.56 gram of it. When purified by recrystallisation from water, with addition of a few drops of ammonia, it is perfectly colourless, and has a beautiful silky lustre. It is tasteless and scentless; hard; grates between the teeth; does not lose weight at 100° ; dissolves sparingly in cold, more easily in warm water, very slightly in aqueous alcohol, not at all in absolute alcohol or in ether, but easily in potash, soda, sodium carbonate, ammonium carbonate, tartaric, hydrochloric, nitric, and sulphuric acids, and in water containing a few drops of ammonia; and crystallises from this last-mentioned solution, as the ammonia evaporates, in rather large tabular rhombic prisms. The aqueous solution does not act on polarised light.

MENEGHINITE. This mineral, hitherto found only at Bottino in Tuscany, has been discovered in the emery bed at Ochsenkopf near Schwarzenberg in Saxony. It occurs in compact masses disseminated through the emery; has a metallic lustre, a black lead-grey colour, a black shining streak, compact to even fracture; hardness = 3; sp. gr. = 6.387. Two analyses gave—

Lead	Copper	Antimony	Sulphur	Iron	
61.33	1.38	19.60	17.04	—	= 99.35
60.09	1.56	19.11	18.22	0.25	= 99.23

indicating the formula $4PbS.Sb^2S^3$, which is that previously assigned to meneghinite (iii. 879; Frenzel, *Jahrbuch f. Mineralogie*, 1871, 200).

MERCURY. *Tension and Diffusion of Mercury Vapour*.—Faraday showed that mercury gives off vapour at ordinary temperatures between 15.5° and 27° ; but his experiments did not indicate the formation of mercurial vapour at temperatures below the freezing point of water (iii. 864). Merget, however (Compt. rend. lxxiii. 1356), by 2nd Sup.

exposing paper streaked with ammoniacal silver nitrate, or in bright sunshine the chlorides of platinum and palladium, to the action of the mercury vapour, has shown that the vaporisation of the metal goes on continuously between $+25^{\circ}$ and -25° , and takes place even as low as -44° , not being interrupted even by the freezing of the metal, and that the vapours possess a considerable diffusive power.

Regnault (*Compt. rend.* lxxiii. 1402) also finds that mercury at -13° gives off sufficient vapour to produce a daguerreotype picture by 24 hours' exposure. His determinations of the vapour-tension of mercury at different temperatures (iii. 94) also show that it emits vapour of measurable tension at 0° .

Estimation.—Two processes for the estimation of mercury are given by J. B. Hannay (*Chem. Soc. J.* [2], xi. 565). The first, which is a volumetric method, depends upon the fact that potassium cyanide dissolves the precipitate produced by ammonia in a solution of mercury chloride. A few drops of ammonia are first added to the solution containing the mercury in the state of chloride, and then a standard solution of potassium cyanide until the turbidity produced by the ammonia disappears. If arsenic, copper, &c., be present, the solution should be precipitated by sulphuretted hydrogen, the arsenic, &c., separated by sulphide of ammonium, and the mercury sulphide dissolved in aqua regia.—The other method consists in decomposing the mercury, in solution as sulphate, by the electric current in a platinum basin, the mercury being deposited on the basin in the state of metal and weighed as such.

Eshka (*Dingl. polyt. J.* civ. 47) estimates mercury in its ores by exposing the ore to a high temperature in contact with metallic iron, and absorbing the volatilised mercury with metallic gold.

A weighed portion of the pulverised sample is placed in a porcelain crucible, with smooth and even edge, and mixed with about half its weight of pure iron filings, and the whole is uniformly covered with a layer of filings from 0.5 to 1 centim. thick. The crucible is covered with a concave, well-fitting gold lid, the cavity of which is filled with distilled water. The crucible is heated for ten minutes by means of a flame, whose point plays on the under surface. The gold lid is now removed from the crucible, the water poured off, and the mercurial mirror on the convex side is washed with alcohol, the lid dried in the water bath, and weighed after cooling. The increase of weight in the gold lid expresses the weight of mercury contained in the sample of ore.

The quantity of ore to be operated on varies from 10 grams for poor ores containing 1 p.c. of mercury to 1 gram for rich ores about 30 p.c.

Amalgams.—Crystalline amalgams of potassium and sodium are described by Kraut & Popp (*Ann. Ch. Pharm.* clix. 188). When sodium amalgam (prepared by triturating 3 parts of sodium with 97 parts of mercury) is added to an aqueous solution of carbonate or hydrate of sodium, or left for several days under a moderate quantity of water, long needles of an amalgam are formed having the composition $\text{Na}^{\text{I}}\text{Hg}^{\text{I}}$. If the sodium amalgam be immersed in a solution of carbonate or hydrate of potassium, hard crystals appear after a few days in the separated mercury, consisting of an amalgam of potassium. These crystals are cubes with rhombic dodecahedral and octohedral faces, the sides of which sometimes attain the length of 5 mm. When left under the liquid they disappear again for some time, but in closed vessels they remain unaltered. They contain mercury, potassium, and sodium, the quantity of the sodium being less the longer the time for which the formation of the crystals has gone on. Supposing the sodium to be in the form of the above described amalgam $\text{Na}^{\text{I}}\text{Hg}^{\text{I}}$, merely mixed with the potassium amalgam, the composition of the latter will be expressed by the formula $\text{K}^{\text{I}}\text{Hg}^{\text{I}}$. These formulae of the potassium and sodium amalgams exhibit some analogy to those of the peroxides of the same metals, viz. $\text{K}^{\text{O}}\text{O}^{\text{I}}$ and $\text{Na}^{\text{O}}\text{O}^{\text{I}}$. Crystallised potassium amalgam was prepared some time ago by Berzelius and Pontin (iii. 889), also by Crookewite (*Jahresb. f. Chem.* 1847-48, 893). Löwig (*ibid.* 1860, 397) obtained sodium amalgam in prisms an inch long by adding sodium to mercury in such quantity that the mixture solidified completely on cooling, then pressing out the excess of mercury, fusing the amalgam, and leaving it to solidify slowly.

Reactions of Mercury Compounds.—A solution of mercuric chloride is completely decomposed in a few hours at ordinary temperatures by metallic silver (especially in the finely divided state) according to the equation—

From a solution of mercuric iodide in potassium iodide, silver likewise precipitates the mercury completely at ordinary temperatures (Campani, *Nuovo Cimento* [2], iii. 73).

Mercuric oxide dissolves completely in solution of potassium iodide, in consequence

of the formation of potassium hydrate and the double iodide 2KI.HgI^2 (John, *Arch. Pharm.* [3], i. 97).

Mercuric sulphide.—This compound occurs in Lake County, California, forming an amorphous crust in clefts and hollows of a siliceous gangue, associated with cinnabar and with iron- and copper-pyrites. Fracture, conchoidal to brittle; hardness = 3; sp. gr. = 7.701–7.748; colour, greyish-black; streak on porcelain, pure black. Before the blowpipe it behaves like cinnabar. The mean of several analyses gave—

S	Hg	Fe	Quartz
13.82	85.79	0.39	0.25 + 100.25

the formula HgS requiring 13.88 sulphur and 86.12 mercury (G. Moore, *Jahrbuch f. Mineralogie*, 1871, 201).

MERCURY-RADIOLES, ORGANIC. See 1st Suppl. (pp. 818–821). On the Naphthyl-mercuric Compounds, see further NAPHTHYL, in this volume.

MESACONIC ACID, $\text{C}^6\text{H}^4\text{O}^4$. On the formation of this acid from the isomeric itaconic acid, see p. 709.

Potassium mesaconate subjected to electrolysis yields at the positive pole carbon dioxide and allylene, C^3H^2 , which is precipitated by silver nitrate. The other products of the decomposition are probably acrylic and itaconic acids. The allylene thus produced is not identical either with ordinary allylene, or with those produced respectively by the electrolysis of citraconic and itaconic acid (p. 708).

Mesaconic acid is slightly coloured by ferric chloride, and the solution when boiled deposits a gelatinous precipitate which redissolves on cooling. The addition of a further quantity of ferric chloride prevents its redissolution. Neutral mesaconates of alkali-metal give with ferric chloride a brown precipitate which is insoluble in excess of the reagents, and does not dissolve when the liquid is heated (Aarland, *J. pr. Chem.* [2], vi. 256).

MESITYLENE, $\text{C}^6\text{H}^{12} = \text{C}^6\text{H}^4(\text{CH}^3)^2$. This hydrocarbon, treated with phosphonium iodide, is hydrogenised more easily than benzene, toluene, or xylene (p. 656), and is converted into hexhydromesitylene, C^6H^{12} . The latter, when freed by nitric acid from unaltered mesitylene, boils at 135° – 138° ; it smells like petroleum, is attacked by bromine, and converted by prolonged treatment with fuming nitric acid into triinitromesitylene (A. Baeyer, *Ann. Ch. Pharm.* clvi. 266).

MESITYLENE-SULPHONIC ACID, $\text{C}^6\text{H}^{12}\text{SO}^3 = \text{C}^6(\text{CH}^3)^2\text{H}^2\text{SO}^3\text{H}$ (Jacobsen, *Ann. Ch. Pharm.* cxlv. 85). The mesitylene required for the preparation of this acid was obtained by a modification of Fittig's process (1st Suppl. 298). Instead of first mixing the acetone with sand and then adding sulphuric acid, the acetone (2 vol.) was at once mixed with strong sulphuric acid in a retort fitted with a long condensing tube directed upwards, so that the acetone volatilised by the heat resulting from the action might flow back again; the liquid after cooling was mixed with a quantity of sand sufficient to form a thick paste, and then distilled. A kilogram of acetone thus treated yields 110 grams of crude mesitylene boiling between 163° and 170° .

To prepare the sulphonic acid, this crude mesitylene was treated with a mixture of ordinary and fuming sulphuric acid in equal volumes, whereupon it dissolved with only slight browning and almost without rise of temperature, the solution beginning to crystallise after a few minutes, and soon afterwards solidifying completely. A small quantity of another hydrocarbon, probably a tetramethyl-benzene, remained undissolved; it dissolved, however, in warm fuming sulphuric acid, yielding a sulphonic acid whose salts were essentially different from these mesitylene-sulphonates. For the preparation of mesitylene-sulphonic acid it would therefore be better to digest the impure mesitylene only with ordinary sulphuric acid.

The aqueous solution of the mesitylene-sulphonic acid, prepared as above described, yielded directly a very pure barium salt, which was recrystallised and used for the preparation of the other mesitylene-sulphonates.

Mesitylene-sulphonic acid is obtained, by slow evaporation of its syrupy solution over sulphuric acid, as a coarsely laminar crystallised mass having the composition $\text{C}^6\text{H}^{12}\text{SO}^3 \cdot 2\text{H}^2\text{O}$. The individual crystals are six-sided tables (Jacobsen). According to H. Rose (*Zeitschr. f. Chem.* [2] vi. 341), they belong to the rhombic system, and the salts, especially the magnesium salt $\text{Mg}(\text{C}^6\text{H}^{12}\text{SO}^3)^2 + 6\text{H}^2\text{O}$, which crystallises in large hard transparent tables, very much resemble the acid in their forms. According to Jacobsen, the acid is not deliquescent, melts near 100° , and is resolved at a higher temperature into mesitylene and sulphuric acid. According to Rose, it melts near 77° , attracts moisture only in very damp air, solidifies again in the crystalline form in dry air, and gives off its water of crystallisation when kept for a long time over sulphuric acid.

Potassium Mesitylene-sulphonate, $\text{KC}^6\text{H}^3\text{SO}^3 + \text{H}^2\text{O}$, usually crystallises in roundish groups of laminae having a silky lustre; it dissolves in 7 parts of water at 12° , somewhat less abundantly in cold alcohol; in both cases the solubility diminishes very rapidly with the temperature. From the alcoholic solution the salt is gradually precipitated by ether in spherical aggregates. The *ammonium salt*, $(\text{NH}^4)\text{C}^6\text{H}^3\text{SO}^3 + \text{H}^2\text{O}$, is very soluble in water and in alcohol, and crystallises by slow cooling in rhombic plates. It gives off its water of crystallisation at 110° , melts with decomposition at 250° , and yields a sublimate of a substance which is insoluble in water, easily soluble in alcohol, and still more in ether, and probably consists of mesitylene-sulphamide. The *calcium salt*, $\text{Ca}(\text{C}^6\text{H}^3\text{SO}^3)^2 + 5\text{H}^2\text{O}$, forms distinct, hard, limpid crystalline crusts which effloresce in dry air. The *strontium salt*, which may be obtained in stellate groups of large laminae, likewise gives off its water with facility. The *barium salt*, $\text{Ba}(\text{C}^6\text{H}^3\text{SO}^3)^2 + 9\text{H}^2\text{O}$, crystallises from a moderately concentrated hot solution in long flat prisms with dihedral summits, or by slower crystallisation in more tabular, shorter, but broader crystals; from alcohol in bright iridescent laminae. It dissolves in 15 parts of water at 28° , the solubility increasing quickly with the temperature. It effloresces very easily in dry air, gives off 8 mol. water at a comparatively low temperature, but retains the last molecule till it is heated above 100° . The *cobalt salt*, $\text{Co}(\text{C}^6\text{H}^3\text{SO}^3)^2 + 6\text{H}^2\text{O}$, crystallises in beautiful groups of shining flesh-coloured laminae, easily soluble in water and in alcohol. When dried at 100° it is rose-red and still appears to retain $4\text{H}^2\text{O}$; the dehydrated salt is of a fine ultramarine colour. The *copper salt*, $\text{Cu}(\text{C}^6\text{H}^3\text{SO}^3)^2 + 4\text{H}^2\text{O}$, crystallises in spherical groups of whitish-green laminae having a silky lustre; after drying at 100° it is grass-green and anhydrous. It dissolves in 17 parts water at 10° , much more freely in hot water. The concentrated solution of the *lead salt*, $\text{Pb}(\text{C}^6\text{H}^3\text{SO}^3)^2 + 9\text{H}^2\text{O}$, solidifies on cooling to a coarsely laminar crystalline mass having a strong mother-of-pearl lustre. It dissolves in 6.4 parts of water at 20° , easily also in alcohol, effloresces very quickly, begins to decompose at about 200° . The lead salt crystallising in needles described by Hofmann (*Chem. Soc. J.* ii. 113) was not obtained by Jacobsen.

The acid obtained from the above-mentioned less soluble hydrocarbon mixed with the mesitylene, was produced in comparatively large quantity from the portion of the crude mesitylene which distilled above 180° . The distillate obtained between 180° and 230° was repeatedly rectified over sodium, and the portion boiling between 195° and 210° , probably tetramethylbenzene, C^6H^{14} , was collected apart and dissolved in fuming sulphuric acid. The *barium salt* prepared by saturating the acid liquid with barium carbonate, probably $\text{Ba}(\text{C}^6\text{H}^3\text{SO}^3)^2 + \text{H}^2\text{O}$, separated, on evaporating the filtrate, in sparingly soluble, hard, indistinctly crystalline crusts, floating on the surface. The same salt was gradually precipitated in the crystalline state from the solution of the potassium salt by barium chloride. It is very much like barium isocumene-sulphonate, but much less soluble, and its solubility is but little increased by heat. The *potassium salt* is easily soluble in water, and crystallises from the hot alcoholic solution in small felted needles (Jacobsen).

Bromomesitylene-sulphonic acid, $\text{C}^6\text{H}^3\text{BrSO}^3\text{H} = \text{C}^6(\text{CH}^3)\text{HBrSO}^3\text{H}$ (H. Rose, *loc. cit.*) Bromine acts strongly on mesitylene-sulphonic acid, producing, however, for the most part, scarcely anything but brominated substitution-products of mesitylene. It is only by great dilution, efficient cooling, and the use of bromine-water, that any considerable quantity of bromomesitylene-sulphonic acid can be obtained. The liquid filtered from separated bromomesitylene and neutralised with lead carbonate first deposits crystals of lead bromide; and on precipitating the remainder of the lead with hydrogen sulphide, repeatedly evaporating, saturating with barium carbonate, evaporating, and treating the residue with hot alcohol, barium bromomesitylene-sulphonate is dissolved, while any barium bromide that may still be present is left behind. From this barium salt the acid may be prepared in the usual way. The brominated acid may also be obtained, and in somewhat larger quantity, by the action of sulphuric acid on bromomesitylene. The salts of the brominated acids prepared by these two processes exhibit identical properties.

Bromomesitylene-sulphonic acid is very soluble in water, alcohol, and ether, and crystallises from ether in shining needles, which are so deliquescent that their melting-point cannot be determined. Its salts are less soluble than those of mesitylene-sulphonic acid, do not effloresce in dry air, and do not readily give up their water of crystallisation below 130° . Their forms, which are well defined, belong to the rhombic system. The *barium salt*, $\text{Ba}(\text{C}^6\text{H}^3\text{BrSO}^3)^2 + \text{H}^2\text{O}$, crystallises in broad needles or laminae, very slightly soluble in alcohol, insoluble in ether. The water of crystallisation is given off only at a temperature near that at which the salt begins to decompose. The *lead salt*, $\text{Pb}(\text{C}^6\text{H}^3\text{BrSO}^3)^2 + 1\frac{1}{2}\text{H}^2\text{O}$, forms beautiful radiate groups of crystals, moderately soluble in hot alcohol, insoluble in ether. The *potassium salt*,

$\text{K}^{\text{C}}\text{H}^{\text{H}}\text{BrSO}^3 + \text{H}^2\text{O}$, crystallises in isolated rhombic tablets easily soluble in water and in hot alcohol. The *copper salt*, $\text{Cu}(\text{C}^{\text{C}}\text{H}^{\text{H}}\text{BrSO}^3)^2 + 4\text{H}^2\text{O}$, crystallises in beautiful tufts of long, nearly white crystals, having a silky lustre, and assuming a grass-green colour when heated above 100° . The *sodium salt*, $\text{NaC}^{\text{C}}\text{H}^{\text{H}}\text{BrSO}^3$, is obtained, by spontaneous evaporation of its aqueous solution, in hard, finely-developed transparent crystals.

Nitromesitylene-sulphonic acid, $\text{C}^{\text{C}}\text{H}^{\text{H}}\text{NO}^2\text{SO}^3\text{H} = \text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{H}(\text{NO}^2)\text{SO}^3\text{H}$ (H. Rose, *Zeitschr. f. Chem.* [2], vi. 74). This acid is prepared by gradually adding mesitylene-sulphonic acid to carefully cooled fuming nitric acid, whereupon it dissolves, forming a deep brown solution, which after a few hours becomes almost colourless. This solution is poured into a large quantity of water, filtered from the white flocks of dinitromesitylene which separate together with a small quantity of an oil, probably impure nitromesitylene, and repeatedly evaporated at 100° with addition of water, in order to remove the excess of nitric acid. The crystalline mass, after being pressed and recrystallised, readily yields the pure acid in brittle, transparent, prismatic crystals, having the composition $\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNO}^2\text{SO}^3\text{H} + 1\frac{1}{2}\text{H}^2\text{O}$, easily soluble in water, alcohol, and ether, and melting at 131° . Exposure to sunlight turns the acid yellow, and when dried over sulphuric acid it becomes opaque, and loses its water of crystallisation. Most of its salts are easily soluble in water, crystallise well, and burn with deflagration.

The *barium salt*, $\text{Ba}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNO}^2\text{SO}^3]^2$, crystallises from its hot aqueous solution in pale yellow tufts of crystals. It is almost insoluble in ether, soluble with difficulty in cold water and in alcohol. The *potassium salt*, $\text{KC}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNO}^2\text{SO}^3 + \text{H}^2\text{O}$, forms large white needles or broad plates, and is readily soluble in alcohol and water. The *copper salt*, $\text{Cu}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNO}^2\text{SO}^3]^2 + 3\text{H}^2\text{O}$, crystallises in pale green lustrous scales, which are moderately soluble in cold water. The *lead salt*, $\text{Pb}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNO}^2\text{SO}^3]^2 + \text{H}^2\text{O}$, is easily soluble in water, and crystallises from hot solutions in white glistening tufts of needles. The *ammonium salt* is readily soluble in alcohol and water, and separates in nodular concretions.

Nitromesitylene-sulphonic acid has not hitherto been produced by the action of sulphuric acid on nitromesitylene.

Amidomesitylene-sulphonic acid, $\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNNH}^2\text{SO}^3\text{H} + \text{H}^2\text{O}$, is prepared from the nitro-acid by dissolving it in ammonia, saturating the solution with sulphuretted hydrogen, and evaporating it almost to dryness; water is then added, and the boiling solution decomposed by hydrochloric acid. The filtered solution, on cooling, deposits the amidomesitylene-sulphonic acid in pale red needles, which may be rendered white by treatment with animal charcoal and recrystallisation. The acid dissolves easily in hot alcohol, with difficulty in cold water, but much more readily in hot water. By slowly cooling its aqueous solution, it is obtained in fine truncated prisms, and from a hot concentrated solution, in needles, which acquire a red tinge on exposure to light. It loses its water of crystallisation when dried over sulphuric acid. It does not combine with hydrochloric acid, and crystallises unchanged from moderately strong sulphuric acid. Its solutions redden litmus-paper, and it expels carbonic acid from the carbonates.

Its salts crystallise well, and are generally easily soluble; their solutions become yellow on evaporation, from incipient decomposition. The *barium salt*, $\text{Ba}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNNH}^2\text{SO}^3]^2$, crystallises from its hot aqueous solution in yellow nodules, which are moderately soluble in cold water. The *magnesium salt*, $\text{Mg}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNNH}^2\text{SO}^3]^2 + 3\text{H}^2\text{O}$, forms hard transparent yellow crystals. The *zinc salt*, $\text{Zn}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNNH}^2\text{SO}^3]^2 + 5\text{H}^2\text{O}$, is readily obtained in fine crystals, easily soluble in cold water. The *lead salt*, $\text{Pb}[\text{C}^{\text{C}}(\text{CH}^{\text{H}})^3\text{HNNH}^2\text{SO}^3]^2 + \text{H}^2\text{O}$, is also readily soluble in cold water, and crystallises well. The *calcium, sodium, and ammonium salts* are readily soluble in cold water; the *silver salt* much less soluble (H. Rose).

MESOCAMPHORIC ACID. See CAMPHORIC ACID (p. 235).

MESOLE. Pisani (*Compt. rend.* lxxiii. 1448) has analysed a mesole from the basaltic amygdaloid of Gignat, near Saint-Germain-Lembron in Auvergne, with the following results:

SiO^2	Al^2O^3	CaO	Na^2O	K^2O	H^2O
42.3	28.1	10.0	6.7	trace	14.1 = 101.2

MESOLITE. The investigations of E. Schmid (*Pogg. Ann.* cxlii. 118) tend to show that this mineral is a distinct species, and not a variety of scolécite, as supposed by Rammelsberg (v. 207). Schmid examined three specimens, two from Iceland (I. and II.), the former consisting of radiated bundles terminating in free crystals, which exhibit the combination of the monoclinic prism with the clin-

pinacoid and the complete pyramid, while the latter and that from Stromb (III.) are finely radiate, the ends not being free. At ordinary temperatures they lose but little water, probably hygroscopic, the quantity not being greatly increased when the heat is raised to 100°. Above the boiling point the loss increases, and by a gentle incandescence continued for half a hour, all the water of the three specimens, amounting to 12.943, 13.190, and 13.355 p.c. respectively, was driven off. Coarse fragments, after lying two days in acid, show signs of gelatinisation. The portions analysed were dried at 100°, and had consequently lost somewhat more than the hygroscopic water; the results were:—

	I.			II.			III.		
		Oxygen	Oxygen ratios		Oxygen	Oxygen ratios		Oxygen	Oxygen ratios
Silicic acid	46.583	24.842	5.802	47.133	25.136	6.102	47.404	25.231	6.107
Alumina, with a trace of iron oxide	27.566	12.845	3.00	26.520	12.358	3.00	27.049	12.605	3.00
Lime	9.105	2.602	0.836	10.365	2.961	1.006	9.163	2.618	0.919
Magnesia	0.076	0.030		0.025	0.00		0.058	0.023	
Soda	3.638	0.948		4.501	1.173		4.689	1.222	
Specific gravity	2.18	—	—	2.18	—	—	2.16	—	—

The ratios of the constituents, with the exception of the water, are those of labradorite. The amounts of water in these three new specimens show as little uniformity as those of earlier analyses, and it is this point, in fact, that has made the recognition of mesolite as a distinct mineral species a matter of doubt. Fuchs held that the water-percentage was dependent on those of soda and lime, and considered mesolite to be formed of scolecite and natrolite as proximate constituents. If then the oxygen of the soda be $\frac{1}{m}$ of that of the total monoxides, the water will, on this assumption, be

$3 - \frac{1}{m}$, and the formula:—

METALDEHYDE. See ALDEHYDE.

METALS. On the Atomic Weights and Classification of the Metals, see ELEMENTS (p. 462).

On the Electric Effects produced by the Contact of Metals with Water, Acids, and Saline Solutions, see ELECTRICITY (pp. 443–446). On the Thermo-electric Actions of Metals and Liquids (p. 457).

On the Colours of Metals, see LIGHT (p. 746).

On the Solution of Metals in Liquid Ammonia, and on the supposed Metal-ammoniums, see AMMONIA (p. 60).

Distinction of Base from Noble Metals.—According to P. Guyot (*Zeitschr. anal. Chem.* ix. 516), a solution of auric chloride or silver nitrate produces on alloys containing base metals, brown or grey spots, whereas on pure gold or on articles gilt therewith, this effect is not produced. Lustres on tapestry or paper-hangings may be tested with *sulphur chloride*, a drop of which placed on impure lustre immediately produces a brown rim, which is not the case when the coating is of pure gold. Thin leaves of metal may be tested with *sulphur chloride* or with a solution of *phosphorus* in carbon sulphide. Aluminium immersed in such a solution remains bright for several months; silver turns brown, and platinum acquires a very faint golden lustre.

Separation of Metals by Electrolysis.—By employing an electric current of suitable intensity, it is possible to separate directly the more easily reducible metals from those

which are less reducible, and to obtain in this manner two distinct groups; the first comprising iron, nickel, cobalt, and zinc; the second, all the other metals capable of reduction, the latter group also representing those metals which are precipitable by a plate of zinc.

In the electrolytic separation of two metals (copper and cadmium, for example), differing but slightly in reducibility, it is found advantageous to employ a current somewhat stronger than would be necessary, supposing it were intended to avoid the precipitation of the less reducible metal. In this way a deposit is in the first instance obtained, containing the whole of the more reducible metal, together with a small quantity of the other metal; the solution is then poured off, replaced by a liquor free from metallic salts, and the direction of the current reversed for a short time. As soon as the deposited metals have passed into solution, the original direction of the current is re-established. The less reducible metal, being now only in very small proportion, remains entirely in solution, while the metal which is more easily reduced is deposited perfectly pure. It is sometimes, though not often, necessary to repeat this operation.

When a solution of cobalt, nickel, or zinc is reduced by galvanic action, it is advisable to superaturate the solution with ammonia, to avoid the deposition of oxide. It is found impossible to estimate iron correctly by the above method, owing to the great tendency of the metal to form sesquioxide (Lecoq de Boisbaudran, *Compt. rend.* lxxiii. 1322).

On the Electrolytic Separation of Copper and other Metals, as practised at the Mansfield Copper Mines, see COPPER (p. 384).

METAMORPHISM. On the metamorphism of rocks, as exhibited in the contact phenomena produced between the clay-slates and granular diabases in the Harz, see E. Kayser (*Zeitschr. geolog. Gesellsch.* xxii. 103; *Jahrb. f. Mineralogie*, 1870, 496; *Jahresh. f. Chemie*, 1870, 1344).

An elaborate Treatise, of historico-critical character, on the Theory of Metamorphism and the Origin of Crystalline Slates, has been published by J. Roth (*Abhandl. d. Berl. Acad.* 1871, *physikalische Classe*, 151; *Verh. geol. Reichsanstalt.* 1871, 362).

On the Metamorphism of Meteorites, see p. 793.

METATHIOHYDROBENZOIC ACID. See TRITHIOHYDROBENZOIC ACID.

METEORITES. *Formation.*—Daubrée (*Compt. rend.* lxii. 200, 369, 666) has made a series of synthetical experiments with the view of throwing light on the mode of formation of meteorites, and on their relation to terrestrial rocks. He finds that ordinary meteorites (chondrites), when exposed in a plumbago crucible to a heat near the melting point of platinum, yield an iron regulus (proceeding partly from the metallic iron present, partly from reduction of ferrous silicate), together with a flux which on cooling solidifies to a crystalline mass containing two different crystallised bodies in very different proportions. The upper layer of this flux consists of olivine either in flat rhombic octohedrons, or in six-sided tables ($OP \cdot \infty P\infty \cdot \infty P2$), or in laminae ($OP \cdot P\infty \cdot nP\infty$). The inner mass consists of enstatite ($MgO.SiO_2$) in prisms, not exactly definable, with rectangular base and fibrous-laminar fracture; sometimes the enstatite is intergrown with olivine or grouped more or less regularly round a nucleus of olivine. Meteorites of different groups (iii. 980) differ in their melting points only in consequence of the predominance of one or the other of these silicates. The Chassigny meteorite gave scarcely anything but olivine, that of Bishopville little besides snow-white enstatite; the aluminiferous meteorites of Jouvenas, Jousac, and Stannern, on the other hand, yielded glasses free from crystals; that from the Jouvenas meteorite was blistered. The enstatite and olivine, which exist in meteorites in a state of very intimate mixture, but may be shown to be present by their different behaviour to acids, crystallise therefore separately from the fused mixture, and enclose the alumina silicates in their mass, if the latter are not present in considerable quantity.

Exactly similar products are obtained by the fusion of terrestrial olivine rocks. Olivine melts completely in a strong gas-furnace, yielding a green translucent crystalline mass which exhibits well-defined crystals on its surface. Lherzolite melts still more readily, exhibiting after fusion distinct needles of enstatite, which occur more abundantly if silica has been added previously to the fusion. Serpentine yields by fusion and solidification crystals of olivine and enstatite; when fused with addition of magnesia, it is converted for the greater part into olivine; with addition of silica into enstatite. When these rocks are fused in a plumbago crucible, the result is essentially the same: the iron of the silicate is reduced and separated in the form of microscopic granules.

The reguline masses of iron obtained by the fusion of meteorites (which from their mode of formation probably contain carbon and silicon) sometimes exhibit on cut and polished faces, after treatment with acids, a dendritically ramified crystalline substance distinct from the dull ground, and in the case of the Montrejean and Aumale meteorites, also distinct crystals of titanium nitrocyanide, but not the regular (Widmanstätten) figures characteristic of the unaltered meteorite. The meteoric iron of Caille (Dep. of Var) after refusion (imbedded in alumina) exhibited the same appearances, although it had become crystalline throughout its mass.

The synthetical preparation of meteoric iron was not quite successful. Soft iron fused with phosphorus, nickel, silicon, and iron sulphide, acquires a distinctly crystalline character and laminar fracture, without, however, exhibiting on the etched cut surfaces the lines and separations of meteoric iron. A product at least resembling meteoric iron was obtained by fusing soft iron (or pig iron) with 2 to 10 p.c. of iron phosphide: it showed on unetched cut surfaces the iron phosphide in shining lines (only less regularly disposed than in meteoric iron) and a black amorphous substance, which was separated somewhat uniformly through the mass, and appeared also to consist of iron phosphide. A still better result was obtained by fusing 1800 grams of soft iron, 170 nickel, 50 iron phosphide, 40 iron monosulphide, and 20 cast iron rich in silicon. An iron containing iron phosphide and nickel, and similar in structure and composition to meteoric iron, separated on fusing olivin, hercynite, hypersthene, basalt, melaphyre, and serpentine in a plumbago crucible; any chromium present in these minerals also passed into the regulus.

Daubrée has also studied the analogies which exist between meteorites and rocks of the olivin family, and show themselves most distinctly in the structure of the fused rock. These rocks, like the meteorites, exhibit indications of cleavage-planes in the form of fine, sharply-drawn straight lines between irregular furrows; they also, like the meteorites, exhibit needles of enstatite; they have partly the granular consistence of the chondrites, and if they have been fused in a plumbago crucible, they assume, when two pieces are rubbed together, the same graphitic lustre that meteorites exhibit on friction surfaces, due in fact to the triturated powder of the imbedded metallic iron. The essential difference between the two consists in this, that in the terrestrial rocks all the constituents are combined with oxygen, whereas in the meteorites some of the constituents are present in the unoxidised state.

From all these facts Daubrée infers that meteorites have been brought to the state in which they fall to the earth, either by partial reduction of a rock of the olivin family, or by partial oxidation of metallic and metalloidal elements of the same rock, not originally combined with oxygen. He has tested the admissibility of both these hypotheses—of which he seems to prefer the second—by further synthetical experiments. When olivin, hercynite, or pyroxene, is heated to redness in a stream of hydrogen, the ferrous oxide contained in it is reduced, and the ferric phosphate is converted into iron phosphide. As meteorites, for the most part, do not contain carbon, it appears most probable that any reduction that may have taken place is due to hydrogen; the water resulting from it might, in consequence of the small size of the fragments, be volatilised. In corroboration of the second hypothesis the following experiments are adduced. Silicide of iron, imbedded in magnesia, and exposed for a quarter of an hour in an imperfectly closed crucible to the heat of a powerful gas-furnace, yielded granules of soft iron retaining only traces of silicon, and a fused magnesio-ferrous silicate, in the cavities of which octohedral crystals of olivin could be recognised. A mixture of 10 parts nickeliferous iron (containing 9 p.c. nickel), 1 part iron phosphide, 1 part iron monosulphide, 43 parts silica, and 57 parts magnesia, gave, when treated in like manner, a ferruginous olivin (free from nickel and phosphorus), partly crystallised in tables, and a regulus in which the sulphur and phosphorus of the mixture were concentrated (the phosphorus as phosphide of magnesium, nickel, and iron).

According to both the preceding hypotheses, the original material of the earth and the planetary bodies which have yielded the meteorites must have been the same, and the olivin rocks, which differ so remarkably from the rest in their basic character and their high specific gravity (up to 3.3), and, according to Daubrée's hypothesis, constitute, at certain depths, the chief constituent of the interior of the earth, must be regarded as the universal slag of the planetary system. In whatever way meteorites may have attained their present condition, their confused crystallisation and the irregular form of the iron-granules contained in them, tend to show that the temperature at which the changes in question took place could not have exceeded the welding heat of iron. In a mixture of hercynite and reduced iron fused at a high temperature, Daubrée found the separate iron-granules completely rounded.

The following observations throw further light on the structure of meteorites. When a polished plate of the meteoric iron of Charcas or Caille is immersed in a solution of

cupric sulphate, there is first formed on the white ground a copper-coloured network of Schreibersite needles, and immediately afterwards each needle becomes surrounded with a ring or aureole of copper, sharply defined on the inner as well as on the outer side. Scarcely have rings formed when the free parts of the surface likewise become coated with copper. This latter deposit cannot be rubbed off, but it may be removed by treatment with ammonia, and the surface of the meteoric iron then shows (still more distinctly if the deposition of the copper be interrupted at the moment when the rings appear, and the excess of the copper salt be removed by washing with a large quantity of water) a structure essentially different from the Widmanstätt figures, and designated by Daubrée as the primary network (*réseau de départ*). The long parallel brilliant needles of schreibersite, surrounded by the ring, may be distinguished on the grey fine-grained ground mass (Daubrée, *Compt. rend.* lxiv. 685).

To determine whether, in a meteoric stone containing both silicates and metallic portions, the iron is present as a coherent mass or in isolated grains, a fragment of the stone heated to redness may be quenched in cold water (or, to prevent oxidation of the metal) under mercury. In this manner Daubrée has found that the iron in the meteorite of Sierra de Chaco is in separate grains, whereas that of Atacama forms a coherent mass intersected by granules of silicate. In the meteorite of Rittersgrün, on the other hand, both the silicate and the iron are coherent masses intergrown with one another (*Compt. rend.* lxvi. 148).

Classification.—Rammelsberg classifies the constituents of meteorites as follows:—

1. *Metallic bodies*: Nickel-iron; schreibersite.
2. *Metallic sulphides*: Oldhamite, CaS ; troilite, FeS ; magnetic pyrites, FeS^2 .
3. *Oxides*: Magnetic iron oxide, Fe^2O^3 ; chromo-iron oxide, FeCr^2O^4 .
4. *Silicates*; a. *Bisilicates or Metasilicates*: Enstatite, MgSiO^2 ; bronzite, $(\text{Mg}; \text{Fe})\text{SiO}^2$; augite $(\text{Mg}; \text{Ca})\text{SiO}^2$; and $(\text{Fe}; \text{Mg}; \text{Ca})\text{SiO}^2$. b. *Singulosilicates or Orthosilicates*: Olivin, $(\text{Mg}; \text{Fe})\text{SiO}^2$; anorthite, $\text{CaAl}^2\text{Si}^2\text{O}^8$.

To these must be added crystallised silica (tridymite?) and carbon, partly combined partly in the form of graphite.

Among the augitic or rhombic bisilicates of meteorites, Rammelsberg further distinguishes MgSiO^2 as enstatite, $n\text{MgSiO}^2 + \text{FeSiO}^2$ as bronzite when $n > 3$, and as hypersthene when $n < 3$ (independently of admixtures of R^2O^3 common to all the three types), and he infers, from a discussion of all the available analyses, that enstatite is contained in the meteorites of Bishopville, Rusti, and Deesa; bronzite in those of Breitenbach, Rittersgrün, Steinbach, and Shalka; non-ferruginous augite in the Rusti stone; ferruginous augite in those of Jouvenas, Stannorn, and Petersburg in Tennessee (*Pogg. Ann.* cxl. 311).

A comprehensive memoir on meteorites and their relation to terrestrial rocks has been published by S. Meunier (*Mouiteur Scientifique* [3], i. 97). He classifies meteorites under forty-three types, the names of which are formed from those of the respective localities with the suffix 'ite.' Many of these individual types exhibit a genetic connection; thus 'Decsite' (from Deesa in Chile) consists of a metallic ground-mass of 'caillite,' enclosing fragments of a mineral identical with 'tadjjerite' (the stone which fell at Tadjera, near Selif, in 1867). Further, though the metallic part of decsite is chemically identical with that of caillite, it is distinguished from the latter by the irregularity of its Widmanstätt figures, a property which may be imparted to caillite by refusion. By less strong heating, aumalite and chantonnite (iii. 980) may be converted into tadjjerite; on the other hand, the black crust of chantonnite consists of tadjjerite, a result which Meunier regards as related to the heat of friction developed in eruption.

From the comparison of a large number of examples, Meunier classifies his types as follows:—

1. *Stratiform meteorites* (caillite).
2. *Eruptive meteorites* (chantonnite); to which, also, belong the eruptive breccias (decsite).
3. *Metamorphic meteorites* (tadjjerite).
4. *Brecciform non-eruptive meteorites* (meteorite of St. Mesmin).

With regard to the analogies between meteorites and terrestrial rocks, Meunier refers serpentine to chantonnite and aumalite, and explains the microscopical identity and chemical resemblance of the three bodies on the supposition that chantonnite is aumalite slightly metamorphosed (by the heat of friction of the eruption), and that serpentine is chantonnite, strongly oxidised and hydrated, forming the outcrop of the veins, just as malachite forms that of veins of copper pyrites. In short, he regards meteorites as the deeper-seated rocks of a star perfectly analogous in structure to the earth.

For Meunier's speculations on the successive transitions of a star from its originally

fluid state to a condition similar to that of the earth, afterwards to that of the moon, and its ultimate resolution into fragments like meteoric stones, we must refer to the original paper; see also *Jahresb. f. Chem.* 1871, 1235.

On the Metamorphosis of Meteorites, see further, Meunier (*Compt. rend.* lxxii. 452, 508, 541; *Chem. Soc. J.* [2], ix. 329 and 503-505).

General Properties and Proximate Constituents of Meteoric Iron.—Meunier (*Ann. Chim. Phys.* [4], xvi. 19) distinguishes the following varieties of nickel-iron:—

1. *Octibbehlite*, FeNi_2 , of sp. gr. 6·854, constituting the entire mass of the meteoric iron of Octibbeha County, Mississippi.

2. *Tenite*, Fe^{Ni} , sp. gr. 7·380, containing 85 p.c. iron, 14·0 nickel, and a trace of cobalt; from the meteoric iron of Caille (*Alpes maritimes*).

3. *Plessite*, Fe^{10}Ni , sp. gr. 7·850 (origin not stated).

4. *Kamacite*, Fe^{14}Ni , sp. gr. 7·652, containing 91·9 p.c. iron, 7·0 nickel, and a trace of cobalt; from the meteoric iron of Caille. Also containing 92·0 iron, and 7·5 nickel from that of Charcas, in Mexico.

Of iron carbide, Meunier distinguishes two varieties, viz.: *Chalybite*, CFe_2 , from the meteoric iron of Naakornak in Greenland; and *Campbellite*, with less carbon (1·50 p.c.), from that of Campbell County, Tennessee.

To *Troilite* Meunier assigns, contrary to ordinary acceptance, the formula $(\text{Fe}; \text{Ni})\text{S}^2$, basing his conclusion on the following analysis:—

	Fe	Ni	Cu	S
a.	59·01	0·14	trace	40·03 = 99·18
b.	56·29	3·10	—	39·21 = 98·60

a. From the meteoric iron of Toluca; b. from that of Charcas.

For *Schreibersite* he gives the formula $\text{Fe}^{\text{Ni}}\text{P}$, deduced from an analysis of schreibersite from the Toluca iron:—

Fe	Ni	Co	Mg	P	Sp. gr.
57·11	28·35	trace	trace	15·01 = 100·47	7·103

In two graphites Meunier found:—

	C	Fe	Ni	Sp. gr.
a.	97·3	2·4	trace = 99·7	1·715
b.	98·0	0·9	— = 99·0	1·309

a. From the meteoric iron of Caille; b. from that of Charcas.

The crust of the Toluca iron was found to consist of—

Fe_2O_3	FeO	NiO	CoO	Sp. gr.
68·93	28·12	2·000	trace = 99·05	4·89

whence it appears to consist of nickeliferous magnetic iron oxide.

The non-metallic granules are distinguished as those which belong to the metallic iron and those which belong to the troilite. Both kinds are indistinctly crystallised, the former from the iron of Tucson, in Mexico, have a sp. gr. of 3·35, and contain silica, ferric oxide, and magnesia. Meunier regards them as hyalosiderite. In the grains from the Caille and Charcas irons he found only silica, and inclines to the opinion that they consist of quartz.

With respect to the gases enclosed in meteoric iron, Meunier was unable to find anything but atmospheric air, whereas Graham found hydrogen in the meteoric iron of Lenarto (*1st Suppl.* 635). Graham, however, remarks that, as Meunier made use of mercuric chloride to dissolve the iron, the hydrogen, from its metallic nature, would give rise to a precipitation of mercury without evolution of hydrogen, and therefore that Meunier's result cannot be regarded as conclusive against the existence of hydrogen in the meteoric iron.

The Widmanstätt figures are attributed by Meunier, not to schreibersite, but to troilite, inasmuch as they are developed by the action of fused potash as well as by that of acids, whereas schreibersite is attacked by melting potash.

Meunier classifies meteoric irons according to the predominance of one or more varieties of nickel-iron contained in them; thus:—

I. Meteoric-iron consisting exclusively or for the most part of one nickel-iron; viz:—

1. *Octibbehlite*, FeNi_2 , from Octibbeha.

2. *Tenite*, Fe^{Ni} , from Tazewell.

3. *Kamacite*, Fe^{14}Ni , from Nelson.

II. Mixtures of two nickel-irons:—

4. *Tenite* and *Kamacite*, from Caille.

5. *Tenite* and *Plessite*, from Jewell hill.

6. *Tenite* and *Campbellite*, from Campbell County.

III. Mixtures of three nickel-irons:—

7. *Tenite*, *Kamacite*, and *Plessite*, from Burlington.

Rammelsberg (*Zeitschr. geolog. Ges.* xxii. 893; *Jahresb. f. Chem.* 1870, 1395) objects to Meunier's conclusion that the iron sulphide of meteorites consists of magnetic pyrites, FeS^8 . By a renewed analysis of troïlite from the meteoric iron of Seelsgen, he obtained:—

P	Fe	Ni ⁸	S
0.18	62.24	1.00	35.68 = 100.

Deducting the nickel and phosphorus, together with the corresponding quantity of iron, as schreibersite, there remains for the iron sulphide 61.97 p.c. iron to 38.03 sulphur, giving the atomic proportion of $\text{Fe} : \text{S} = 100 : 107$, instead of $100 : 100$. Nevertheless Rammelsberg is inclined, according to the analogy of the older analyses, to admit the formula FeS ; and the more so as he regards Meunier's method of analysis, which led to the formula FeS^8 , as inadmissible.

J. L. Smith (*Sill. Am. J.* [2], xlix. 331) directs attention to the general occurrence of cobalt and copper in meteoric iron, and is inclined to regard both these elements as essential constituents of it. Tin he has never found; lead only in the Tarapaca iron, its occurrence in which is also mentioned by Greg (*Jahresb. f. Chem.* 1855, 1027). Smith is, however, of opinion that the presence of the lead must be attributed to fusion-experiments which had been made with this iron with the view of obtaining noble metals from it. Pieces from the interior, free from cracks, contained no lead.

The composition and physical character of the meteorites which had been most exactly investigated down to the year 1859, are given in vol. iii. pp. 977-982. To describe the large number which have been examined since that date would take up more space than can be devoted to the subject in this volume (see *Jahresb. f. Chem.* 1860-1871). The following have been recently examined:—

Meteoric iron.—1. J. W. Mallet (*Sill. Am. J.* [3], ii. 200) describes three masses of meteoric iron found in Augusta County, Virginia, weighing 56, 36, and $3\frac{1}{2}$ lbs.

All three specimens presented the same general appearance. They were of a very irregular pear shape, one end of each mass being larger and more rounded than the other. On the exterior they were covered with a dark brown crust, consisting essentially of hydrated ferric oxide, which varied from about one-eighth to one-third of an inch in thickness. The masses were of course magnetic, and on examination gave evidence of feeble magnetic polarity, with multiple poles. The interior structure of the iron was compact, and highly crystalline, of much the same general character throughout; but a few small grains and streaks of a brownish-yellow mineral were noticed, which on being picked out and examined, proved to be *troïlite*. Minute fissures also were observed running through several portions of the metal, from which a watery liquid containing chlorine exuded. Traces of Widmanstätten figures might be detected upon a polished surface, even without the aid of an acid; and when the iron had been etched with nitric acid, the markings became very distinct and beautiful. In all three specimens, upon the principal cut surfaces, narrow, well defined bands of alternate nickel-iron and schreibersite were visible, the alternations sometimes running parallel, but more often intersecting each other at angles of 60° , 90° , or 120° .

The iron was not passive, but very easily rendered so by nitric acid.

The following are the results of analysis, No. 1 representing the largest, and No. 3 the smallest specimen:—

	No. 1	No. 2	No. 3
Specific gravity at 15°C	7.853	7.856	7.839
Iron	88.706	88.365	89.007
Nickel	10.163	10.242	9.964
Cobalt396	.428	.387
Copper003	.004	.003
Tin002	.002	.003
Manganese	trace	—	trace
Phosphorus341	.362	.375
Sulphur019	.008	.026
Chlorine003	.002	.004
Carbon172	.185	.122
Silica067	.061	.066
	99.872	99.659	99.947

Each specimen contained a small quantity of tin, a metal which has been said seldom or never to accompany meteoric iron. The chlorine is probably not an essential constituent of the original masses, but has been derived from the soil in which the iron has lain imbedded. No chlorine could be detected in a specially selected solid piece, of some 50 grams weight, taken from a part of No. 1 destitute of fissures and flaws.

The siliceous residue, although returned as silicic acid, appeared upon examination to have existed partly in combination as silicide of iron.

Cuttings of this iron, heated in a porcelain tube connected with a Sprengel pump, gave off gas having the following composition:—

H	CO	CO ²	N
35.83	38.33	9.75	16.09 = 100

124.59 grams of the iron having a volume of 15.87 c.c. yielded 36.33 c.c. of gas at 0° C. and 760 mm. in 14½ hours, the greater portion being given off in the first 2½ hours.

The proportion of hydrogen in the Virginia iron is much less than in that of Lenarto analysed by Graham (1st Suppl. 635), and that of carbon monoxide much greater. Graham's analysis of the Lenarto iron shows no carbon dioxide (Mallet, *Proc. Roy. Soc.* xx. 365).

2. *Meteoric iron from Trenton*, Washington Co., Wisconsin, has been analysed by J. L. Smith (*Jahresb. f. Min.* 1871, 178), and from the desert of Atacama by E. Ludwig (*Wien. Acad. Ber.* lxiii. [2], 323)—

	Fe	Ni	Co	Cu	P	Insoluble	
Wisconsin	91.03	7.20	0.53	trace	0.14	0.45	= 99.35
Atacama	91.53	7.14	0.41	trace	0.15	—	= 99.53

The Wisconsin iron is in several masses, the largest of which is 14 inches long, 8 inches broad, 4 inches thick, and weighs 62 lbs. Sp. gr. = 7.82. The Atacama specimens are polished on the surface, quite free from oxide, and dissolve without residue in warm nitric acid. One of the smaller fragments was found to contain a very small quantity of sulphur.

3. C. U. Shepard (*Sill. Am. J.* [3], iii. 438) describes meteoric iron from El Dorado Co., California. The mass, weighing 85 lbs., was found in a field; its surface shows the indentations common to these bodies, the crust or coating being slightly oxidised. Turnings taken from it exhibit a sp. gr. of 7.80, which is perhaps a little above that of the mass.

The fragments examined were free from sulphur. A single analysis made on a gram of material gave 88.02 p.c. iron, 8.88 nickel, and 3.50 insoluble matter consisting of a mixture of ferrous and ferric oxides, with many silvery particles of supposed metallic phosphides (schreibersite).

4. *Meteoric Iron from Greenland*.—This iron, described by Nordenskiöld (*Deut. Chem. Ges. Ber.* iv. 987), was found by the Swedish expedition of 1871 on the sea-shore at Oviak near Disco Bay, at the foot of a basalt mountain, in three masses, weighing 300, 200, and 100 centners, together with several smaller pieces. It is very hard, crystalline, and brittle, but when moved to a warmer climate, weathers very rapidly and crumbles to a coarse-grained powder.

Metallic iron is also found in the solid basalt near the locality of the loose blocks, and on the other hand many of these loose masses are partly encrusted with rock of the same character as the neighbouring basalt, a circumstance which seems to indicate that the loose blocks also originally belonged to the basalt. The composition of the loose and imbedded masses is likewise consistent with the supposition of a community of origin, as the following analyses will show:—

a. One of the larger blocks, analysed by Nordenskiöld; b. One of the smaller loose masses, analysed by Nordström; c. Iron from a vein in the basalt, analysed by Lindström.

All the three samples contain nickel. The unusually large, though varying amount of carbon is also common to them all; so likewise is the considerable proportion of chlorine, which shows itself during the weathering of the iron by the exudation of watery drops of iron chloride. The Widmanstätt and Setven figures are most distinct in the iron from the basalt.

	<i>a</i>	<i>b</i>	<i>c</i>
Iron	81.40	86.34	93.24
Nickel	2.48	1.64	1.24
Cobalt	0.07	0.35	0.56
Copper	0.27	0.19	0.19
Alumina	trace	0.24	—
Limo	—	0.48	—
Magnesia	0.04	0.29	trace
Potash	trace	0.07	0.08
Soda	—	0.14	0.12
Phosphorus	0.20	0.07	0.03
Sulphur	1.52	0.22	1.21
Chlorine	0.72	1.16	0.16
Silica	trace	6.66	0.59
" undissolved	0.05	4.37	—
Carbon, organic matters, } oxygen, and loss . }	10.16	3.71	{ C 2.30 H 0.07
	100.00	105.93	99.70

From this community of character it might perhaps be inferred that the whole consists of native metallic iron. The discoverer, however, is more inclined to regard it as due to a fall of meteorites at a very remote epoch, before the volcanic ashes had hardened into the existing basalt. The decided meteoric shape of the masses, their porosity, and the presence of organic matter—circumstances which cannot well be reconciled with the supposition that the iron has been ejected from the interior of the earth in a state of igneous fusion—together with the presence of nickel, &c., all afford evidence of meteoric origin (Nordenskiöld).

Near the large iron masses above described other iron was found in grains and spherular masses; also a vein of the metal several inches wide and some feet in length, enclosed in a rock which is apparently trap, but shows a marked difference in composition from the basalt-breccia from which it protrudes. The metal of this vein, which has been examined by Wöhler (*Ann. Ch. Pharm.* clxii. 247), resembles grey cast iron; it has a bright lustre, is very hard, quite unalterable in air, and has a specific gravity of 5.82. Nordenskiöld obtained gas from the metal of the larger masses by heating them; Wöhler finds that the iron of the vein evolves more than 100 times its volume of a gas which burns with a pale blue flame, and consists of carbon monoxide mixed with a little dioxide. The 'iron,' in fact, contains a considerable amount of carbon and a compound of oxygen, and has evidently not been at any time exposed to a high temperature. By heating, the iron becomes brighter in appearance, and though more soluble in acid, still leaves a carbonaceous residue. A fragment heated in hydrogen lost however 11.09 p.c., or, in other words, was shown to contain that amount of oxygen. Hydrochloric acid acts but slowly and partially on this metal, evolving sulphuretted hydrogen and then hydrogen having the odour of a hydrocarbon, and leaves a black granular magnetic powder which, though insoluble in acid when cold, generates, on the application of heat, a gas with a strong odour of a hydrocarbon, and leaves a residue of amorphous sooty carbon and slightly lustrous graphitic particles. In ferric chloride the 'iron' dissolves without evolution of gas, leaving about 30 p.c. of a black residue which, after having been dried at 200°, loses by subsequent ignition in hydrogen 19 p.c. of its weight, water being formed. This residue is very readily attacked by acid, evolves sulphuretted hydrogen, and leaves a nearly pure carbon in powder and graphitic scales. Ferric chloride and hydrogen chloride appear, therefore, to remove the free metal only, and to be without action on its compounds with sulphur and oxygen. The 'iron' has the following ultimate composition:—

Iron	Nickel	Cobalt	Phosphorus	Sulphur	Carbon	Oxygen	
80.64	1.19	0.49	0.15	2.82	3.69	11.09	= 100.07

The oxygen which constitutes so considerable a part of an apparently metallic mass might be regarded as present in the form of a differrous oxide, Fe^{O} , were it not that this view provides no iron for combination with sulphur and carbon. As Nordenskiöld found magnetite, Fe^{O} , in other Ovifak irons, Wöhler regards the iron compound which constitutes the veins as an intimate mixture of magnetite, of which there would be 40.2 p.c., with metallic iron, its sulphide, carbide, and phosphide, its alloys with nickel and cobalt, and some carbon in isolated particles. The latter undergoes no change when the magnetite and carbide, by the action of heat, generate carbonic oxide.

Meteorite Stones. 1. *The Hesse Meteorites.* A remarkable fall of meteoric stones, which took place on January 1, 1860, at Aerno near Hesse on the Mälar Lake, in Sweden, is recorded by Haidinger (*Wien. Acad. Ber.* lix. [2], 224). These stones, some of which were twice the size of the fist, were spread over a tract of country 16 km. long and 5 km. broad. They have been analysed by A. E. Nordenskiöld (*Pogg. Ann.* cxli. 205). Their weight varies from 0.07 gram to 1791 grams, and their specific gravity from 3.671 to 4.004. Some of them which fell on ice or snow crumbled to a black-brown powder, which contained, together with a few magnetic particles, 4.3 p.c. water (at 110°) and glowed when heated, giving off a small quantity of a brown distillation-product and leaving a red-brown powder. The analysis of this powder gave, together with traces of lithia—

C	H	O	SiO ²	FeO	MgO	CaO	Na ² O	
51.6	3.8	16.7	16.7	8.4	1.5	0.8	1.5	= 100

These stones are encrusted, black on the outside, grey within, porous, and adhere to the tongue. They are composed of silicates and metallic grains bound together by a whitish-grey porous mass.

(1.) *Total Analysis.*—*a* (Lindström). Stone from Hesse; *b* and *c* (Nordenskiöld). *b* found in the ice between Arnö and Hesse, *c* at Arnö.

(2.) Silicate of 1*a*, analysed by Lindström: *a*. After digestion with mercuric chloride. *b*. After separation of the magnetic particles.

(3.) Nickel-iron. *a*. The portion dissolved in mercuric chloride from analysis 1, after deduction of a portion of iron which binds the S to FeS (Lindström). *b* from 1*b*; *c* from 1*c* (Nordenskiöld). The analyses lead to the formula Fe⁸Ni.

(4.) Portion of the silicate of 1*a*, which is soluble in strong hydrochloric acid; 48.67 p.c. of the total quantity of silicate after deduction of FeS (Lindström).

(5.) Insoluble portion after deduction of 1.90 p.c. chromiferous residue undecomposable by hydrofluoric acid (Lindström).

(6.) Analysis of the spherules which make up the chief mass of the Balingsta stone, after deduction of nickel-iron and ferrous sulphide (Nordenskiöld).

(7.) Powder of the stone obtained by pressure between the fingers and sifting through a thick cloth, after deduction of the magnetic particles and ferrous sulphide; *a* and *b*, total analysis; *c*, undissolved matter (42.8 p.c.); *d*, dissolved (56.2 p.c.) (Nordenskiöld).

The proximate constituents of the Hesse meteorites are, according to Nordenskiöld, 20 p.c. nickel-iron (Fe⁸Ni), small quantities of schreibersite, chrome-iron, troilite, and carbonaceous matter, 10 p.c. labradorite and anorthite, 37 p.c. olivin, and 23 p.c. shepardite, the last two not separately recognisable.

2. *Meteorite of Ibbenbüren, Westphalia.*—This meteorite fell on June 17, 1870. Its fall was witnessed by a peasant, who two days afterwards found it buried in a path-way, 27 inches below the surface. Before reaching the ground, one end of the stone had split off, and a fragment of the detached portion, weighing 30 grams, was found some 300 yards away.

The general form of the meteorite is that of a flattened spheroid. Its dimensions are: length, 0.125; breadth, 0.112; thickness, 0.093 meter; probable length before fracture, 0.180 meter. The exterior of the stone consists of a black layer, scarcely 0.1 mm. thick, which is not smooth and even, but covered with a number of extremely fine fused granulations. When examined with a magnifying glass, the surface exhibits innumerable branching cracks, which penetrate into the interior of the stone, and are filled with the fused mass of the exterior. Inside, the meteorite is much lighter in colour than meteorites generally. It consists of a greyish-white mass, interspersed with a very large number of irregularly distributed crystalline granules of a light yellowish-green colour, some imperceptibly small, others of considerable size, and mostly several millimeters in length. These crystals belong to the rhombic system, but it has not been found possible to determine their exact form. Their mean sp. gr. is 3.426. An analysis of them gave the following result:—

SiO ²	FeO	MnO	MgO	CaO	Al ² O ³
54.51	17.53	0.29	28.43	1.04	1.26 = 101.06,

showing that the crystals are bronzite, with a large proportion of iron.

The mass of the meteorite, in which the crystals are embedded, is finely granular, white or light grey, and very brittle. Its sp. gr. is 3.404. Two analyses of it show that it is almost identical in composition with the crystals of bronzite contained in it.

The Ibbenbüren meteorite is remarkable for the simplicity of its constitution, consisting almost entirely of a single silicate, bronzite. It contains no chrome-iron ore, which is almost always present in meteorites, and no trace of any sulphur-compound. Traces of metallic iron, however, appear to be present. The surface is distinctly attracted by the magnet, a portion of the ferrous oxide of the bronzite

METEORITES.

799

METEORITES OF HESSEL, IN SWEDEN.

* With traces of lithia and potash.

having been converted into magnetic oxide by the combined action of the oxygen of the air and a high temperature. At present only three other meteorites of similar constitution are known: the Chassigny meteorite, consisting of olivin; the Bishopville, of enstatite; and that which fell at Manegaum, in Hindostan, in 1843, and consists, like the present, almost entirely of bronzite (*G. vom Rath, Pogg. Ann.* cxlvi. 463).

3. *Meteorite from Bandong, Java.*—This stone, weighing 2,240 grams, fell, with five others, on December 10, 1871. It is an irregular rounded fragment, of sp. gr. 3.519, with a dull blackish surface, presenting numerous spherical indentations. The fracture shows a pale grey stony matrix of silicates, in which are distinguished metallic grains of three different kinds. The first, of an iron-grey colour, consist of nickel-iron; others, of a bronze-yellow colour and iridescent, are iron sulphide; and a third kind, black and insoluble in hydrochloric acid, consists of chromic iron. Under the microscope a thin section of the matrix is crystalline and transparent.

Analysis gave the following results:—

Soluble in Hydrochloric Acid, 60.17 p.c.

S	Fe	Ni	Co	MnO	FeO	MgO	CaO	K ² O	Na ² O	Al ² O ³	SiO ²
2.13	4.95	1.03	0.14	0.12	16.87	12.81	0.30	0.89	0.70	1.43	17.25 = 58.62

Insoluble in Hydrochloric Acid, 39.83 p.c.

Chromo-iron	MnO	Fe ² O ³	MgO	CaO	K ² O	Na ² O	Al ² O ³	SiO ²
4.41	trace	4.30	0.43	0.76	0.18	1.49	2.53	20.40 = 39.50
								98.12

Hence the meteorite appears to consist of:—

Nickel-iron	Iron sulphide	Chromo-iron ore	Peridote	Augite	Felspathic mineral
2.81	5.44	4.41	47.26	20.08	17.00 = 97.90

(Daubrée, *Compt. rend.* lxxv. 1676).

4. *Meteorite of Lodran*, near Moulton in India: October 1, 1868. (*G. Tschermak, Pogg. Ann.* cxl. 321). This partially encrusted stone is a very distinct mixture of nickel-iron, olivin, bronzite, magnetic pyrites, and chromo-iron. The nickel-iron contains:

Fe	Ni	MgO	Residue
85.44	12.79	0.25	0.81 = 99.29

The olivin (A) and bronzite (B) have been examined crystallographically by V. v. Lang. The former, which is of a blue or bluish-grey colour, is fringed on its cracks with mineral dendrites, probably proceeding from chromo-iron, as indicated by the analysis. The olivin substance contains 82 p.c. magnesium silicate to 18 p.c. iron silicate. The green or yellow-green bronzite exhibits three kinds of microscopic imbedded crystals, besides capillary bodies, apparently consisting of felspar and chromo-iron. The composition answers to 78 p.c. magnesium silicate to 22 p.c. iron silicate.

SiO ²	Al ² O ³	Cr ² O ³	FeO	MgO	CaO	
40.14	—	0.60	13.35	46.01	—	= 100.30
55.35	0.60	—	12.13	32.85	0.58	= 101.51

Sp. gr. of A = 3.307; of B = 3.313

The ferrous sulphide does not exhibit crystalline forms, but in the chromo-iron the forms O, ∞O and 3O3 are recognisable. An approximate estimation of the entire mass gave 32.5 p.c. nickel-iron, 28.9 olivin, 31.2 bronzite, with a little chromo-iron and anorthite (?) and 7.4 magnetic pyrites.

5. *Meteorite of Shalka, in Bengal.*—This meteorite, which fell on November 30, 1850, is, according to G. Rose (*Pogg. Ann.* cxxiv. 193), a fine-grained mixture of dark green olivin with a white silicate, and isolated granules of chromo-iron. It is coated with a dull blackish-brown crust. Rammelsberg (*ibid.* cxli. 276) finds that its powder may be separated by levigation into a lighter (A) and a heavier portion (B), and the former by the action of acid into a decomposable portion (a) and an undecomposable portion (b).

	SiO ²	FeO	MgO	CaO	Na ² O	Cr ² O ³ , FeO	Insoluble
A. a	3.84	3.01	3.17	trace	—	2.11	86.43 = 99.46
b	55.55	16.53	77.73	0.09	0.92	0.33	— = 101.15
B.	52.25	20.02	25.96	1.03	—	0.73	— = 100

From these numbers the proximate constituents, independently of the chrome-iron, may be calculated as

	A	B
Bronzite	83.67	83.9
Olivin	11.33	16.1

This analysis confirms G. Rose's conclusion as to the existence of two silicates in the meteorite.

6. The meteorite of *Goalpara*, in Assam, of unknown date, has the appearance of a coarse-grained olivin, of dark grey colour, and consists of 8.49 p.c. metallic iron, 0.85 hydrocarbon, 61.72 olivin, and 30.01 onstatite (Tschermak n. Teclu, *Wien. Akad. Ber.* lxii. [2], 852, 855).

7. The meteorite of *Dusti*, in India, contains globules of calcium sulphide and small golden-yellow octohedrons called osbornite, apparently consisting of an oxysulphide of titanium and calcium; these, together with the calcium sulphide, are imbedded in angite (Muskolyne n. Flight, *Proc. Roy. Soc.*)

8. The meteorite which fell at *Khetree*, Rajputana, has been analysed by D. Waldie (*Chem. News*, xxi. 278). It exhibits light and dark grey portions, partly arranged in layers, partly forming small spherules which are difficult to separate from one another. Sp. gr. 3.612-3.818. It consists of nickel-iron (A), troilite, FeS², and schreibersite (B), soluble silicates (C), and insoluble silicates (D):—

	Fe	Ni	Co	Cr	S	P	
	16.98	1.26	0.21	0.10	—	—	= 18.55
	3.34	—	—	—	1.76	0.12	= 5.22

101.31

9. A meteorite which fell in *Stewart Co., Georgia*, on October 6, 1869, has been examined by J. E. Willet (*Sill. Am. J.* [2], xl. 331). Its fall was accompanied by seven explosions, and the stone immediately after its fall was found buried to the depth of about a foot, and not sensibly hot. It was coated, excepting on a few small portions, with a black crust of the thickness of paper. It had the form of an irregular cone, and weighed about 365 grams. The surface, when freed from the black crust, was grey and studded with green spherules of fibrous structure, the fibres, however, radiating, not from the centre of the spherule, but from a point on its surface; between these were whitish grains, dark particles, and spots of chrome-iron. The chemical analysis by J. L. Smith showed that the stone consists of:—

Nickel-iron	7.00	
Ferrous sulphide	6.10	
Bronzite or hornblende	}	86.90
Olivin		
Albite or oligoclase		
Chrome iron		

The nickel-iron contains 86.02 p.c. Fe, 12.01 nickel, and 0.75 cobalt.

10. *Meteorite of Tjube, India*.—This meteorite fell on December 9, 1869. Nine hours after its fall it was still too hot to be touched by the hands. It weighed 10 kilograms and had a specific gravity of 3.496. A portion (14 p.c.) was separable by the magnet and had a specific gravity of 6.8 at 15°. The ratio of nickel to iron in the magnetic portion was 1 : 16. The siliceous portion gave by analysis:—

Matter insol. in HCl	Iron sulphide	SiO ²	MgO	FeO	CaO	Na ² O with trace of K ² O	Al ² O ³	MnO	NiO	
50.14	3.71	14.95	16.40	12.01	0.74	0.32	0.22	0.30	traces	= 98.79

11. *Meteorite of Tadjera*.—This stone, which fell on June 6, 1867, at Tadjera, near Sétif in Algeria, contains, according to Meunier (*Ann. Ch. Phys.* [4], vii. 5), 54.64 p.c. decomposable silicates, 28.80 undecomposable silicates, 0.20 chrome-iron ore, 8.04 troilite, and 8.32 nickel-iron.

12. *Meteorites of Danville in Alabama*.—A number of stones fell in this locality at 5 p.m. on November 27, 1868. The one examined had the usual black crust, was of a grey colour on a freshly-broken surface, and somewhat oolitic in its structure. Troilite and nickeliferous iron were easily recognisable, and another mineral was observed

* Loss by solution of separated silica.

† With traces of K²O.

which was probably enstatite. The specific gravity of the stone is 3.398. The iron has the following composition:—

Fe	Ni	Co	P	S
89.613	9.050	0.521	0.019	0.105 = 99.208

The troilite consists of 61.11 iron and 39.56 sulphur (= 100.67).

The stony portion of this meteorite is made up of 60.88 p.c. soluble, and 39.12 p.c. insoluble silicate, the latter being thus composed:—

SiO ^a	Al ^a O ^a	FeO	MgO	CaO
50.08	4.11	19.85	20.14	3.90 = 98.08

These numbers denote a mineral of the augite group. The analysis of the soluble portion (in which were found silica 45.90, magnesia 26.52, iron protoxide 23.64, alumina 1.78, and lime 2.31) yielded numbers corresponding with the constitution of an olivin (J. Lawrence Smith, *Jahrbuch. f. Mineralogie*, 1871, 82).

13. *The Franklin Meteorite*.—This stone fell four miles from Frankfort, in Franklin county, Alabama, on December 5, 1868. It weighed 1 lb. 9½ oz., and has a mean specific gravity = 3.31. It contains:—

SiO ^a	Al ^a O ^a	Iron oxide	Chromium oxide	MgO	CaO	K ^a O	Na ^a O	S
51.33	8.05	13.70	0.42	17.59	7.03	0.22	0.45	0.23 = 98.02

with a trace of nickeliferous iron.

The chromium oxide corresponds with 0.62 p.c. chromite, the sulphur with 0.63 p.c. troilite. This stone belongs to the class to which G. Rose has given the name of *Howardite*, and resembles in its physical character the meteorite of Petersburg, Tennessee (G. J. Brush, *ibid.* 178).

14. *Meteorite of Seasmont, Maine*.—The original mass of this meteoric stone would appear to have presented an oval sub-conical outline, the exterior being covered with a thick crust of at least one-sixteenth of an inch in thickness. Its colour is bluish-white, and remarkably uniform, but it is slightly stained in one or two places with ferric oxide. More than one-half of the meteorite is composed of small, rounded, translucent grains, vitreous in lustre, and rarely exceeding a mustard-seed in size. Between these, and often partially coating them, is a fine-grained white, or greyish-white mineral, which is supposed to be chladnite; it constitutes about one-fourth of the stone, is without visible crystalline structure, and rather loosely coherent. Minute points of bright meteoric iron are very thickly scattered throughout the mass, and a few grains of troilite are visible. In one spot only a peculiar blackish substance of small dimensions was noticed, which, on being touched with the point of a knife, was found to be soft, and to leave a bright metallic streak; it was probably a plumbaginous aggregate.

In appearance, especially in the well marked character of its granules, this stone closely resembles the Aussum (France) meteorite of December 1858, while in the thickness and general character of the crust it also corresponds with the celebrated Mauerkirchen stone of 1768.

It was analysed by J. L. Smith, with the following results: sp. gr. 3.701; stony matter, 85.38 p.c.; nickeliferous iron, 14.62 p.c. The iron yielded: iron, 90.02; nickel, 9.05; cobalt, 0.43. The stony portion, treated with a mixture of hydrochloric and nitric acids, gave: 52.3 p.c. soluble in acid, and 47.7 insoluble.

Both the soluble and insoluble portions consisted essentially of double silicates of iron and magnesium, the soluble part being classed as an olivin, while the insoluble was considered to be either bronzite or enstatite.

The proximate composition of the stone would therefore be:—

Nickeliferous iron	14.63
Magnetic pyrites	3.06
Olivin	43.04
Bronzite, with a little orthoclase and chrome-iron	39.27

(C. U. Shepard, *Sill. Am. J.* [3], 133, 200).

15. A meteorite which fell at *Adare*, in the county of Limerick, in 1810, has been analysed by R. A. Apjohn (*Chem. Soc. J.* [2], xii, 104). It consists of an earthy matrix in which are imbedded numerous small, shining, metallic particles. Its surface is dark-coloured and has a fused appearance. Sp. gr. = 3.94. Its proximate composition is:

Nickel-iron	19.07
Magnetic pyrites	6.54
Chrome-iron	1.75
Soluble silicate	35.44
Insoluble silicate	37.07
	<hr/>
	99.87

The metallic portion consists of 85.120 p.c. iron, 14.275 nickel, 0.602 cobalt, with a trace of phosphorus.

The composition of the soluble silicate (A) and insoluble silicate (B) is as follows:—

SiO ²	Al ² O ³	FeO	MnO	CaO	MgO	Na ² O	K ² O	P ² O ⁵
42.91	2.35	16.93	6.26	5.34	24.32	0.29	0.02	— = 98.42
59.48	3.24	7.94	8.84	4.62	13.17	1.86	0.30	trace = 99.45

This meteorite is especially interesting as containing also a small quantity of vanadium, affording indeed the first instance in which that element has been discovered in a meteoric stone.

METHENYL-DIAMINES. When orthoformic ether and acetamide are heated together in sealed tubes to 180°, cubic crystals are formed consisting of methenyl-diacetyl-diamine, $\text{CH} \begin{Bmatrix} \text{NH}(\text{C}^2\text{H}^3\text{O}) \\ [\text{N}(\text{C}^2\text{H}^3\text{O})]'' \end{Bmatrix}$, or $\text{N}^2 \begin{Bmatrix} (\text{CH})'' \\ (\text{C}^2\text{H}^3\text{O})^2 \\ \text{H} \end{Bmatrix}$. Their formation may be represented by the equation—

Besides these products, there are formed ethyl acetate and an amidomethenyliumide, $\text{CH} \begin{Bmatrix} \text{NH}^2 \\ (\text{NH}) \end{Bmatrix}$, or methenyl-diamine $\text{N}^2 \begin{Bmatrix} (\text{CH})'' \\ \text{H}^2 \end{Bmatrix}$, which latter remains in solution, but has not yet been obtained in the free state. Its hydrochloride has the composition $\text{CN}^2\text{H}^4.2\text{HCl}$; the platinochloride is $\text{CN}^2\text{H}^4.2\text{HCl.PtCl}^4$. Methenyl-diacetyl-diamine heated with water is converted into the acetate of methenyl-diamine—

(Wichelhaus, *Deut. Chem. Ges. Ber.* iii. 2).

METHYL ALCOHOL, CH³O. On the formation of methyl alcohol by reduction of formic acid, see **FORMIC ACID** (p. 533).

Testing and Estimation.—Methyl alcohol does not give Lieben's iodoform reaction with iodine and potash (1st *Suppl.* 593; 2nd *Suppl.* 674), and may therefore easily be tested, by means of this reaction, for ethyl alcohol, acetone, and other compounds which yield iodoform when thus treated (Lieben).

The proportion of methyl alcohol in commercial wood-spirit may be estimated as follows:—A dry flask holding 100 c.c., and containing 30 grams of phosphorus di-iodide, is closed with a double-perforated stopper (best of glass) provided with a small tap-burette in which 5 c.c. of the wood-spirit, measured at 16°, are placed. In the other hole a condensing-tube, bent at an obtuse angle, is fitted. The wood-spirit is then added drop by drop, and when all is introduced, the flask is heated for five minutes in boiling water, and then inclined, to distil off the methyl iodide. The receiver consists of a glass tube holding 25 c.c., the lower end being narrowed and calibrated. When the distillation is finished, the condenser is rinsed out with water, the receiver filled with water to the mark, and after the contents have been well shaken, the volume of the iodide is read off. As 5 c.c. of pure methyl alcohol yield under these conditions 7.19 c.c. of iodide, the quantity of the alcohol in the wood-spirit can be found by a simple proportion. If the wood-spirit contains methyl acetate, this compound will also be converted into the iodide; but in the valuation of wood-spirit for the manufacture of aniline-colours, which is the chief object of the process here described, the error arising from this substance may be neglected, because it also forms methylated anilines; moreover its quantity can be easily determined by heating the wood-spirit with standard soda, and finding the quantity used by means of standard acid. Acetone yields, under the above conditions, only a few drops of a distillate which

METHYL ALCOHOL.

is soluble in water, and the other impurities are converted into resinous bodies (G. Kroll, *Deut. Chem. Ges. Ber.* vi. 1310).

Mixtures of Methyl Alcohol and Water.—The specific heats, heat of combination, boiling point, capillarity, expansion by heat, and compressibility of mixtures of methyl alcohol and water in various proportions have been determined by A. Dupré (*Proc. Roy. Soc.* xx. 336).

METHYL ETHERS. *Chloride*, CH^*Cl .—The best method of preparing this compound is to pass a current of hydrogen chloride into a boiling solution of zinc chloride in twice its weight of wood-spirit, in a flask connected with an inverted condenser and a wash-bottle containing water. The hydrochloric acid is then completely absorbed, and the whole of the methyl alcohol is converted into chloride, while the impurities which accompany it in the wood-spirit are converted into a black tarry mass (Groves, *Chem. Soc. J.* [2], xii. 641).

Iodide, CH^*I .—Methyl iodide, in the dry state, is very slowly decomposed by a copper-zinc couple; but if the couple be wet with water, decomposition takes place, even at ordinary temperatures, the products being chiefly methane and zinc iodhydrate:—

With a mixture of methyl alcohol and ethyl alcohol the products are methane and zinc iodethylate, $\text{ZnI}(\text{OC}^*\text{H}^*)$ (Gladstone & Tribe, *Chem. Soc. J.* [2], xi. 682).

METHYLAMINE, CH^*N . *Formation*.—When crude methyl alcohol, after being separated by distillation from pyroligneous acid, is further purified by distillation over lime, the first portion of the distillate has a strong alkaline reaction and an ammoniacal odour, and contains a large quantity of methylamine. If the methyl alcohol be redistilled for a longer time, the quantity of methylamine is increased, and it is accompanied by di- and tri-methylamine. The crude wood-spirit, before these distillations, contains only traces of methylamine, but abundance of ammonia. The ammonia is, therefore, an agent in the production of the methylamine. It does not, however, act directly on the methyl alcohol, for these two bodies may be heated together for several hours without production of methylamine. The reaction takes place between ammonia and acetone, which is always present in crude wood-spirit, as represented by the following equations:—

The aldehyde found in methyl alcohol is derived from the same reaction (C. W. Vincent, *Bull. Soc. Chim.* [2], xix. 14; *Compt. rend.* lxxvii. 898).

According to Berthelot, methyl alcohol and ammonium chloride, heated together to 320° , yield a small quantity of methylamine. Dusart & Berdy (*Compt. rend.* lxxiv. 188), by heating 2 parts ammonium chloride, 3 parts methyl alcohol, and 1 part hydrochloric acid to 207° for 30 hours, obtain oxide and chloride of methyl, together with methylamine hydrochloride amounting to one-third of the ammonium chloride used. From the lower temperature required in this reaction they consider that methyl chloride is essential to it, and that the formation of methylamine in Berthelot's process must have been due to decomposition of the sal-ammoniac into ammonia and hydrochloric acid.

METHYL-ANILINE. See ANILINE (p. 73).

METHYL-BUTYL CARBINOL, $\text{CHOH} \begin{Bmatrix} \text{CH}^3 \\ \text{C}^2\text{H}^5 \end{Bmatrix}$. See **HEXYL ALCOHOLS** (1st Suppl. 6, 98).

METHYL-BROMACETOL, $\text{CH}^3\text{—CBr}^2\text{—CH}^3$. Syn. with dibromopropane. See **PROPANES**.

METHYL-CAPROONE, or **METHYL-AMYL KETONE**, $\text{CO} \begin{Bmatrix} \text{CH}^3 \\ \text{C}^5\text{H}_{11} \end{Bmatrix}$. See **CAPROONE** (p. 251).

METHYL-CHLORACETOL, $\text{CH}^3\text{—CCl}^2\text{—CH}^3$. Syn. with dichloropropane. See **PROPANES**.

METHYL-CHLOROPHENETOL, $\text{C}^6\text{H}^4\text{Cl.O.C}^2\text{H}^3$. This compound, the ethylic ether of chlorinated methyl-phenol or chlorocresol, is obtained by heating the sulphate of diazochlorotoluene with absolute alcohol:

a. **Methyl-chlorophenetol** prepared from the *a*-diazotoluene salt (obtained by the action of nitrous acid on liquid chlorotoluidine), is an aromatic liquid insoluble in water, easily soluble in alcohol; boils at $210^\circ\text{--}220^\circ$; has a specific gravity of 1.127 at 19.5° .

b. **Methyl-chlorophenetol**, derived in like manner from solid *β*-chlorotoluidine, has the same odour as the *a*-compound, boils at $210^\circ\text{--}220^\circ$, and has a specific gravity of 1.131 at 18° . The *a*-compound is produced in larger proportion than the *β*-compound (Wroblevsky, *Zeitschr. f. Chem.* [2], vi. 164).

METHYLENE ACETOCHLORIDE, $\text{C}^2\text{H}^4\text{ClO}^2$ (L. Henry, *Deut. Chem. Ges. Ber.* vi. 739). When chlorine is passed into cooled methyl acetate until hydrochloric acid is evolved in considerable quantity, and the product is distilled, a portion passes over between 100° and 120° ; and this, when dried and submitted to fractionation, yields methylene acetochloride as a colourless liquid, having a penetrating and suffocating odour, and a burning taste. It has a specific gravity of 1.1953, and a vapour-density of 3.70, is insoluble in water, soluble in alcohol or ether, and boils at $115^\circ\text{--}116^\circ$. It is decomposed by water, or alkalis, with formation of hydrochloric acid, acetic acid, and probably formic aldehyde. Sulphuric acid decomposes it, hydrochloric acid being evolved, and a sulpho-acid of methylene [probably $\text{CH}^2(\text{HSO}^4)^2$] being formed. When this acid is distilled with water, it appears to yield formic aldehyde or a polymeric of that substance. When methylene acetochloride is warmed with alcoholic potassium acetate, it yields methylene diacetate; and when it is treated with potassium sulphocyanate, a violent reaction takes place, a substance which has the

composition $\text{CH}^2 \begin{Bmatrix} \text{CNS} \\ \text{C}^2\text{H}^3\text{O}^2 \end{Bmatrix}$ being probably formed. Ammonia and aniline react on methylene acetochloride, apparently forming methylene bases.

Methylene formochloride, $\text{CH}^2 \begin{Bmatrix} \text{Cl} \\ \text{CHO}^2 \end{Bmatrix}$, appears to be formed in like manner by the action of chlorine on methyl formate; the product boils at about 100° .

METHYLENE IODIDE, CH^2I^2 . From experiments by J. Bljuducho (*Zeitschr. f. Chem.* [2], vii. 91) it appears that the greatest yield of this compound is obtained when a mixture of chloroform and hydriodic acid in the proportions required by the following equation is heated to 130° for 24 hours:

METHYLENE SULPHIDE. See **THIOFORMIC ALDEHYDE**.

METHYLENE-PROTOCATECHUIC ACID. Syn. with **PIPERONYLIC ACID** (q.v.)

METHYL-GUANIDINE. See **GUANIDINE** (p. 582).

METHYL-ISETHIONIC ACID. See **ISETHIONIC ACID** (p. 705).

METHYL KETONES. **Methyl-propyl Ketone**, $\text{CH}^3.\text{CO.C}^3\text{H}^7$, is produced by oxidation of the secondary amyl alcohol obtained from normal pentane (p. 63). It boils at $102^\circ\text{--}105^\circ$, unites with alkaline bisulphites, and yields by oxidation, acetic and propionic acids, with a small quantity of carbonic acid (Schorlemmer, *Chem. Soc. J.* [2], x. 1085).

808 METHYL KETONES—METHYL-PROPARGYLIC ETHER.

Methyl-butyl Ketone, $\text{CH}_3\text{CO.C}^4\text{H}_9$, is formed by oxidation of the secondary neryl alcohol obtained from normal hexane (p. 645), and converted by further oxidation into acetic and normal butyric acids (Schorlemmer, *Ann. Ch. Pharm.* clxi, 263).

Methyl-pentyl Ketone, $\text{CH}_3\text{CO.C}^5\text{H}_{11}$, is formed by oxidation of the secondary alcohol obtained from normal heptane (p. 643). It is a fragrant liquid which boils between 150° and 152° , unites with alkaline bisulphites, and yields by oxidation acetic and normal valeric acids (Schorlemmer, *loc. cit.*)

Methyl-nonyl Ketone, $\text{C}^{11}\text{H}_{22}\text{O} = \text{CH}_3\text{CO.C}^9\text{H}_{19}$, is produced by distilling a mixture of the calcium salts of acetic and capric acids:

The crude distillate separates by fractional distillation into three portions, the first boiling at 200° , the second at 210° – 215° , the third above 300° . The second fraction mixed with alcohol and ammonia, and saturated with sulphurous acid, yields a crystalline ketone-bisulphite which, when purified by crystallisation from alcohol, has the composition $\text{C}^{11}\text{H}_{22}\text{O} \cdot (\text{NH}_4)\text{HSO}_3 + \text{H}_2\text{O}$; and the ketone separated from this salt by sodium carbonate, dried with potash, and rectified, has exactly the composition $\text{C}^{11}\text{H}_{22}\text{O}$.

Methyl-nonyl ketone thus prepared is a colourless, strongly refracting oil having an odour slightly resembling that of rue oil, a specific gravity = 0.8295 at 175° , and boiling at 223° – 224° . At 5° – 6° it solidifies to a crystalline mass, which does not resume the liquid form till heated to 15° – 16° . It is insoluble in water, but dissolves easily in alcohol (Gorup-Besanez a. Grimm, *Deut. Chem. Ges. Ber.* iii, 528).

Methyl-nonyl ketone forms the chief constituent of the volatile oil of garden rue (v. 133). Gorup-Besanez a. Grimm, by treating the rectified oil with ammonium bisulphite, obtained a crystalline compound, from which sodium carbonate separated a liquid having a sp. gr. of 0.8281 at 187° , boiling at 224° – 225° , and agreeing in melting and solidifying point with the synthetically prepared ketone. Gieseecke (*Zeitschr. f. Chem.* vi, 429), by subjecting 500 grams of a sample of *Ol. Ruta*, nearly free from hydrocarbons, to fractional distillation, obtained 300 grams of a colourless oil having exactly the composition $\text{C}^{11}\text{H}_{22}\text{O}$. It had a violet fluorescence, an odour like that of oranges, a sp. gr. = 0.8268 at 20.5° , boiled at 225° – 226° , and solidified at 6° to a mass which melted at 16° . By oxidation with chromic acid mixture, it was converted into pelargonic and acetic acids, agreeing therein with Popoff's law of the oxidation of ketones, according to which the lower alcohol-radicle of the ketone remains with the carbonyl, while the higher radicle is oxidised (p. 711).

Methyl-nonyl ketone, treated with phosphorus pentachloride, is converted into a chloride $\text{C}^{11}\text{H}_{21}\text{Cl}_2$, which is resolved by distillation into hydrogen chloride and a chloride $\text{C}^{11}\text{H}_{21}\text{Cl}$, boiling at 221° – 223° . Both these chlorides, when heated to 130° with alcoholic potash, yield a hydrocarbon of the acetylene series, boiling at 198° – 202° (Gieseecke).

Methyl-nonyl ketone is converted by nascent hydrogen into secondary hendecatyl alcohol, $\text{CH}_3\text{CHOH.C}^9\text{H}_{19}$. The ketone is placed in a glass cylinder together with a quantity of dilute alcohol not sufficient to dissolve it, and sodium in thin slices is gradually added. On fractionating the crude product, the greater part distills at 228° – 233° , leaving a body of very high boiling point, probably belonging to the pinacone group; and by shaking up the portion boiling between 228° and 233° with solution of sodium bisulphite, exhausting the mixture with ether, again treating the residue with sodium bisulphite, and repeating these operations several times, the hendecatyl alcohol is finally obtained free from the ketone.

Secondary hendecatyl alcohol is a liquid having nearly the thickness of glycerin, a sp. gr. of 0.826 at 19° , boiling at 228° – 229° , insoluble in water. The bromide formed from it by the action of bromine and phosphorus is resolved, on distillation, into hydrogen bromide and hendecatene, $\text{C}^{11}\text{H}_{22}$, boiling at 192° – 193° (Gieseecke).

MICA. The two following analyses of mica are included amongst the results of the investigation of the mineral constituents of Scotch granites by S. Houghton (*Phil. Mag.* [4], xl. 59): a. From Rubislaw, Aberdeen; large white tables, with angles of 60° and 120° ; angle of the optic axes $= 72^\circ 30'$. Contains no lithia. b. Black mica, rarely found in large crystals, but occurring in nearly all granites in the form of small laminae. Contains no fluorine. The specimen analysed is from Aberdeen:—

	SiO ^a	SiF ^a	Al ^a O ^a	Fe ^a O ^a	FeO	MnO	CaO	MgO	Na ^a O	K ^a O	H ^a O
a.	44.40	0.16	37.36	2.04	—	0.24	0.78	0.57	0.93	9.87	1.84 = 98.19
b.	36.50	—	16.50	18.49	6.76	1.30	1.11	7.44	0.02	8.77	1.60 = 99.89

In a mica imbedded in selagite, a dark-coloured volcanic rock of Monte Catini, E. Bechi found:—

SiO ^a	Al ^a O ^a	Fe ^a O ^a	MgO	CaO	K ^a O	F	H ^a O
40.8	22.1	21.0	0.5	5.6	5.9	0.8	3.5 = 100.2

Hardness = 2.5. Sp. gr. = 3.15 (*Jahresb. f. Chem.* 1870, 1298).

On the mica of Adamellogranite, see p. 27 of this volume.

MIGNONETTE. The root of this plant has a pungent taste, and emits, when cut up, an unmistakable odour of horse-radish. When macerated with hot water and distilled, it yields an oily distillate which is converted into sinapoline by boiling with laryta-water, and into thiosinaminine by treatment with ammonia. These reactions show that the root contains allyl sulphocyanate (A. Vollrath, *Arch. Pharm.* [2], cxlviii. 166).

MILANITE. This name is given by E. Tietze (*Jahrbuch geol. Reichsanst.* xx. 588) to a hydrated aluminium silicate from Maidanpek, in Servia, hitherto regarded as agalmatolite. It feels like soap-stone, has a conchoidal fracture, crumbles easily, becomes transiently dark-coloured when heated, and dissolves in hydrochloric acid with separation of silica. It is most nearly related to halloysite. The following analysis by Pateru—

SiO ^a	Al ^a O ^a	Fe ^a O ^a	H ^a O
44.06	25.20	trace	29.50 = 99.56

agrees nearly with the formula $4(Al^aO^a.2SiO^a) + 27H^aO$.

MILARITE. This mineral was named by Kennigott (*Jahrbuch f. Mineralogie*, 1870, 80) after the Val Milar, near Ruáras, in the canton of Graubünden, Switzerland, where it was supposed to occur; but, according to a notice by Kuschel-Köhler, cited by Frenzel (*ibid.* 1873, 785), it is found, not in the Val Milar, but in the Val Ginf, north-west of Ruáras.

Milarite occurs, together with smoky quartz, orthoclase, apatite, chabasite, titanite, and chlorite, implanted on granite, and forms hexagonal crystals sometimes 10 mm. long, exhibiting the combination $\infty P2.P$, frequently also with OP , more rarely with ∞I . The terminal dihedral angle of the pyramid was found by direct measurement $= 144^\circ 48' 5'$, by indirect measurement $= 144^\circ 41' 50'$. Cleavage indistinct, parallel to OP . The mineral is transparent and nearly colourless, with a faint tinge of green, transparent or translucent, and has a vitreous lustre. Hardness $= 5.5$ to 6. It swells up and forms a white glass when heated, dissolves but slightly in hydrochloric acid; its powder, both in the natural state and after ignition, has a faint alkaline reaction (Kennigott).

From a quantitative analysis of the mineral, Kennigott inferred that it was a zeolite, consisting of a hydrated silicate of aluminium, calcium, and sodium. Frenzel, however, by a quantitative analysis of pure selected materials, finds its composition to be:—

SiO ^a	Al ^a O ^a	CaO	Na ^a O	H ^a O
71.12	8.45	11.27	7.61	1.55 = 100

The mineral does not sustain any loss of weight at 100° , the water not being given off till the powder is heated to a very high temperature, at which it begins to melt. It is but little attacked by acids.

If the water be regarded as basic, the analytical results may be represented by the formula:

According to this, milarite is not a zeolite, but a mineral related to petalite (Frenzel).

MILK. Influence of Food on the production of Milk in the Cow.—G. Kühn and M. Fieischer (*Landw. Versuchstationen*, xii. 197, 361, 405) have made experiments on two

milk-cows, fed daily on a normal diet of 20 lbs. meadow-hay and 0.06 lb. salt, to which were added, in different experiments, known weights of rape-flour, starch, oil, or bruised beans. The results showed that an increase in the production of milk took place after addition of oil or bruised beans, but not after addition of starch or rape-flour. These variations in the feeding affected, however, only the total quantity of milk secreted, its composition remaining nearly the same in all cases. The progress of the lactation was accompanied by a continuous alteration in the composition of the milk of both animals, the total amount of the nitrogenous constituents increasing regularly in proportion to that of the non-nitrogenous constituents, the proportion of milk-sugar and butter steadily decreasing, while the amount of casein increased, and that of albumin diminished, but in smaller proportion. The experiments did not show decidedly whether the formation of butter is due to the carbohydrates or to the albuminous constituents of the food.

These results have been confirmed by a further series of experiments made by Kühn (*Chem. Centr.* 1871, 102; *Chem. Soc. J.* [2], ix. 414) on four cows fed on a diet of moderate amount, not sufficient for the highest yield of milk. The food consisted of hay, barley-straw, and turnips, the albuminous elements of the food being increased at a certain stage of the experiments by the addition of bruised beans.

The general result of these experiments is to show that an increase in the albumin and fatty elements of a moderate diet produces an increase in the milk-yield, which gradually rises (simultaneously with bodily condition) to a certain maximum, corresponding in each case with the maximum increase of the above elements. Sooner or later, however, the natural diminution depending on the period of lactation occurs, and no further increase can be produced by increasing the food. Diminution of the above elements of the food produces a diminution in the milk-yield. The addition of fat increases the ingredients of milk generally, but has no special influence on the amount of fat in the milk. The percentage of sugar in the milk does not appear to be affected by the diet, and the variations in the amount of albumin are too small to be quantitatively determined. No variation in the amount of casein could be traced to the food; indeed, the variations in the percentage of casein and fat appear to be due to irregularities in the action of the gland.

It appears from these results that it is not possible by variations in the food, to produce a 'butter-cow' or a 'cheese-cow.' Differences in this respect are differences of stock and individuals.

For tables of the numerical results of these experiments, see the references above cited.

On the influence of Food on the production of Milk, see further, Fleischer (*Arch. f. pathol. Anatomie*, li. 30; *Jahresb. f. Chem.* 1870, 912); Stohmann (*Zeitschr. f. Biologie*, vi. 204; *Jahresb.* 1870, 911).

Weiske-Proskau (*Ann. d. Landw. Wochenblatt*, Sept. 6, 1871), by experiments on two cows supplied during twelve days with precipitated calcium phosphate in addition to their ordinary food, found that no increase was thereby produced in the percentage of ash, of lime, or of phosphoric acid contained in the milk; neither was there any increase in the absolute quantity of these substances yielded as milk.

According to Stohmann (*Chem. Centr.* 1872, 722) the proportion of phosphoric acid to nitrogen in goat's milk is the same as in the grain of cereals, viz. $P_2O_5 : N^2$.

Reactions of Milk: (1) *With Litmus.*—The most contradictory statements have been made as to the reaction of normal fresh cows' milk with litmus, numerous observers having found the reaction of milk to be acid, while an equal number describe it as alkaline.

Soxhlet (*J. pr. Chem.* [2], vi. 1; *Chem. Soc. J.* [2], xi. 187) considers that milk possesses what he calls an *amphoteric* or *amphigenic* reaction, i.e. that it has the remarkable property of turning simultaneously red litmus blue and blue litmus red; and this arises from the fact that milk contains both acid and neutral phosphates of the alkali-metals. Heintz maintains that a fluid containing both acid and ordinary alkaline phosphates, simply imparts a violet colour to red and to blue litmus-paper.

A. Vogel (*J. pr. Chem.* [2], viii. 137) has examined this question further, using, instead of litmus-paper, a carefully prepared neutral tincture of litmus, and, as the result of his experiments, states that he has never yet found freshly drawn cows' milk to exhibit a decided alkaline reaction.

If litmus-tincture which has been reddened by milk is left exposed to the air in a watch-glass, it gradually loses the red colour and passes into blue, while, if it be closely corked up, it retains the red colour, though in some cases it seemed to become slightly blue in the course of an hour or two. In either case it acquires, after three or four days, a deep red colour, owing to formation of lactic acid. Hence it follows that in normal fresh cows' milk there is no free lactic acid. Litmus-tincture reddened by milk also becomes blue if shaken up and poured backwards and forwards from one vessel to another, and more especially on heating.

Vogel thinks that the restoration of the blue colour in these cases is due to the escape of the carbonic acid which fresh milk contains. Soxhlet also found that milk, when subjected to the action of the air-pump, gave up carbonic acid and became decidedly alkaline. Other tests for alkalinity in liquids were also applied by Vogel to milk, with negative results.

Out of the milk of 30 cows, which was examined by Bischoff at Schleisheim, only two specimens showed the double reaction with certainty. In the greater number of cases the reaction was either neutral or transiently acid. Some specimens, however, gave, at first, a weak alkaline reaction, quickly passing into acid reaction. This effect was probably due to the absorption of ammonia by the milk, since the experiments were made in the stalls.

(2) *With Boric Acid*.—According to A. Hirschberg (*Chem. Centr.* 1872, 496) the addition of a small quantity of boric acid to milk retards the separation of cream, and preserves the milk from turning sour for several days.

(3) *With Mustard-oil*.—According to Schwalbe (*Deut. Chem. Ges. Ber.* v. 286) the addition of mustard-oil to cows' milk (1 drop to 20 grams) prevents coagulation. The mixture may be kept in summer for weeks in half-filled bottles without coagulating. After 5-7 weeks the casein was found to be converted into albumin, and the liquid was strongly acid.

(4) On the relative quantities of ammonia eliminated from milk by the action of potash and of potassium permanganate, see *ANIMONTA* (p. 61).

Condensed Milk.—Trommer (*Dingl. pol. J.* cxviii. 168) prepares condensed milk as follows: 1 part of fresh milk is mixed with 1 part of the cream which rises to the surface when the milk is mixed with sodium bicarbonate in the proportion of $\frac{1}{2}$ to $\frac{3}{4}$ oz. of the latter to 10 quarts. The mixture is heated nearly to boiling, then strained, and after addition of pure sugar (in the form of a boiled and clarified solution cooled to 75° C.) in the proportion of 3 to 3½ oz. to a quart, it is evaporated over the water-bath till the residue falls from the stirrer in thick masses. The temperature during the evaporation should not exceed 87-92°. The condensed milk is preserved in tins.

L. Koffer (*Dingl. pol. J.* cxvi. 161) has examined the following kinds of condensed milk: (1.) From the Anglo-Swiss Condensed Milk Company in Cham (Canton Zug); (2.) From the factory in Sassin. (3.) From the Swiss-German Extract Company at Vivis in Switzerland, and Kompten in Bavaria; preserved in glasses. (4.) The same in tins. (5.) From the Emserenth. The various samples contained from 25 to 36 p.c. sugar and 14 to 18 p.c. milk-sugar. These being deducted, the composition of the several sorts is as follows:—

	1	2	3	4	5
Water	22.180	18.824	22.421	18.810	20.770
Fat (butter)	12.260	12.625	12.030	18.650	12.830
Casein and albumin .	28.100	24.240	25.960	24.000	29.600
Ash (salts)	2.180	2.482	2.673	2.430	2.865

All the samples, when mixed with 4 or 5 times their volume of water, yielded a good sweet milk, and all, when mixed with 5 or 6 vol. water, could be converted into butter, differing from one another only by the greater or lesser facility with which the individual fat-globules ran together.

According to the *British Medical Journal*, Newnham's condensed milk contains 10 p.c. water, 10 casein, 2 ash, 69 fat milk-sugar and cane-sugar. Hence it appears that a pound of the condensed milk contains the constituents of 3 to 4 pounds of fresh milk (*Pharm. J. Trans.* [3], 1, 606).

Analysis of MILK. E. H. v. Baumhauer (*Zeitschr. anal. Chem.* ix. 422) discusses the several methods hitherto adopted for the analysis of milk. He rejects as worthless all modes of testing depending on the use of hydrometers, inasmuch as the milk, which is a solution of substances specifically heavier than water, contains in suspension a much lighter body, namely, the cream, and consequently exhibits a mean specific gravity which, after the removal of part of the cream, may be again imparted to the liquid by addition of water. A further objection to the use of hydrometers for the purpose is that the expansion-coefficient of milk is unknown, and moreover uncertain, on account of the varying proportions of the dissolved constituents. To obtain comparable results, it would therefore be necessary to work always at the same temperature. Moreover, the quantity of milk which becomes attached to the unimmersed part of the instrument may give rise to an error equivalent to 5 p.c. of water. In skimmed milk the specific gravity exhibits no constant relation to the sum of the dissolved constituents, since the relative quantities of these are variable. Experiments showed, also, that very little accordance exists between the indications of the cremometer (a graduated glass cylinder in which the volume of cream which rises to the surface on

standing is directly read off) and the amount of fat which can be extracted from the milk by ether. When one cremometer was filled with milk which had not been shaken, a second with milk which had been shaken for a minute, and a third with milk which had been shaken for two minutes, the indications of these instruments varied from 6 to 10 p.c. This diversity is due to the influence of agitation on the mode of separation of the fat-globules.

Heeren (*Dingl. pol. J.* xciii. 396) likewise objects to the use of the cremometer, because only a part of the fat contained in the milk rises as cream to the surface, so that not unfrequently an error of 40 p.c. may occur in the estimation. He further points out that the opacity of milk depends upon the size of the fat-globules, and therefore that all the optical methods depending on comparison of the opacity of a given sample with that of normal milk, must yield different values for the same actual amount of fat present, according as the milk has been skimmed (freed from the larger fat-globules) or not. A difference between the results of the optical and chemical testing indicates previous skimming, inasmuch as perfectly normal milk would exhibit a nearly equal amount of fat by both methods.

The following method of analysis is described by Pribram (*Dingl. polyt. J.* xcvi. 448): 50 grams of the milk are mixed in a tared beaker glass with 15 grams of purified and pulverised common salt, and the mixture, after being stirred with a tared glass rod, is heated to gentle ebullition. After cooling, a quantity of water is added sufficient to raise the liquid contents to 100 grams, care being taken to ensure complete solution and uniform mixture. A large portion of the liquid is then passed through a filter not previously wetted, a portion of the filtrate is exactly weighed out, and the quantity of milk-sugar in it is determined by means of Fehling's solution (10 c.c. = 0.06875 grams of milk-sugar), or better by means of circular polarisation. In another weighed portion of the filtrate, the amount of chlorine—and thence the amount of common salt—is determined by means of a decinormal silver solution. From this the weight of the liquid contents of the beaker, that is to say, the total weight x of the liquid, is easily determined by means of the proportion—

$$a : b = x : 15$$

where a is the weight of the filtrate, b that of the quantity of sodium chloride found therein. The quantity of milk-sugar determined as above is calculated to this quantity of solution, and thence the quantity of milk-sugar in 50 grams is determined.

The remaining contents of the beaker, together with the unused filtrate and any solid portions that may have been collected on the filter, are evaporated to dryness, and the residue is exhausted with ether. This is effected by placing the residue in a glass cylinder connected at one end with a flask containing ether and at the other with an inverted Liebig's condenser, so that the residue is completely exhausted by the condensed ether which runs down upon it. The residue obtained by evaporating the ethereal solution gives the amount of fat.

The residue thus exhausted with ether is dried at 100° and weighed. It consists of casein + milk-sugar + sodium chloride, less the portions of the two latter which have passed into the filtrate; and as these have been previously determined, the amount of casein is easily found by subtraction.

The following method is given by Schukoffsky (*Dout. Chem. Ges. Ber.* v. 76) as especially adapted to the analysis of woman's milk: 20 c.c. of ether are added to 20 c.c. of the milk; the mixture is stirred, and to it 30 c.c. of strong alcohol are added. This mixture is allowed to stand for about 24 hours, in which time the milk-sugar separates in crystals on the sides of the vessel. The sugar and casein are filtered off and washed with anhydrous ether and strong alcohol; the filtrate and washings are evaporated on a water-bath till free from alcohol; and the residue is again treated with ether, then allowed to evaporate spontaneously, and finally dried at 100° and weighed.

J. A. Wanklyn (*Pharm J. Trans.* [3], i. 606) directs attention to a hitherto unappreciated source of inaccuracy in the ordinary methods of examining milk. He finds that the exact molecular condition of the casein influences the specific gravity of the milk; in other words, that samples of milk of the same strength vary in specific gravity according to the molecular condition of the casein. The following examples are given to show how this may cause a want of correspondence between the specific gravity of milk and the amount of its solid contents. The specimens of milk had been kept in corked bottles for four days.

	Sp. gr. at 60° F.	Per cent. of solids dried at 212° F.	Per cent. of ash
Sample A	1.0004	11.34	0.94
" B	1.0060	10.48	0.75
" C	1.0184	8.92	0.66

To be of any value at all, the specific gravity must be taken while the milk is very fresh, for when milk is kept for two or three days, even in a closed vessel, the density falls in a very remarkable manner. Wanklyn therefore proposes, in judging of the strength of milk, to adhere to the method of evaporating to dryness in the water-bath, and weighing the residue, as described in the 1st Suppl. (p. 830).

Estimation of the Casein in Milk by the Ammonia Process.—Casein when distilled with alkaline permanganate yields 6.5 p.c. of ammonia. Now normal milk contains 4.0 p.c. casein: consequently 100 parts of milk should give 0.26 p.c. albuminoid ammonia, i.e. ammonia derived immediately from the decomposition of an albuminous body; and this result is confirmed by experiment.

To examine milk by the ammonia process, the following method of procedure may be adopted. Five c.c. of milk are diluted with pure distilled water to half a litre, and 5 c.c. of the dilute milk taken for analysis. 250 c.c. of water perfectly free from ammonia are placed in a retort, together with 50 c.c. of alkaline permanganate solution, and the 5 c.c. of diluted milk added. Distillation is then proceeded with as long as ammonia comes over, the ammonia in the distillate being estimated from time to time by the Nessler test in the usual manner.

The following are some examples of milk analysis by the ammonia process:—

Milk yielding 12.92 p.c. of Solids, and 8 p.c. of Cream.

	Quantity of milk taken	NH ³ obtained
I. . .	100 milligrams	0.27 milligram
II. . .	50 "	0.13 "

Slightly Watered Milk. Solids, 10.20 p.c.

	Quantity taken	NH ³ obtained
I. . .	100 milligrams	0.22 milligram
II. . .	50 "	0.095 "

Highly Watered Milk. Solids, 6.18 p.c.

	Quantity taken	NH ³ obtained
I. . .	50 milligrams	0.075 milligram
II. . .	50 "	{ 0.070 Solids, 8.10 p.c.

In order to translate these results into percentages of casein, all that is required is to multiply the percentage of ammonia by 100, and divide the result by 6.5. The figures so obtained represent the percentage of casein in the milk (Wanklyn, *Chem. News*, xxvi. 28).

A. E. Davies (*Chem. News*, xxii. 61) tests milk for adulteration with water by determining the specific gravity of the serum obtained by filtering after the casein and fat have been coagulated. In unadulterated milk this liquid exhibits a tolerably constant density ranging between 1.026 and 1.028.

MILK-SUGAR. See SUGAR.

MILLERITE. See NICKEL SULPHIDES.

MILOSCHIN. An analysis of a specimen of this mineral which had been microscopically examined by Kennigott, and shown to be a mixture of an amorphous substance with numerous crystalline particles, was found by Marco Lecco, of Belgrade, to contain, when dried at 100°, 38.71 p.c. SiO₂, 43.45 Al₂O₃, 0.17 Cr₂O₃, and 8.47 water, agreeing approximately with the formula 3SiO₂.2Al₂O₃ + 4H₂O. The analytical numbers differ considerably from those formerly obtained by Kersten (iii. 1024), viz., 27.50 p.c. SiO₂, 46.01 Al₂O₃, 3.61 Cr₂O₃, and 23.30 water, the difference doubtless arising from the mixed constitution of the mineral, as shown by the microscopical examination. It is better, therefore, not to regard the mineral as a simple aluminium silicate, represented by the formula 3SiO₂.2Al₂O₃ + 4H₂O, but rather to conclude, from the resemblance of the crystalline particles to many specimens of kaolin when examined by the microscope, that it consists of kaolin (H₂O.Al₂O₃ + H₂O.2SiO₂) imbedded in an amorphous substance having the composition H₂O.Al₂O₃ + H₂O.SiO₂. This view represents the mineral as allied to the species called carolathin (Kennigott, *Jahrbuch. f. Mineralogie*, 1872, 961).

MILLET. Under the general name of millet are included various species of *Panicum*, *Setaria*, and *Sorghum*; only those growing in temperate climates have been examined by the chemist.

The seeds of *Panicum miliaceum* (Fr. millet, Ger. Hirse) serve as human food.

Setaria italica (Fr. Millet des oiseaux, Ger. Mohar) is used in the green state as fodder for horses in Hungary; the seeds form the ordinary bird-millet. *Sorghum vulgare* (Fr. millet grand, Ger. Mohrhirse), the Durra of Egypt and India, also known as Guinea-corn, has the largest grain of any of the millets, and in hot countries is extensively grown as human food. *Sorghum saccharatum* (Fr. millet noir, Ger. Zucker-mohrhirse) is also largely grown in China and in other warm countries; the seed is employed as human food, while from the ripe stalks sugar may be extracted.

In the following table is given the mean of the analyses made. The composition given for Sorghum is the average adopted by Wolff.

	Number of analyses	Water	Albumi- noids	Fat	Extract- ive matter	Fibre	Ash
<i>Composition of Millet-grain.</i>							
<i>Panicum miliaceum</i> , with husk	1	13.15	10.91	3.67	56.89	13.06	2.32
<i>Panicum miliaceum</i> , without husk	3	13.03	15.39	5.05	62.08	2.71	1
<i>Composition of Millet-hay.</i>							
<i>Setaria italica</i>	4	12.75	10.28	2.34	38.61	30.13	5.89
<i>Composition of Green Sorghum.</i>							
<i>Sorghum vulgare</i>	—	77.3	2.9	11.9		6.7	1.1
<i>Sorghum saccharatum</i>	—	74.0	2.5	1.4	13.0	7.3	.9

The grain of *P. miliaceum*, when deprived of the husk, contains, according to the complete analysis of Pillitz: Water, 12.9; starch, 60.22; dextrin, 1.12; sugar, .45; cellulose, 3.73; soluble albuminoid, 1.18; insoluble albuminoid, 14.11; soluble ash, 1.03; insoluble ash, .56. Guinea-corn, from the West Indies, contains, according to analyses by Dr. Sheir and Johnston, 7.43 p.c. of albuminoids. A specimen of Durra gave Johnston 11.19 p.c. of albuminoids; it contained legumin.

The sap of *S. saccharatum*, according to C. T. Jackson (*Jahresb. Agri. Chem.* 1858, 79), contains glucose till ripening commences, when cane-sugar is developed. J. Moser (*Jahresb. Agri. Chem.* 1866, 315) found in the sap pressed from the stalks at the end of October, 12.45 p.c. of cane-sugar, and 2.32 p.c. of fruit-sugar. Voelcker (*Jour. Roy. Agri. Soc.* xx. 378) found no sugar in sorghum grown in England at the middle of August; a month afterwards it amounted to 5.85 p.c. of the plant.

Metzdorf (*Jahresb. Agri. Chem.* 1860, 136) made a complete examination of German millet (*Setaria italica*) in five stages of growth; the results are an excellent illustration of the change in composition which a plant undergoes as it develops.

Percentage composition of Setaria italica, whole plant, dried at 100°.

	July 11, height 3-4 inches	July 26, height 8-10 inches	August 10, height 18-16 inches	August 24, in bloom, 15-24 inches	Septem- ber 7
Albuminoids	25.72	25.01	19.44	17.01	15.97
Extractive matter and fat	37.29	37.75	41.46	43.33	43.76
Fibre	23.93	25.67	31.30	32.96	31.22
Ash	13.06	11.57	7.31	6.65	6.66
Water in fresh state	80.95	78.65	69.91	66.36	64.09

Percentage Composition of the Ash.

	July 11, height 8-9 inches	July 20, height 8-10 inches	August 10, height 15-16 inches	August 24, in bloom, 18-24 inches	Septem- ber 7
Potash	57.90	54.59	38.75	36.01	27.49
Soda81	none	none	none	none
Lime	4.84	5.56	9.67	11.91	7.42
Magnesia	6.50	6.22	9.80	6.14	11.83
Oxide of iron73	1.20	.73	.70	.64
Phosphoric acid	4.88	4.76	5.40	5.47	5.84
Sulphuric acid	3.58	3.22	3.65	3.54	3.43
Chlorine	7.61	8.94	7.44	5.43	4.34
Silica	15.06	17.52	26.23	32.03	39.99

In the above table the increase of fibre, and the diminution of albuminoids and ash as the plant matures, are plainly seen. In the composition of the ash the diminution of potash and chlorine, and the increase in silica, lime, and magnesia, are equally evident. The carbonic acid of the ash has evidently been deducted, and the ash re-calculated to 100 parts.

The following are the mean ash analyses of millet-grain :—

	Number of analyses	Ash in dry	K ² O	Na ² O	MgO	CaO	P ² O ⁵	SO ³	SiO ²

R. W.

MOLECULE. According to Avogadro's law, which, as already shown (p. 546), is a necessary consequence of the physical constitution of gases, all perfect gases at equal pressure and temperature contain equal numbers of molecules in equal volumes. Hence it follows that the weights of the individual molecules of any two gases are proportional to the weights of equal volumes of these gases at equal pressure and temperature—that is to say, to their specific gravities.

If now we express the specific gravities of gases on the hydrogen scale, in other words, if we assume as the unit of volume, that volume of hydrogen which weighs the unit of weight (say 1 gram), the specific gravities, or weights of equal volumes, of some of the more important gaseous elements and compounds will be represented by the following numbers—

	Weight of 1 volume	Weight of 2 volumes
Hydrogen	1	2
Chlorine	35.5	71
Oxygen	16	32
Nitrogen	14	28
Hydrochloric acid	10.25	36.5
Water-vapour	9	18
Ammonia	8.5	17
Marsh-gas	8	16

Now hydrochloric acid gas is formed by the combination of equal volumes of hydrogen and chlorine united without condensation, or 2 volumes of hydrochloric acid gas are made up of 1 vol. hydrogen and 1 vol. chlorine, the weights of which are as 1 to 35.5. Hence it is assumed that a molecule of hydrochloric acid contains 1 atom of hydrogen and 1 atom of chlorine; and, taking the weight of the atom of hydrogen as 1, the weight of the atom of chlorine will be 35.5, and that of the molecule of hydrochloric acid 36.5.

Secondly, the specific gravity of water-vapour on the hydrogen scale being 9, the weights of equal volumes of hydrochloric acid gas and water-vapour are as the

numbers 36.5 and 18. This last number represents therefore the molecular weight of water-vapour; and since 18 parts of water contain 2 parts hydrogen and 16 of oxygen, it follows that the molecule of water contains 2 atoms of hydrogen.

In like manner it is found that the molecular weight of ammonia gas is 17, and that it contains 3 parts by weight, or 3 atoms, of hydrogen united with 14 parts by weight of nitrogen; also that the molecule of marsh-gas weighs 16, and contains 4 parts by weight, or 4 atoms, of hydrogen.

These conclusions respecting the numbers of hydrogen-atoms contained respectively in the molecules of hydrochloric acid, water, ammonia, and marsh-gas, are confirmed by the well-known differences in the behaviour of these compounds with regard to their power of taking up other elements in exchange for hydrogen, the hydrogen in marsh-gas being replaceable by *fourths*, that of ammonia by *thirds*, that of water by *halves*, while that of hydrochloric acid can be replaced only *as a whole*, the quantity of hydrogen in the molecule of hydrochloric acid being indivisible, or, in other words, an atom.

The structure of the molecules of the four compounds may therefore, so far as the preceding considerations are concerned, be represented by the formulæ—

The reasons for regarding the indices w , x , y , z , as all equal to unity, or for representing the compounds in question by the formulæ—

are fully developed in the article **ATOMIC WEIGHTS** (i. 456-463) and need not be here repeated.

The weights of equal volumes of hydrochloric acid, hydrogen, chlorine, oxygen, and nitrogen being as the numbers

36.5 2 71 32 28,

and the first of these numbers representing the weight of a molecule of hydrochloric acid, it follows that the molecules of hydrogen, chlorine, oxygen, and nitrogen weigh respectively 2, 71, 32, and 28, inasmuch as any given volume of either of these gases contains the same number of molecules as an equal volume of hydrochloric acid; and as these numbers are the doubles of the respective atomic weights, it follows that *a molecule of each of these elementary gases is made up of two atoms*, so that these gases in the free state may be represented by the formulæ—

The same considerations are of course applicable to the vapours of bromine, iodine, sulphur, and selenium.

With regard to these gases then the law holds good that: *Equal volumes of Elementary Gases contain equal numbers of Atoms*. The exceptions presented to this law by the vapours of phosphorus, arsenic, mercury, and cadmium have been discussed in the article relating to the Combining Volumes of Gases (ii. 810).

It is unnecessary to pursue the subject further in this place, as the determination of atomic weights and the volume-relations of gases have already been fully considered from different points of view in previous articles (**ATOMIC WEIGHTS**, i. 455-466, and **GASES, COMBINATION OF**, BY VOLUME, ii. 809-812).

The object of the preceding considerations is to show how the determination of the atomic and molecular weights of gaseous elements and compounds may be established on the basis of Avogadro's law.

See further Gmelin-Kraut's *Handbuch der Chemie*, Erster Band, Erste Abtheilung, pp. 29-34; also Cannizzaro, *Considerations on some Points in the Theoretic Teaching of Chemistry* (Chem. Soc. J. [2], x. 941-967).

MOLYBDENUM. *Atomic Weight.*—Lothar Meyer (*Ann. Ch. Pharm.* clxix. 360) from the analysis of the chlorides, and the conversion of the trichloride into trisulphate (making use of the atomic weights of silver, chlorine, and sulphur, determined by Stas), estimates the atomic weight of molybdenum at 95.8.

Chlorides. These compounds have recently been examined by Liechti & Kamps (*Ann. Ch. Pharm.* clxix. 344), who have confirmed the result obtained by Debray (*1st Suppl.* 831) that the highest chloride, obtained by heating metallic molybdenum in chlorine gas, is a pentachloride, MoCl_5 . To prepare this compound, metallic molybdenum is heated in a stream of dry hydrogen chloride as long as any woolly sublimate is formed; this sublimate is driven out of the tube by heat; the tube filled with the hydrochloric acid gas is left to cool; dry chlorine gas is then passed through it for an hour to expel all remaining atmospheric air from the apparatus; and the metal

is heated till it begins to glow and brown-red vapours begin to appear. By careful heating the whole of the metal may be converted in a short time into the black pentachloride.

The pentachloride heated to about 250° in a stream of hydrogen is reduced to the red, difficultly volatile trichloride, MoCl_3 or $\text{Mo}^{\text{III}}\text{Cl}_3$; and this compound, heated to redness in an atmosphere of carbon dioxide free from oxygen, is resolved, according to the equation $\text{Mo}^{\text{V}}\text{Cl}_5 = \text{MoCl}_3 + \text{MoCl}_2$, into the yellow dichloride which remains in the tube, and the brown tetrachloride which sublimes or is carried forward by the stream of gas.

Of these four chlorides the pentachloride is the only one which crystallises distinctly, and melts and volatilises without decomposition. The pure pentachloride is black; the green shimmer ascribed to it by Dobray indicates admixture of oxychloride. Its vapour has a dark brown-red colour. The sulphur-yellow dichloride and the red trichloride, which is deceptively like amorphous phosphorus, have been obtained only in the amorphous state; the tetrachloride is an indistinctly crystalline brown sublimate. In an atmosphere of carbon dioxide the dichloride bears a bright red heat without melting or volatilising; the trichloride under the same circumstances is resolved into di- and tetrachloride, which when again heated splits up into pentachloride which sublimes, and trichloride which remains behind.

The di- and trichloride are quite permanent in the air at ordinary temperatures, and insoluble in water; the tetra- and pentachloride on the other hand are extremely susceptible of the action of oxygen, and more particularly of moisture, so that their manipulation is attended with great difficulty.

The dichloride is insoluble in *nitric acid*, which, however, dissolves all the other chlorides. The dichloride dissolves easily in hot *hydrochloric acid*, with aid of heat, and crystallises therefrom on cooling, in long, shining, yellow needles, having the composition $\text{Mo}^{\text{II}}\text{Cl}_2 \cdot 3\text{H}_2\text{O}$. The crystals when heated to 100° give off two-thirds of their water without disintegrating, losing, however, little hydrochloric acid at the same time. At a somewhat higher temperature the loss of hydrochloric acid is more considerable, the greater part of the salt being, however, converted into the anhydrous dichloride, which retains the form of the crystals, and may be recrystallised from water.

Trioxide, MoO_3 . *Recovery from the residues of Phosphoric Acid determinations.*—

F. Muck (*Zeitschr. anal. Chem.* viii. 377) treats the filtrate from phosphoric acid precipitations with solution of sodium phosphato (1 part P_2O_5 to 30 parts MoO_3 of the quantity of the latter is previously known). The yellow precipitate of ammonium phosphomolybdate is collected on a filter, washed with water, dried and weighed, and to 100 parts of it are added 360 parts of ammonin, 1,350 nitric acid, and 2 to 3 parts pure magnesia, the magnesia being dissolved in the requisite quantity of nitric acid, the yellow precipitate in the smallest possible quantity of ammonia, the two solutions united, and the liquid after standing for some time filtered from the ammonio-magnesian phosphate. This latter precipitate is washed with the remainder of the weighed quantity of ammonia, the filtrate is poured into the bulk of the nitric acid, and the yellow precipitate which separates after a while is removed by filtration. The filtrate, which contains about 5 p.c. molybdenum trioxide, is now again ready for use.

Fresenius (*ibid.* x. 204) evaporates the filtrate from phosphoric acid precipitations to dryness, and ignites the residue till the ammonium nitrate has for the most part been destroyed; the residue is then digested with ammonia, which dissolves out the molybdic acid. The filtered solution is treated with sufficient magnesia mixture to precipitate any phosphoric acid that may be present. The precipitate, if any, is allowed to subside well before filtering, and to the filtrate is added just sufficient nitric acid to render the liquid slightly acid. Molybdic acid is thus precipitated, and may be obtained pure by syphoning off the supernatant liquid, and washing with a little water. The filtrate contains but little molybdic acid, and can be worked up again with fresh residues.

Fresenius prefers this method to that of Muck above described. Muck on the other hand (*ibid.* x. 307) objects to Fresenius's method that it involves the evaporation of large quantities of liquid, the addition of ammonium salts, and the treatment of the residue after evaporation with ammonia, which last operation is often very troublesome, in consequence of the presence of iron and calcium salts.

Estimation.—Chatard (*Deut. Chem. Ges. Ber.* iv. 280) adds to the boiling solution of a molybdate a slight excess of lead acetate, and boils the resulting precipitate for about two minutes, whereupon it becomes granular and quickly settles down. It is then washed, first with pure water, afterwards with a very dilute solution of ammonium nitrate, dried at 100° , separated from the filter, and ignited in a porcelain crucible.

2nd Sup.

Reaction with Phosphorus Trichloride. See PHOSPHORUS CHLORIDES.

MONAZITE. *Native Cerous Phosphate.*—G. vom Rath (*Jahrbuch f. Mineralogie*, 1871, 172) observed in a cavity of a sunadine bomb from Lake Laach a crystal of orthite, on which lay another crystal, 1 mm. in length, olive-green in colour, and with a brilliant lustre; the latter he believes to be monazite, a mineral hitherto unknown not only at Laach, but in any volcanic rocks whatever; from its minute size he was unable to analyse it, but its immediate association with the orthite renders it highly probable that it also is a cerium compound. The crystal is tabular and exhibits the form, $+P, \pm P\infty, (P\infty), \infty P, (\infty P\infty)$ and $\infty P\infty$. Ratio of clinodiagonal : orthodiagonal : principal axis = 0.965886 : 1 : 0.92169; angle of inclined axes $103^{\circ} 28'$. The directions of cleavage of the Laach crystal also accord with those of monazite. A strong lustre arising from internal fissures is seen along the edges of the positive and negative hemidomes, and indicates a distinct direction of cleavage parallel to the base which does not form a face of the crystal. There is a second cleavage parallel to the orthopinacoid. Monazite has hitherto been found only in the old plutonic rocks or in alluvium derived from them; its mode of occurrence in Lake Laach therefore is peculiar. It furnishes a second instance of the occurrence of a cerium mineral in volcanic masses, vom Rath having previously found orthite (cerium silicate) at Lake Laach and on Monte Somma.

MONTEBRASITE. See PHOSPHATES OF ALUMINIUM.

MONZONITE. This mineral, from the Monte Monzoni in the Fassa Valley, near the small lake of La Selle, is compact and occurs in fragments. Hardness = 6; sp. gr. = 3. Fracture, splintery to imperfectly conchoidal. Colour, light green, like that of many green hornstones. Slightly translucent on the edges. Melts easily before the blowpipe to a shining greyish-green glass. Gives off a little water when heated in a tube. Insoluble in hydrochloric and sulphuric acid, but dissolves in strong aqueous phosphoric acid. Analysis gave—

SiO ²	Al ² O ³	FeO	CaO	MgO	Na ² O	K ² O	H ² O
62.60	17.10	9.00	9.65	2.10	6.60	1.90	1.50 = 100.45

leading to the formula $12(R'O.SiO^2) + 4Al^2O^3.9SiO^2$. The mineral, when examined in a thin slice under the microscope, shows no signs of mixed constitution, and may therefore be regarded as a distinct species (F. v. Kobell, *Jahrbuch f. Mineralogie*, 1871, 640).

MORPHINE, $C^8H^8N^2O^4$.—*Detection.* According to Flückiger (*Arch. Pharm.* [3], i. 117), morphine may be detected in a solution containing 1 part in 100 by the addition of chlorine-water and ammonia. A red colour is thereby produced, which soon changes to brown. The iodic acid reaction, however (iii. 1052), by which a brown colour is produced and the odour of iodine developed, is capable of detecting about 1 part in 10,000.

Detection in Quinine.—Morphine may be detected in quinine by adding a little of the salt to a solution of potassium ferrocyanide mixed with ferric chloride and a small quantity of hydrochloric acid. If morphine (or any other deoxidising substance) is present, the solution speedily becomes blue (H. Hager, *Chem. Centr.* 1872, 727).

Separation of Morphine and Strychnine.—Otto, in his 'Anleitung zur Ermittlung der Gifte,' states that these two alkaloids may be separated by agitating the solution, previously rendered alkaline, with ether, the strychnine then dissolving in the ether, while the morphine remains in the aqueous liquid. Neubauer, however, finds that the separation is not complete, the earlier ethereal extracts containing a mixture of strychnine and morphine, while the later ones yield crystallisations in which only morphine can be detected. From the residues exhausted by ether, an additional quantity of morphine can always be extracted by amyl alcohol (*Zeitschr. anal. Chem.* ix. 134).

For the detection of morphine Neubauer recommends the test proposed by Fréhdé (*Zeitschr. anal. Chem.* v. 214), which consists in adding to the suspected liquid a recently prepared solution of molybdic acid in strong sulphuric acid, whereupon the liquid assumes a violet colour, changing to blue and dirty-green.

Estimation of Morphine in Opium.—Methods of estimation founded on the liberation of iodine from iodic acid by morphine are given by W. Stein (*Arch. Pharm.* [2], cxviii. 156; *Chem. Soc. J.* [2], x. 180), and by J. T. Miller (*Pharm. J. Trans.* [2], ii. 466, *Chem. Soc. J.* [2], x. 181).

A modification of Guillemond's method of estimation (iii. 1053) is described by Revell (*Monit. Scient.* xiii. 312; *Jahresb. f. Chem.* 1871, 824).

Morphine Salts. *Acetate.*—J. M. Marsch (*Pharm. J. Trans.* [2], i. 304), observes

that aqueous solutions of officinal alkaloid salts, especially of morphine acetate, are apt to deposit quantities of flocculent substance. In a solution of morphine acetate in which this had taken place, nearly all the acetic acid had disappeared, and the morphine had separated in crystals.

Hydrocyanide.—A solution of pure ammonium cyanide added to a neutral morphine solution (even diluted to $\frac{1}{100}$) throws down a crystalline precipitate of morphine hydrocyanide, very slightly soluble in water (Marsch, *ibid.* 1005).

Derivatives and Polymerides of Morphine.

Nitrosyl-derivatives. When morphine suspended in water is subjected to a very rapid stream of nitrous acid vapour (obtained from nitric acid and arsenious acid) a yellow to reddish-yellow crystalline powder (A) is obtained, having the composition $C^{17}H^{19}(NO)^2N^2O^4 + 2H^2O$. It produces a black colour with ferric chloride, and gives off its water at 125° . By gradually dissolving this substance in considerable quantities of alcohol and distilling off the alcohol, a compound, $C^{17}H^{19}(NO)^2N^2O^4 + 4H^2O$, (B) is produced, which, when boiled with water, gives off an inodorous gas, and yields a filtrate which deposits a finely divided precipitate (C). The residue (D) left after repeated boiling has, after solution in large quantities of alcohol and distillation of the alcohol, the composition $C^{17}H^{19}N^2O^4$. When the body A is treated in the cold with a mixture of $\frac{1}{3}$ strong sulphuric acid and $\frac{2}{3}$ part water, a violent evolution of vapours takes place, which turns red in contact with the air, and a substance (E) is formed, insoluble in the resulting liquid. The same substance is formed, with evolution of an inodorous gas, by similar treatment of D. This substance does not exhibit any particular reaction with ferric chloride. Strong sulphuric acid colours it yellow with a tinge of red. Its analysis gave numbers which may be represented by the formula $C^{17}H^{19}N^2O^4 \cdot 2H^2O \cdot H^2SO^4$. The base of this salt is precipitated by ammonia in a state of very fine division; it gives a black colour with ferric chloride, but has not been further investigated. The body A has the composition of morphine nitrite, but does not appear to be identical therewith; neither does the body D appear to be identical with Schützenberger's oxymorphine (1st Suppl. 849).—(E. L. Mayer, *Deut. Chem. Ges. Ber.* iv. 121).

Chlorinated Derivative produced by the action of Hypochlorous acid. When a solution of morphine in excess of hydrochloric acid is treated with chloride of lime, greenish flocks are obtained, which, after solution in alcohol, precipitation with water, solution in ether, and distillation of the latter (whereby the flocks are converted into an oil which solidifies to a crystalline mass) have the composition $C^{17}H^{19}Cl^2N^2O^4$ (Mayer, *loc. cit.*)

Acetyl Derivatives. (Wright, *Chem. Soc. J.* [2], xii. 1033). Three of these bodies have been obtained, viz.—

Monoacetyl-morphine	$C^{17}H^{17}(C^2H^3O)N^2O^4$,
Diacetyl-morphine	$C^{17}H^{15}(C^2H^3O)^2N^2O^4$,
Tetraacetyl-morphine	$C^{17}H^{13}(C^2H^3O)^4N^2O^4$.

They are produced by the action of acetic acid and acetic anhydride on morphine. Tetraacetyl-morphine is formed by treating morphine with acetic anhydride in excess. Diacetyl-morphine is known in two modifications, one of which (α) is produced by heating morphine with glacial acetic acid, the other (β), by the action of acetic anhydride, in quantity less than sufficient to form tetraacetyl-morphine. Monoacetyl-morphine is produced by heating morphine to 100° for an hour, with a quantity of acetic anhydride considerably less than that which is required to produce β diacetyl-morphine.

Monoacetyl-morphine precipitated from the solution of its acetate, which is the direct product of the reaction above mentioned, by sodium carbonate, exhibits properties very much like those of β diacetyl-morphine (*infra*). It is soluble in ether, a property which shows that it is not a mere mixture of morphine and diacetyl-morphine, since morphine itself is nearly insoluble in ether. Its hydrochloride, $C^{17}H^{17}(C^2H^3O)N^2O^4 \cdot 2HCl$, obtained by treating the base with a quantity of hydrochloric acid less than sufficient to dissolve the whole, dries up to a varnish over sulphuric acid, whereas a mixture of the hydrochlorides of morphine and diacetyl-morphine in equal quantities dissolved in a little water allows almost the whole of the former to crystallise out, and dries up to a crystalline mass wetted by a syrup which finally dries up to a glaze over the crystals. The platinochloride prepared with the neutral liquid obtained by shaking up the ethereal solution of the base with hydrochloric acid, has the composition $C^{17}H^{17}(C^2H^3O)N^2O^4 \cdot 2HCl \cdot PtCl^4$.

The existence of this monoacetyl derivative shows that the ordinary formula of morphine, $C^{17}H^{19}NO^4$, must be doubled.

a. Diacetyl-morphine is obtained, together with the β modification, by boiling morphine for several hours with twice its weight of glacial acetic acid in a vessel with inverted condenser. On dissolving the product in water, adding ammonia, and shaking up with ether, an ethereal solution is obtained which when shaken with hydrochloric acid yields a copious crystalline hydrochloride; and from this salt the base may be separated by ammonia as a flocculent non-crystalline precipitate, easily soluble in ammonia, sodium carbonate, caustic potash, ether, alcohol, and benzene; from the last three solutions it separates by spontaneous evaporation as a gummy mass. It has also been obtained by a process the description of which is not yet published, in crystals containing $C^{11}H^{10}(C^2H^3O)^2N^2O^6 + 2H^2O$. The *hydrochloride*, $C^{11}H^{10}(C^2H^3O)^2N^2O^6 \cdot 2HCl + 6H^2O$, is but sparingly soluble in cold water, but may be recrystallised without change from hot water. The *platinochloride*, $C^{11}H^{10}(C^2H^3O)^2N^2O^6 \cdot 2HCl.PtCl^4$, is amorphous.

When pure neither the free base nor its salts give any coloration with ferric chloride; this property distinguishes the α from the β modification, which gives a blue colour.

B. Diacetyl-morphine is the chief product obtained by heating morphine to 100° for an hour with the quantity of acetic anhydride required by the equation

The free base separated from the acetate by sodium carbonate is readily soluble in ether, ammonia, sodium carbonate, and caustic potash, and is precipitated from its salts in amorphous flakes by alkalis. It is much less stable than α -diacetyl-morphine, ordinary morphine soon crystallising out from its ammoniacal solution while ammonium acetate remains dissolved—

The *hydrochloride*, $C^{11}H^{10}(C^2H^3O)^2N^2O^6 \cdot 2HCl$, obtained by treating the base with a quantity of hydrochloric acid not sufficient to dissolve the whole, dries up over sulphuric acid to a gummy mass, which if perfectly dry may be heated to 100° without decomposition, but is decomposed by heating if moist, giving off acetic acid. By boiling with water, or by contact with excess of hydrochloric acid, it is decomposed like the free base, morphine hydrochloride crystallising out, and acetic acid being set free. It is extremely hygroscopic and strikes a blue colour with ferric chloride.

Tetracetyl-morphine, $C^{11}H^{10}(C^2H^3O)^4N^2O^6$, is produced by treating morphine with excess of acetic anhydride, according to the equation—

The same result is brought about whether the materials are allowed to remain in contact at the ordinary temperature for several days, or heated to 100° or to 140° for some hours; on adding sodium carbonate to the product dissolved in water, a precipitate is obtained, flocculent at first, but soon becoming crystalline; this dissolves readily in ether and is obtained in fine anhydrous crystals by evaporation; it can also be recrystallised without change from hot alcohol or benzene, and from chloroform; long-continued boiling with alcohol partially decomposes it, whilst boiling with water quickly alters it.

Tetracetyl-morphine gives no colour-reaction with ferric chloride; like morphine, it is but very sparingly soluble in ammonia and sodium carbonate, but dissolves readily in caustic potash. When *exactly* neutralised with dilute hydrochloric acid, it yields a solution which on standing over sulphuric acid deposits crystals of the *hydrochloride*, $C^{11}H^{10}N^2O^6 \cdot 2HCl$; these are extremely soluble in water, so that they form only just before the whole mass has evaporated to dryness; if any excess of hydrochloric acid be present, partial decomposition takes place during the evaporation, acetic acid being evolved.

The *platinochloride*, $C^{11}H^{10}N^2O^6 \cdot 2HCl.PtCl^4$, is amorphous.

Tetracetyl-morphine when boiled with water gradually dissolves; and if the process be interrupted just as the last portions are on the point of solution (at the end of an hour or two) the liquid consists almost wholly of acetate of α -diacetyl-morphine, formed thus:—

If the action be prolonged, morphine acetate and free acetic acid are produced

The syrupy mother-liquors from which tetracetyl-morphine has crystallised, slowly

contain more or less α -diacetyl-morphine, probably formed by the action of the trace of water taken up by the ether used in the preparation of the tetracetyl-morphine.

Appendix to the Acetyl-derivatives of Morphine.

Diacetyl-codeine, $C^{10}H^{14}N^2O^4 = C^{10}H^{14}(C^2H^3O)^2N^2O^2$. This base is produced by boiling codeine dried at 140° with twice its weight of glacial acetic acid for eight hours in a vessel with inverted condenser:

On evaporating the resulting liquid to dryness on the water-bath, dissolving the residue in water, and adding sodium carbonate, a white precipitate is thrown down, flocculent at first, but soon becoming crystalline on standing; by rapid filtration this is separated from unaltered codeine, which is not immediately precipitated in this manner, save in very concentrated solutions. By dissolving the precipitate in dilute hydrochloric acid, and repeating the precipitation by sodium carbonate three or four times, a product is obtained quite free from codeine; the last precipitate is dissolved in ether or hot dilute alcohol, from either of which solvents the diacetyl-codeine crystallises in bold, well-defined anhydrous crystals; it can also be recrystallised from benzene, chloroform, and boiling water without change, being readily soluble in all these solvents except water, in which it is only sparingly soluble even when boiling.

Diacetyl-codeine salts give no coloration with ferric chloride; the precipitated base is but slightly soluble in ammonia or in sodium carbonate, but dissolves more readily in caustic potash.

The *hydrochloride*, $C^{10}H^{16}N^2O^4.2HCl + 4H^2O$, crystallises well, and dissolves in water more freely than the hydrochloride of codeine. The *platinochloride*, $C^{10}H^{16}N^2O^4.2HCl.PtCl_4$, is a yellow non-crystalline precipitate.

No other acetyl-derivatives of codeine have yet been obtained (Wright).

Polymerides of Morphine and their Derivatives.

1. **Polymerisation by the action of Sulphuric acid.** The investigations of Arppe and of Laurent a. Gorhardt led to the conclusion that the final product of the action of dilute sulphuric acid upon morphine was a kind of amide called *sulphomorphide*, having the composition of morphine sulphate minus water (iii. 1065). Matthiessen a. Wright, however (*Proc. Roy. Soc.* xvii. 455), in repeating Arppe's experiments, obtained a small quantity of a base exhibiting the quantitative reactions of apomorphine; and Wright (*Chem. Soc. J.* [2], xi. 220) has shown that the main result of the action of dilute sulphuric acid on morphine, first at 100° and afterwards at 140° , is *polymerisation without dehydration*, the products successively formed being trimorphine, $C^{102}H^{114}N^6O^{18}$, homologous with tricodeine, and tetramorphine, $C^{126}H^{142}N^8O^{24}$, homologous with tetracodeine (p. 372). No dimorphine is produced, although dicodeine is easily formed under similar circumstances. These results show that the so-called sulphomorphide is really the sulphate of tetracodeine.

When trimorphine hydrochloride is dissolved in strong hydrochloric acid, and the whole kept at 100° for eight hours, a change is produced indicated by the reaction—

The acid liquid, when diluted with water, neutralised with caustic soda, and precipitated with sodium carbonate, yields a white precipitate, for the most part soluble in ether; and the ethereal solution, agitated with a few drops of hydrochloric acid, gives a viscid liquid which wholly refuses to crystallise, and accordingly does not appear to contain any appreciable quantity of apomorphine. On leaving it over sulphuric acid, a brittle gum was obtained which, after heating to 100° , exhibited the composition $C^{102}H^{114}N^6O^{18}.6HCl$, which is that of the hydrochloride of a base formed from trimorphine by substitution of Cl^2 for $(HO)^2$.

The occurrence of this reaction in the substance which evidently corresponds in the morphine series with the polymeride provisionally viewed as *tricodeine* in the codeine series (p. 372), corroborates the view that these substances are actually the threefold polymerides of morphine and codeine respectively. The action of hydrochloric acid on tricodeine is a simple dehydration (see above),

whereas that on trimorphine is of an entirely different character, the elements of HCl being added on, as well as those of H^2O subtracted (see above).

Tetramorphine, heated with hydrochloric acid, does not undergo any transformation,

but simply forms the hydrochloride $C^{12}H^{12}N^2O^2 \cdot 8HCl$. In this respect it resembles tetracodeine, but differs from diapotetramorphine, which undergoes a transformation similar to that of trimorphine:

2. **Polymerisation by the action of Phosphoric acid** (Wright, *Chem. Soc. J.* [2], x. 652). Phosphoric acid acts on morphine in the same manner as on codeine (p. 372), excepting that the resulting polymerides of morphine are converted by abstraction of water into apo-derivatives.*

When 1 part of morphine is treated with phosphoric acid solution (3 glacial acid to 5 water), and the liquid gently boiled until the boiling-point rises to 180° – 190° , a brown liquid is obtained which, when diluted with water, gives an immediate amorphous precipitate with excess of sodium carbonate; the filtrate from this, if quickly separated, contains unchanged morphine, which gradually crystallises out on standing. This precipitate is purified by solution in hydrochloric acid, reprecipitation by sodium carbonate, and rapid filtration; other extracts a very small quantity (less than 0.6 p.c.) of a base soluble in that liquid; on agitation with hydrochloric acid, anhydrous crystals are obtained which present all the appearances and reactions of the hydrochloride of apomorphine, $C^{12}H^{12}N^2O^2 \cdot 2HCl$.

The formula here given to apomorphine, which is double of that originally assigned to it (1st Suppl. 839), appears to be justified by a comparison of the results of the action of phosphoric and sulphuric acids on morphine and codeine, the apomorphine being in all probability derived by dehydration from the previously formed dimorphine, by the reaction:

Comparison of the physical properties of apomorphine and its salts with those of the different polymerides of codeine, likewise indicates a greater analogy to diodeine than to codeine itself, or to tetracodeine. The systematic name of apomorphine is accordingly tetraapo-dimorphine.

The portion of the precipitate produced by sodium carbonate, which is insoluble in ether, oxidises by exposure to air with great rapidity; dissolved in hydrochloric acid, and fractionally precipitated by sodium carbonate, it finally yields a light fawn-coloured precipitate, which rapidly darkens and absorbs oxygen while drying. Washed and dried as rapidly as possible, it gave numbers agreeing with the formula $C^{12}H^{12}N^2O^{12}$. Wright, however, supposes that of the 40 atoms of oxygen, 18 were derived from atmospheric oxidation, and that the true formula of the recently formed base is $C^{12}H^{12}N^2O^{22}$. According to this view it is diapo-tetramorphine, formed by the reaction:

This base exerts upon dogs an emetic action quite as powerful as that of apomorphine, but does not appear to produce so much after-depression.

Action of Hydrochloric acid on Diapo-tetramorphine.—When freshly prepared diapo-tetramorphine (unoxidised) is dissolved in a large excess of strong warm hydrochloric acid, the solution boiled down gently, almost to dryness, and finally evaporated to dryness on the water-bath, a tarry residue is obtained, readily soluble in water; addition of strong hydrochloric acid to this aqueous solution throws down flakes of the hydrochloride of a new base which is obtained in greatest purity by fractional precipitation with strong hydrochloric acid; and the last precipitate being washed with weak acid, and dried at 100° , yields a brownish, tarry, brittle mass, much resembling the hydrochloride of chlorotetramorphine (p. 370), and having the composition $C^{12}H^{12}Cl^2N^2O^2 \cdot 8HCl$. It appears to be formed by the reaction:

In physical and chemical properties this substance much resembles chlorotetramorphine, from which it differs in composition by $-H^2O$; sodium carbonate throws down from its aqueous solution fawn-coloured flakes, almost wholly insoluble in ether, and darkening by exposure to air; like all the other 'tetra' bases it yields a blood-red colour on warming with an acid solution of silver nitrate.

Action of Hydriodic acid and Phosphorus on Diapo-tetramorphine.—When freshly prepared unoxidised diapo-tetramorphine is dissolved in dilute hydriodic acid by the aid of heat, and the solution gently boiled down with the addition of excess of hydriodic acid and a piece of phosphorus, till the boiling-point rises to 125° , a viscous liquid is obtained, from which, on filtration through asbestos and precipitation by water, a

* The prefix *apo* may be conveniently used to designate generally the removal of the elements of H^2O ; *diapo*, for the removal of $2H^2O$; *tetraapo*, for $4H^2O$, and so on.

substance may be obtained undistinguishable in appearance from the similar body resulting from analogous treatment of tetracodeine (p. 373), and having the composition $C^{136}H^{116}I^{16}N^4O^{22}.8HI$. It is produced by the reaction:

which is perfectly parallel with the reaction with hydrochloric acid (*infra*) and with the action of hydriodic acid and phosphorus on tetracodeine (methyl being eliminated in the latter case):

When heated it leaves a very difficultly combustible charcoal. With nitric acid and silver nitrate it strikes a blood-red colour.

3. **Polymerisation by the action of Zinc Chloride** (Mayer a. Wright, *Chem. Soc. J.* [2], xi. 211). When morphine hydrochloride is heated for a short time with a concentrated solution of zinc chloride, a crystalline compound of the two is obtained, from which, by repeated solution in water and crystallisation, the zinc chloride may be removed, the morphine hydrochloride remaining undissolved. But if the heating be continued, there are formed, according to the temperature and duration of the action, the hydrochlorides of the following bases:

- | | |
|--|----------------------------------|
| A. <i>Tetrapodimorphine</i> (apomorphine) | $C^{608}H^{388}N^4O^4.4HCl$ |
| B. A chlorinated base, soluble in ether, and yielding
an uncrystallisable hydrochloride | $C^{84}H^{72}ClN^2O^2.2HCl$ |
| C. <i>Octapotetramorphine</i> , polymeric with apomor-
phine, insoluble in ether, and yielding an un-
crystallisable hydrochloride | $C^{1128}H^{1128}N^4O^{16}.8HCl$ |
| D. A chlorinated base, insoluble in ether, and yield-
ing an uncrystallisable hydrochloride | $C^{136}H^{114}ClN^4O^{22}.8HCl$ |
| E. A base probably isomeric with apomorphine, or
perhaps impure apomorphine. | |

The apomorphine is formed when the mass is kept at a temperature of 120° – 125° for more than twenty minutes, the yield being larger the lower the temperature between these limits, and the more concentrated the solution of zinc chloride. The base F, isomeric with apomorphine, but differing from it by forming an unstable platinum-chloride, and the chlorinated base B, were formed after treatment for an hour at 170° . *Octapotetramorphine* (C) was produced when nearly equal volumes of solid zinc chloride, strong hydrochloric acid, and morphine, were heated together in sealed tubes to 180° – 220° for 24 hours. Its hydrochloride is much like those of chlorotetramorphine and bromotetramorphine, but has a darker colour; it is insoluble in absolute but soluble in dilute alcohol; with nitric acid it gives a dirty-red colour, and with sodium carbonate an amorphous precipitate almost insoluble in ether. This base differs strikingly from apomorphine in being destitute of emetic properties.

The chlorinated base, D, is formed by prolonged exposure of the mixture to a lower temperature (36–48 hours at 100°). Its hydrochloride yielded, with sodium carbonate, a precipitate insoluble in ether and only sparingly soluble in chloroform. If it is a single substance, it may be regarded as formed from the chlorinated base, B, by polymerisation and abstraction of the elements of hydrogen chloride—

4. **Polymerisation by the action of Hydrochloric Acid.** The experiments of Matthiessen a. Wright have shown that when hydrochloric acid acts on morphine in sealed tubes at 140° – 150° , apomorphine is produced (*1st Suppl.* 839). Other products are, however, formed at the same time, varying in composition according to the temperature, the proportions of the materials used, and the duration of the action. The following have been obtained:—(A) By heating morphine in a flask on the water-bath for six hours with 5–6 times its weight of strong hydrochloric acid, then diluting with water, nearly neutralising with caustic soda, precipitating with sodium carbonate, dissolving the precipitate in ether, and agitating the ethereal solution with a few drops of hydrochloric acid. (B) By heating morphine as in A for five hours, and evaporating on the water-bath in an open basin for four hours, more. (C) By gently boiling morphine with about 6 parts of hydrochloric acid for four hours, the product being treated as in A.

The analyses of these products leads to the following formulae—

which are those required for mixtures of bases denoted by the formulae—

where—

whence it is considered probable that the following reactions take place—

i.e., that the elements of HCl become added on to morphine *previously* to the abstraction of the elements of H²O, a reaction similar to that which takes place in the case of several codeine derivatives (p. 371).

The last-formed base, R, is homologous with chlorocodide (p. 369), the reactions which express the formation of the two bases from morphine and codeine respectively being precisely similar—

Now as chlorocodide reproduces ordinary codeine by the action of water (1st Suppl. 481), it is evident that no polymerisation has taken place during its formation; and as its formation appears to be *preceded* by the formation of a base homologous with base P, it follows that the formula of codeine must be written C¹⁴H¹⁰N²O⁴, instead of the half of this, as formerly, while by analogy morphine must be written C¹⁴H¹⁰N²O⁴, a result in accordance with the composition of mono-acetyl-morphine (p. 819).

Base Q is no doubt identical with the body of the same composition obtained by the action of zinc chloride on morphine.

When the action of hydrochloric acid on morphine is continued beyond the point reached in C, apomorphine hydrochloride is produced, together with the hydrochloride of a chlorinated tetrabase, C¹⁴H¹⁴Cl²N²O⁴. These bases are probably formed by polymerisation of the bases P and R, and subsequent elimination of the elements of hydrogen chloride: thus—

This view is corroborated by the fact that when the mixture of P and R obtained in experiment B was gently boiled with hydrochloric acid for two hours, apomorphine and the chlorinated base were produced in considerable quantity.

5. Polymerisation by the action of Hydriodic Acid in presence of phosphorus (Wright, *Chem. Cent.* 1872, 313). When morphine is heated with about four times its weight of aqueous hydriodic acid (containing 54–55 p.c. HI), the liquid becomes brown from separation of iodine; but if phosphorus be then added, the colour disappears, and a syrupy liquid is obtained, which, when treated in the same manner as in the corresponding codeine reaction (p. 371), yields a product having the composition—

where X denotes the hypothetical base, $C^{14}H^{12}N^2O^2$; and the reaction takes place according to the equation—

This product closely resembles that which is obtained in like manner from codeine. Heated for about 5 hours with about 300 times its weight of water, it yields, by elimination of 2HI, the compound $C^{14}H^{12}I^2N^2O^2 \cdot 8HI$. If this product be further treated with water, one half of the basic iodine is again eliminated as HI, yielding

All these iodised derivatives of morphine resemble the corresponding codeine derivatives in chemical properties and in physiological action.

The table on p. 826 exhibits the relations to morphine and its polymerides of the derivatives above described, such derivatives being actually derived from morphine as starting point; several bodies derived from codeine as starting point, and also belonging to one or other of these series, are tabulated under CODEINE (p. 375). In this, as in the preceding table, the symbols M , M^2 , M^3 , M^4 , are applied respectively to morphine, dimorphine (hypothetical), trimorphine, and tetramorphine. Each of these bases forms a hydrochloride (and probably other analogous salts) in which the number of molecules of HCl associated in the salt with the base is equal to the number of nitrogen-atoms in the molecule of the base, i.e., two for derivatives from morphine, four for those from dimorphine, six from trimorphine, and eight from tetramorphine.

Another class of bases included in the table, and designated as the *tetrahydro-series*, is formed by the derivatives obtained by the joint action of hydriodic acid and phosphorus on morphine; these may be all viewed as derived from a hypothetical base related to tetramorphine, and containing H^{10} more in its molecule than that substance; or, what amounts to the same thing, from the tetra-polymeride of a base containing H^4 more than morphine, i.e. having the formula $(C^{14}H^{12}N^2O^2)^4 = (M + H^4)^4$.

Oxidation of Morphine Derivatives. When apomorphine hydrochloride is heated with excess of potash-ley, the base, which is at first precipitated, redissolves, and the solution quickly turns brown in consequence of absorption of oxygen from the air. By agitation with ether, after neutralisation with hydrochloric acid, a peculiar colouring matter is extracted, which imparts to the ether a fine purple-violet tint, affording a good test for the presence of apomorphine. On agitating the ethereal solution with an alkali, a grass-green watery layer separates, from which hydrochloric acid precipitates indigo-blue flakes insoluble in water and in acids, but soluble in alkalis with green colour, in water containing ammoniacal salts with light blue colour, and in alcohol, benzene, carbon sulphide, ether and chloroform with various shades of purple and violet. Especially remarkable are the variations in the depth of colour produced by equal quantities of this substance in equal volumes of different solvents. The analysis of the purified blue precipitate led to the empirical formula, $C^{14}H^{12}N^2O^2$. No means have, however, been yet discovered of fixing its molecular weight; it does not unite either with acids or with bases; its neutral ammoniacal solution, prepared by dissolving it in aqueous ammonia, and leaving the solution for some days over sulphuric acid, gives no precipitates with silver nitrate, lead acetate, barium nitrate, &c.; with mercuric chloride, however, it forms a dark-brown precipitate containing chlorine and a large quantity of mercury, and probably consisting of a mixture of calomel with the mercury salt of some oxidation-product of the blue compound.

Diapodimorphine and deoxymorphine treated in like manner likewise yield the blue compound, but it is not produced from the monomorphine derivatives, or from any derivative of the tetra-series (Mayer a. Wright, *Chem. Soc. J.* [2], xi. 1082).

Action of Heat on Morphine Derivatives. The hydrochlorides of the monomorphine derivatives are decomposed by gradual heating to 150° – 180° , and the products mixed with caustic potash and distilled yield pyridine, together with small quantities of methylamine, the latter probably arising from decomposition of a polymerised base formed during the reaction. The tetra-derivatives treated in like manner yield methylamine but no pyridine, and the di-derivatives yield no volatile bases whatever. These results indicate a different relation of the nitrogen to the other elements in the several polymeric groups (Mayer a. Wright, *Chem. Soc. J.* [2], xi. 1086).

DERIVATIVES AND POLYMERIDES OF MORPHINE.

Name	Origin	Formula	Relation to Morphine or polymerides thereof
<i>Mono-Series.</i>			
Morphine	—	$C^{17}H^{19}N^3O^6$	$\bar{M}^1 + HCl$

MOSCHATIN. A nitrogenous substance contained in the Iva plant (*Achillea moschata*; see *ACHILLEA*, p. 21).

MUCIO ACID, $C^8H^{10}O^4$ (Lamprecht, *Ann. Ch. Pharm.* clxv. 253). *Normal ethyl mucate, $C^8H^{14}(C^2H^5)^2O^4$* , is not formed by the action of hydrochloric acid or sulphuric acid on a mixture of mucic acid and alcohol, and can only be obtained by Malaguti's method; i.e., by heating mucic acid with sulphuric acid until the mass blackens, and adding alcohol to it after 12 hours' standing. The crystalline product is again allowed to stand for 24 hours, then washed with cold alcohol, and recrystallised from hot alcohol; it melts at 158° . By boiling with water it is decomposed, mucic acid separating out. Hot alcohol also decomposes it partially, with formation of the acid ether, $C^8H^{10}O^4(C^2H^5)$, which remains in the mother-liquor. It crystallises in white silky needles containing 3 mol. of water, and is readily soluble in alcohol and water; at 100° the water escapes, and the ether melts to a glassy hygroscopic mass. When the normal ether is carefully heated in a retort, alcohol distils over, and an amber-coloured mass is left behind, which is readily soluble in water, the solution containing mucic acid. On heating it gradually to 240° , the distillate contains water, alcohol, pyromucic acid, and a volatile crystalline substance, which is insoluble in hot water. The residue forms a black humus-like mass dissolving in alkalis.

Chloromucic Acid, $C^8H^7ClO^4$. This acid, which was discovered by Liébig and Bode (iii. 1058), and afterwards investigated by Bode and Wichelhaus (v. 1093), is obtained by heating mucic acid with phosphorus pentachloride and decomposing the product with water.* It forms long white needles, dissolving readily in alcohol and ether, and in 19 parts of boiling water, but only very sparingly in cold water; it is a bibasic acid. When it is heated, a small quantity sublimes, but the greater part undergoes decomposition. Bromine does not act on it in presence of water at a gentle heat, but by heating the substances in closed tubes, a great quantity of carbon dioxide is formed, together with a crystalline compound and an oily liquid smelling like pepper. Alcoholic potash acts but slowly on the acid; below 190° a large quantity remains unaltered, whilst above 200° a most violent explosion takes place. By keeping the temperature between these limits, the acid is resolved into hydrochloric acid, acetic acid, and oxalic acid:—

Hydromucic Acid, $C^8H^9O^4$. This compound, which has been already described by Bode and Wichelhaus, and by Schmelz and Beilstein (iv. 764), under the name of *mucic acid*, is produced by the action of sodium-amalgam and water on chloromucic acid. It is a bibasic acid, forming long white needles, melting at 195° and dissolving readily in alcohol and hot water, but only sparingly in cold water.

Bromhydromucic Acid, $C^8H^7BrO^4 + H^2O$, is formed by dissolving 1 mol. of hydromucic acid in hot water and adding 1 mol. of bromine. It forms white, shining, hard prisms, melting at 183° ; it is easily decomposed by heat, and dissolves readily in hot, but sparingly in cold water; on evaporating the aqueous solution on a water-bath, hydrobromic acid is given off.

Oxyhydromucic Acid, $C^8H^9O^4$, is produced by adding freshly precipitated silver oxide to an aqueous solution of bromhydromucic acid. It is readily soluble in water, alcohol, and ether, and crystallises with difficulty. It volatilizes without decomposition. The *barium salt*, $C^8H^7BaO^4 + 2H^2O$, is precipitated from a concentrated aqueous solution by absolute alcohol, as a crystalline powder which gives off part of its water at 105° , being converted into $2C^8H^7BaO^4 + H^2O$.

The mother-liquors of bromhydromucic acid contain dibromadic acid, $C^8H^7Br^2O^4$, which by the action of moist silver oxide is converted into dioxynadic acid, $C^8H^9O^4$; and by heating hydromucic acid with bromine and water in different proportions, tribromadic acid, $C^8H^7Br^3O^4$, and tetrabromadic acid, $C^8H^7Br^4O^4$, are produced, the former of which is converted by moist silver oxide into trioxynadic acid, $C^8H^9O^4$ (see *ADIPIC ACID*, p. 28).

Mucic Acid, $C^8H^{10}O^4$, is obtained by adding silver oxide to a hot solution of isodibromadic acid (formed by adding bromine to a warm solution of hydromucic acid in glacial acetic acid) and decomposing the resulting silver salt with hydrochloric or sulphuric acid. It forms large, apparently monoclinic, crystals, melting above 100° , and dissolving freely in water, alcohol, and ether. The *barium salt*, $(C^8H^{10}O^4)Ba + 4H^2O$, forms warty crystals and is freely soluble in water, but not in alcohol. The *sodium salt* forms a syrup; the *ammonium salt* gives a white precipitate with

* According to Ador (*Dest. Chem. Ges. Ber.* iv. 827) the product is considerably increased by addition of phosphorus oxychloride to the pentachloride.

silver nitrate, and its aqueous solution becomes acid on evaporation. When mucous acid is heated for some time to 100°, or a little higher, carbon dioxide is evolved and the residue assumes a dark colour. By boiling the acid with baryta-water it yields carbon dioxide, acetic acid, succinic acid, and another acid which could not be obtained in the pure state.

Mucobromic Acid, $C^4H^2Br^2O^3$. This acid, discovered by Schmelz a. Beilstein (iv. 763), is obtained by adding bromine in excess to pyromucic acid in presence of water—

It crystallises in shining white plates, melting at 120°–130°, and dissolves readily in ether, alcohol, and hot water, but only sparingly in cold water.

One mol. mucobromic acid heated with 3 mol. bromine and water in closed tubes to 120°–130°, yields tribromomethylene dibromide and hexabromethane, together with compounds isomeric or identical with dibromofumaric acid and tetrabromobutyric acid.

Dibromofumaric Acid, $C^4H^2Br^2O^4$, forms warty crystals melting at 108°–120°; on heating it in a current of carbon dioxide to 100°–105°, the anhydride, $C^4H^2Br^2O^3$, sublimes in needles, melting at 95°–120°, and volatilising readily at 70°, and at the common temperature *in vacuo*. On dissolving the anhydride in cold baryta-water, and evaporating the solution over sulphuric acid, the salt, $C^4H^2Br^2O^3Ba + 2H^2O$, crystallises in fine plates. The mother-liquor gives with alcohol a crystalline precipitate, $C^4H^2Br^2O^3Ba + H^2O$. The aqueous solution of the barium salt gives with silver nitrate a white explosive precipitate.

Tetrabromobutyric Acid, $C^4H^2Br^4O^3$, crystallises from a hot aqueous solution in transparent oblique plates, melting at 115°, and dissolving but sparingly in cold water.

Tribromomethylene dibromide, C^2HBr^2 , crystallises from alcohol in long, brittle needles, melting at 50°–52°; on heating it with alcoholic potash, it is converted into *tetrabromomethylene*, C^2HBr^4 , crystallising in thin plates melting at 50°. **Hexabromethane**, $C^2H_2Br^6$, forms thick colourless prisms which are insoluble in alcohol, and decompose at 170° (Limprecht).

MUCIN. Mucin from the submaxillary gland has been examined by J. Obolensky (*Med.-Chem. Untersuchungen*, 1871, 590). It was prepared as follows. The salivary glands of the ox were cleaned as much as possible, and finely rubbed down with pounded glass. The mass was placed in water and allowed to stand over-night, then filtered, the residue being again treated in the same manner. The filtrate was precipitated by excess of acetic acid, and the precipitate was well washed with water and a little acetic acid, afterwards with warm alcohol, and then dried. This substance, insoluble in acetic acid, is obtained only from the submaxillary gland, the parotid yielding only albuminoids (globulin). The glands contain none of the substance described by Miescher as nuclein.

Dry mucin gives 2.44 p.c. of pure ash, of which 1.64 parts are soluble in water, the rest in hydrochloric acid. Mucin contains no sulphur. The amount of phosphoric acid (1.06–1.07 p.c.) agrees with the quantity of ash. Mucin free from ash has a composition (the mean of two analyses) 52.2 C., 7.18 H., 11.87 N., 28.75 O. This agrees very nearly with Scherer's analysis of mucin from a cystin fluid, viz., 52 C., 7.0 H., 12.6 N., 28.2 O. It differs from Eichwald's analysis (48.9 C., 6.8 H., 8.6 N., 35.8 O.) chiefly in the amount of nitrogen.

Freshly precipitated and moist mucin swells readily in water, is easily soluble in lime- and baryta-water, not precipitated by tannic acid, ferric chloride, or mercuric chloride. It is soluble in concentrated hydrochloric and nitric acid, also in sodium carbonate. When mucin is treated with hot alcohol and dried on the water-bath, it scarcely swells in water, and is very slowly soluble in lime- or baryta-water, or soda solution. The solutions behave like the former in regard to the above-mentioned reagents.

Dried and pulverised mucin, heated for 25 minutes with dilute sulphuric acid, is partly dissolved, and gives, with excess of caustic soda and copper sulphate, a red precipitate of cuprous oxide. If it be heated for a longer time, the quantity of reducing agent diminishes, and ultimately disappears. This fact, and the insolubility of the reducing agent in absolute alcohol, show that it is not identical either with grape sugar or milk-sugar.

MULBERRY-LEAVES. E. Reichenbach (*Ann. Ch. Pharm.* cxlii. 46) has examined the composition of mulberry-leaves from different countries with reference to the view, suggested by Liebig, that the silkworm disease which prevails in Europe but not in China or Japan, has its origin in deficient or unsuitable nourishment. The following table gives the results of his analyses for 1,000 parts of the dry leaves.

Mulberry-leaves from	Nitrogen	Protein substance	Ash free from carbon	K ₂ O	CaO	MgO	P ₂ O ₅	SiO ₂	NaCl
Japan . . .	32.8	201	125.9	30.02	37.93	7.35	7.99	41.11	3.41

From these numbers Liebig and Reichenbach conclude that French and Italian mulberry-leaves, on account of their comparative poorness in nitrogenous constituents, do not afford sufficient nourishment for the silkworms imported from China and Japan, which are accustomed to a more nutritive fodder.

In mulberry-leaves from Turkestan, where also the silkworms are free from disease, Reichenbach found from 3.38 to 4.05 (average 3.73) p.c. nitrogen, which is equivalent to 211–253 lbs. of protein substance in 1,000 lbs. of leaves (*Ann. Ch. Pharm.* civiii. 92; *Chem. Soc. J.* [2], ix. 435).

On the other hand, Sestini (*Landwirth. Versuchs-Stationen*, xv. 286) finds that the leaves of mulberry-trees grown at Friaul in Italy contain a larger proportion of nitrogen than those from China, Japan, or Turkestan. The trees had all been manured with dung, and were usually stripped of leaves every second year. The following table shows the percentage of water in the fresh leaves, and of organic matter, ash, and nitrogen in the dry leaves; also the composition of the ash at various stages of growth:—

Mulberries	<i>Morus alba silvatica</i>				<i>Morus alba domestica</i>				Chinese mulberries	Improved native

MUSCARINE (Schmiedberg & Poppe, *Deut. Chem. Ges. Ber.* iii. 281; Ruckert, *N. Rep. Pharm.* xxi. 193). An alkaloid of unknown composition contained in the hyacinth (*Agaricus muscarius*). To prepare it, the alcoholic extract of the evaporated juice is dissolved in water; the solution precipitated with basic lead acetate and ammonia; the filtered liquid is evaporated to dryness; the residue again dissolved, and the solution treated with basic lead acetate and ammonia; the filtrate, after concentration to a syrup, is mixed with excess of lead hydrate and evaporated down to expel the ammonia; the residue exhausted with absolute alcohol, the filtrate evaporated, and the residue dissolved in water; the bases are converted into sulphates, which are shaken with ether to remove acetic acid; the ether evaporated; barium hydrate added in sufficient quantity to leave the solution slightly acid; and the muscarine precipitated either with potassium-mercury iodide or with potassium-bismuth iodide. If the

former reagent is employed, the precipitate is washed on a filter with water containing sulphuric acid, then suspended in water; an equal volume of moist barium hydrate is added; and the liquid is treated with hydrogen sulphide, and the filtrate with silver sulphate. After another filtration the liquid contains nothing but muscarine, together with the silver salt, which is easily removed. When potassium-bismuth iodide is used, the product is larger but less pure (Schmiedberg a. Poppe). Ruckert finds that when potassium-mercury iodide is employed, a kilogram of thick extract yields from 7 to 8 decigrams of muscarine sulphate.

Muscarine forms a colourless or yellowish syrupy substance, without taste or smell, soluble in all proportions of water and alcohol, insoluble in ether, and only sparingly soluble in chloroform; it becomes crystalline over sulphuric acid, but is very deliquescent. It has a strong alkaline reaction, and precipitates iron and copper salts; boiling for 5-10 minutes with potash-ley or diluted sulphuric acid has no apparent action on it; heated with moist solid potash, it evolves ammoniacal vapours having a fishy odour, no browning taking place until the heat has been continued for some time. Manganese dioxide and sulphuric acid, chlorine-water, permanganate of potassium, and a mixture of potassium chromate and sulphuric acid, produce no coloration, the oxidising agents being, however, reduced. Excess of bromine-water gives a yellow precipitate, soon redissolving, and forming a yellow solution which soon becomes colourless.

Mercury-potassium iodide and bismuth-potassium iodide give amorphous precipitates, becoming crystalline on standing; gold chloride yields a non-crystalline precipitate, while mercury chloride yields crystals on long standing; platonic chloride, potassium ferrocyanide, potassium platino-cyanide and tannin do not precipitate the sulphate. This salt is deliquescent, and crystallises by evaporation over sulphuric acid.

Muscarine is a strong narcotic poison, and is antagonistic in its action to atropine.

MUSCULAR TISSUE. (Pick a. Wislicenus, *Phil. Mag.* xxxi. 486; Parkes, *Proc. Roy. Soc.* xv. 339, xvi. 44; Pettenkofer a. Voit, *Zeitschr. f. Biologie*, ii. 566; *Chem. Centr.* 1867, 790; *Sitz. d. k. Bayer. Akad. d. Wiss.* 1867, i. 364; M'Donnell, *Obs. on the Functions of the Liver*, Dublin, 1865; O. Nasse, *Beiträge z. Phys. d. contractilen Substanz*, *Arch. f. d. Ges. Phys.* ii. 97; L. Hermann, *Unters. über die Stoffwech. d. Muskeln*, Berlin, 1867). The nature of the chemical changes which give rise to muscular energy can hardly be yet considered as fully elucidated, though we are in a position to make some pretty positive statements on the subject. It would appear that the older idea, that the combustion of some nitrogenous substance was the source of muscular work must be definitely abandoned, or at least must be understood in a very different sense from that in which it was formerly accepted. Pick a. Wislicenus, Parkes, and others, have proved that the nitrogen excreted from the body during muscular work and some hours after it, is, even when its energy of combustion is calculated as high as possible, quite insufficient to account for the work done (see *1st Suppl. NUTRITION*, p. 874); and Naurocki (*Beiträge z. Stoffwech. im Muskel*; *Central. f. d. Med. Wiss.* 385), Voit, &c., have shown that the products of nitrogenous waste (creatine, creatinine, &c.) are not increased in tetanised muscles. We are thus reduced for a starting-point to the old observation that the venous blood which leaves a contracting muscle contains more carbonic anhydride and less oxygen than that leaving a resting muscle, and are led to suspect that whatever changes may occur in the proteid matters of a contracting muscle, the substances which the muscle loses by its contraction contain no nitrogen. M'Donnell has shown that muscular tissue contains glycogen, and that this, during contraction, is converted into glucose; and Nasse, who confirms this, also finds that the total quantity of glycogen and dextrose in a muscle in a state of *rigor mortis* is less than that in muscle killed without stiffening; and this gains importance from the fact that, as we shall hereafter see, *rigor mortis* and muscular contraction are probably fundamentally of the same nature; however, the quantity of carbon which disappears in the form of the above compounds is not sufficient to account for that in the sarco-lactic acid which is formed at the same time, so that the observation does not, by itself, go for much.

Hermann, by a series of most careful analyses and estimations of the gases evolved by frogs' muscles under different conditions, has thrown much light on the chemical processes which occur during muscular contraction and also on the nature of *rigor mortis*, and, as the result of his experiments, has put forward a theory which seems to unite previous observations in a consistent manner. He shows first that the evolution of carbonic anhydride and the taking up of oxygen, though they go on side by side in a contracting muscle in the body, are yet quite independent processes; a living muscle, deprived of blood, gives off in a vacuum a certain amount of carbonic anhydride and some nitrogen, but no oxygen whatever; but although it is thus shown to contain no free oxygen, yet, if it be made to contract or be thrown into a state of *rigor mortis*, it

will give off a large additional quantity of carbonic anhydride, while at the same time sarco-lactic acid forms in it. Moreover, if a muscle be tetanised as long as it will contract, the total quantity of carbonic anhydride given off by it is less than that which would have been given off by throwing the muscle directly into *rigor mortis*; but if this latter condition be induced after the tetanisation, exactly the missing quantity of carbonic anhydride is evolved. We must therefore conclude that a living muscle contains a definite store of some unknown substance which yields carbonic anhydride and sarco-lactic acid, and that the breaking up of this substance lies at the base of both muscular contraction and *rigor mortis*; and, further, that the process can go on quite independently of any simultaneous taking up of oxygen. When the experiments were repeated in a gaseous mixture containing oxygen, Hermann found that he could establish no physiological absorption of that gas; a small amount of it disappeared, and there was a small increase in the quantity of carbonic anhydride evolved, but both these phenomena were dependent on decomposition going on at the surface of the muscle, and were proportional to its area and not to the work done; the irritability of the muscle, however, was somewhat longer preserved in gaseous mixtures containing oxygen than in others; and this may be attributed either to a very small and otherwise unrecognisable physiological assumption of oxygen, or perhaps to some specific action of the oxygen, promoting the excretion of the carbonic anhydride formed in the muscle.

If we now consider the relationship of contraction and *rigor mortis*, we find that, so far as the carbonic anhydride and lactic acid are concerned, the chemistry of the two processes is identical, and that they are also quantitatively related; for, as above stated, if a muscle be thrown into a state of *rigor* after having been made to contract, the quantity of carbonic anhydride which it evolves is less than that which an unworked muscle would have evolved, by exactly the amount which was evolved during its contraction; we have apparently, however, a difference between the two processes in the stiffening of *rigor mortis*. Du Bois Reymond and Kuhne maintain that the acidity of tetanised muscle differs from that of stiffened muscle in the fact that the former can be removed by restoring the circulation through the muscle, and the latter not. Hermann, however, shows that this difference is really only one of degree, for if a muscle be rendered acid by commencing *rigor* (induced by heat), while the blood current is not interrupted in it, this acidity can be removed by the blood flow; in other words, if the *rigor mortis* is not allowed to go too far, the state of the muscle as regards the acidity is the same both in tetanus and in death-stiffening. Du Bois Reymond also points out that if a muscle be tetanised till it will no longer contract, and be then left to itself for a time, it will again become contractile; and he maintains that such restoration never occurs after *rigor mortis*; this statement, however, is also true only of advanced, not of incipient *rigor*. Fresh muscle-plasma sets, soon after extraction, into a clear semi-solid jelly (myosin), which after a time separates into a completely fluid portion and a dense clot (coagulated myosin), the latter at the same time becoming opaque. It is evidently this second stage of the myosin coagulation which corresponds with the condition of things in a completely stiffened and opaque muscle; but it must be preceded by the former, in which the setting of the myosin is not sufficiently firm to make any rigidity recognisable, and when as yet no opacity has been developed. This early stage of *rigor mortis*, which can only be recognised by the development of an acid reaction in the muscle, and the concomitant evolution of carbonic anhydride, is evidently the stage which should be compared with the state of a muscle exhausted by tetanus. The non-coagulated jelly-like myosin of this early stage of *rigor* can be restored to its original state by the blood, the muscle at the same time losing its acidity and returning in every respect to its normal state. If, however, the myosin has coagulated and become opaque, the blood is unable alone to restore the muscle; but, as Preyer (*Centr. f. d. Med. Wiss.* 1864, s. 769-773) has shown, if the coagulated myosin be dissolved by soaking the muscle in a 10 p.c. solution of sodium chloride, then restitution by the blood is possible. Coagulated myosin must then present an obstacle to the restoration of the muscle, which myosin before it has coagulated does not present.

The conclusion which Hermann arrives at is therefore as follows: That muscular work, though in the long run dependent on oxidation, is not immediately so; but that a living muscle contains a store of some substance (*inogen*) which, when the muscle contracts, breaks up in proportion to the work done (and independently of any taking up of oxygen) into carbonic anhydride, lactic acid, myosin, and possibly some other bodies. In these products of decomposition stronger affinities are satisfied than in the original compound, and thus energy is set free and manifests itself as muscular work. The substances which the muscle loses during contraction (and which are normally carried off by the blood) contain no nitrogen: for the myosin remains in the muscle in its jelly-like form, and is used again, being built up, by the aid of oxygen and non-nitrogenised compounds conveyed to it by the blood, into the original unstable muscle com-

pound, which is again stored away ready for use. If, however, the muscle be removed from the blood-current, or be heated to 50° C., the jelly-like myosin first separated soon passes into its firmly coagulated stage, and is then unfit for further use in the muscle; possibly a small amount of this may be formed in an overworked muscle, and be afterwards broken up and carried away in the form of simpler compounds; but if any great amount of it is formed, then the blood cannot restore the muscle, which remains (until decomposition sets in) in a state of *rigor mortis*. The energy set free during the formation of the carbonic anhydride, &c., and showing itself normally as a muscular contraction, must, of course, in a muscle passing into the state of death-stiffening, take some other form, and probably appears as heat. Whether the lactic acid formed in a contracting muscle is carried away, or is used again like the myosin, is uncertain.

H. N. M.

MUSTARD. White mustard seed contains a glucoside, sinalbin, which is soluble in alcohol, and, like potassium myronate, decomposes in contact with aqueous extract of mustard:—

an albuminous substance being likewise formed. Acrylyl sulphocyanate resembles oil of mustard, is soluble in ether, very pungent, insoluble in water, but not volatile; after warming with an alkali and neutralisation with an acid, it gives a red colour with ferric chloride. Sinapisine sulphate is insoluble in ether.

Sinalbin gives a white precipitate with silver nitrate, from which sulphydric acid removes the silver, leaving acrylyl cyanate, $\text{C}^6\text{H}^7\text{NO}$, fusible at 60°, easily soluble in water, alcohol, and ether. When boiled with potash it gives ammoniac and the potassium salt of an acid, $\text{C}^6\text{H}^7\text{O}^3$, fusible at 136°, but apparently different from the known acid of this composition (Will, *Zeitschr. f. Chem.* [2], vii. 89).

The relations of these compounds to the other constituents of mustard do not appear to have been made out.

On Volatile Oil of Mustard, see SULPHOCYANATES.

MYCOMELIC ACID, $\text{C}^6\text{H}^7\text{N}^4\text{O}^2$. This compound, which Liebig & Wöhler obtained by the action of ammonia on alloxan (iii. 1068), is likewise produced by the action of boiling water on azulmic acid or hydrazalmozin (p. 416).

MYELIN. The lithomarge from Rochlitz in Saxony, known as myelin, has been variously represented by the formulæ $\text{Al}^2\text{O}^3 \cdot \text{SiO}^2$ (Kersten) and $2\text{Al}^2\text{O}^3 \cdot \text{SiO}^2 + \text{H}^2\text{O}$ (Breithaupt). To ascertain its true composition, Frenzel (*J. pr. Chem.* [2], v. 401) analysed a pure snow-white kidney-shaped specimen carefully freed from adhering ferric oxide. This mineral gave, in two analyses, the following results:—

	SiO^2	Al^2O^3	CaO	H^2O
a.	43.94	39.40	0.42	17.11 = 100.87
b.	44.19	39.68	0.47	16.67 = 100.81

The pulverised mineral heated to 100° gives off 2.56 and 2.30 p.c. hygroscopic water. On deducting this water and the lime, the preceding analyses gave:—

	SiO^2	Al^2O^3	H^2O
a.	45.27	40.59	14.55
b.	45.44	40.60	14.27

leading to the formula $\text{Al}^2\text{O}^3 \cdot 2\text{SiO}^2 + 2\text{H}^2\text{O}$, which agrees with that of nacrite, kaolin, carnat, and the lithomarge of Schenckenstein-near Auerbach, Cainsdorf near Zwickau, and a few other localities. All these minerals give up more or less hygroscopic water at 100°, namely: carnat from Rochlitz, 1.8; lithomarge from Auerbach, 1.2; nacrite from Freiberg, 0.8; and kaolin from Seilitz, 0.15 p.c.

Myelin appears homogeneous under the microscope, and does not polarise light, in which respect it resembles carnat. Nacrite, on the other hand, crystallises in hexagonal plates; kaolin and lithomarge from the above-mentioned localities are likewise crystalline. The crystalline characters of nacrite, kaolin, and crystalline lithomarge, are not sufficiently well made out to enable us to decide whether these minerals belong to one and the same species. Kennigott proposed to unite nacrite with kaolin; crystalline lithomarge is regarded as a hardened kaolin. On the other hand, the amorphous varieties of lithomarge, namely myelin and carnat, are identical, and it would therefore be advisable to discard the name carnat altogether.

Myelin of the same composition as that found by Kersten is said to occur at Ziboraz near Temesvar in Hungary.

MYRISTICENE, $\text{C}^{14}\text{H}^{28}$. The terpene obtained from nutmeg.

* There is an error in this equation: either sinalbin must contain H^{12} , or sinapisine must contain H^{12} .

MYRISTICOL. An oxidised oil forming the chief constituent of the volatile oil of nutmeg, from which it may be separated by fractional distillation. It was first obtained by Gladstone (*Chem. Soc. J.* [2], x. 11), and has been further examined by Wright (*ibid.* xi. 549, 686). It has the characteristic smell of nutmeg; boils at about 220° (Gladstone) or between 212° and 218° (Wright); has a high refractive power (p. 739). Gladstone obtained by its analysis numbers agreeing approximately with the formula $C^{10}H^{16}O$. Wright, on the other hand, regards it as isomeric with ordinary camphor, $C^{10}H^{16}O$, his analysis giving 78.8 and 78.3 p.c. carbon and 10.3 hydrogen, and the formula $C^{10}H^{16}O$ requiring 78.94 C. and 10.53 H., whereas $C^{10}H^{16}O$ requires 80.00 C. and 9.33 H.

Myristicol, treated with phosphorus pentachloride, is decomposed in the manner of alcohols, according to the equation:

The chlorinated compound thus obtained is crystalline, and melts at 100°. When heated for some time, or repeatedly distilled at a very slow rate, it splits up in the manner of secondary alcohols, yielding hydrogen chloride and a hydrocarbon containing the elements of water less than myristicol:

The hydrocarbon thus obtained is ordinary cymene (p. 419).

MYRTENE, $C^{10}H^{14}$. The terpene from volatile oil of myrtle.

N

NADORITE. This name is given by Flajolot (*Compt. rend.* lxxi. 237) to a lead-ore from a vein of galena near the hot spring of Hamman-Nbail-Nador, in the province of Constantine, Algeria, to which he originally assigned the formula $Sb^{20}O^4.PbO$, deduced from an analysis which gave 44 p.c. $Sb^{20}O^4$, and 56 PbO. Pisani, on the other hand (*ibid.* 319), finds that the mineral contains chlorine as an essential constituent, and gives by analysis numbers agreeing with the formula $Sb^{20}O^4.PbCl^2$ —

	$Sb^{20}O^4$	PbO	Pb	Cl	
Analysis	37.40	27.60	26.27	9.00	= 100.27
Calculation	36.82	28.12	26.11	8.95	= 100

Flajolot (*ibid.* 406), on repeating his analysis, found 51.60 p.c. Pb, 32.25 Sb, 8.00 O, and 8.85 Cl, whence he deduces the formula $SbOCl.PbO$, agreeing in percentage composition with that of Pisani.

In an oxidation-product of nadorite Flajolot found—

$Sb^{20}O^4$	$Sb^{20}O^4$	CO^2	PbO	H^2O
4.80	35.50	4.20	51.50	4.00

and supposing the antimonious oxide to be an incompletely oxidised residue of the original substance, he regards the mineral as a definite compound, represented by the formula $PbO.Sb^{20}O^4 + PbO.CO^2 + 2H^2O$. Pisani, on the contrary, regards it as a mixture of bleinorite (i. 326) and cerussite, crystals of the latter of which are indeed implanted on it.

Lastly, Flajolot regards an amorphous argillaceous mass from the same locality, containing 63.50 p.c. $Sb^{20}O^4$, 31.40 $Fe^{20}O^3$ and 5.10 H^2O , likewise as a distinct mineral species, represented by the formula $2(Fe^{20}O^3.Sb^{20}O^4).3H^2O$.

NAPHELINE. See ACONITE ALKALOIDS (p. 23).

NAPHTHALENE, $C^{10}H^8$. *Synthesis.*—This hydrocarbon is formed by passing the vapour of phenylbutylene bromide, $C^{10}H^{12}Br^2$, over quicklime heated to dull redness—

The phenylbutylene (*q. v.*) is obtained by treating an ethereal solution of benzyl bromide and allyl iodide with sodium, distilling, and collecting the portion which passes over between 176° and 178°. The decomposition of its bromide yields nearly the theoretical quantity of naphthalene (Aronheim, *Deut. Chem. Ges. Ber.* vi. 67).

Properties.—According to Ballé, perfectly pure naphthalene has merely a faint and

by no means unpleasant odour, the pungent odour of (so-called) pure commercial naphthalene being due to admixed leucoline oil, which may be separated from it by boiling with strong sulphuric acid, and precipitating the resulting brown solutions with ammonia (p. 787).

Reactions.—Naphthalene exposed to the vapour of *nitromuriatic acid* at ordinary temperatures, is converted into naphthalene tetrachloride, $C^{10}H^4Cl^4$, and chloronaphthalene tetrachloride, $C^{10}H^3Cl^4$ (Bunge, *Deut. Chem. Ges. Ber.* iv. 289). It is not acted upon by phosgene (Berthelot, *Bull. Soc. Chim.* [2], xiii. 301). For its reaction with *sulphuryl hydroxychloride*, SO^2HCl , see NAPHTHALENE-SULPHONIC ACID (p. 835).

Compounds and Derivatives of Naphthalene.

Acenaphthene, $C^{12}H^{10}$. This hydrocarbon, which occurs in heavy coal-tar oil, and is formed synthetically by passing a mixture of naphthalene-vapour and ethylene through a red-hot tube (1st *Suppl.* p. 3), may also be produced from ethyl-naphthalene (*ibid.* 849) by passing the vapour of that compound through a porcelain tube at a bright red heat, whereby naphthalene and acenaphthene are produced, and may be separated by fractional distillation. The change may be also effected in the wet way by heating ethylene-naphthalene to 180° with two equivalents of bromine, treating the crude liquid (which cannot be purified by distillation) with alcoholic potash at 100° , and at the end of twelve hours pouring the mother-liquor into water. The heavy oily layer which separates is distilled, and the portion passing over at 300° is treated with alcoholic picric acid. The red precipitate, decomposed by ammonia, gives a liquid which deposits crystals of acenaphthene (Berthelot a. Bardy, *Compt. rend.* lxxiv.). According to Graebe (*Deut. Chem. Ges. Ber.* v. 15), acenaphthene melts at 99° – 100° , and has a vapour-density of 5.35 (calc. 5.33). According to Behr and van Dorp (*ibid.* vi. 60) it melts at 94° – 96° , distils at 267° – 269° (uncorrected), and is oxidised by boiling with chromic acid mixture to naphthophthalic acid, $C^{10}H^4(CO^2H)^2$.

On Naphthalene Tetrachloride and the Chloronaphthalenes, see 1st *Suppl.* 846–847.

According to Grimaux (*Bull. Soc. Chim.* [2], xviii. 205) the tetrachloride heated with 30 parts of water to 180° – 190° for some hours, or boiled with water, is converted into dichloronaphthhydrenglycol, $C^{10}H^2Cl^2(OH)^2$.

Nitronaphthalenes (A. de Aguiar, *Deut. Chem. Ges. Ber.* v. 370). Compare iv. 14 and 1st *Suppl.* p. 848. At least seven distinct nitro-compounds are producible by the action of nitric acid on naphthalene, and may be separated with more or less difficulty by fractional crystallisation, glacial acetic acid serving better as a solvent than ethyl or methyl alcohol, benzene, or chloroform.

Mononitronaphthalene is best prepared by treating naphthalene dissolved in boiling glacial acid, with ordinary nitric acid, and boiling for half an hour. No red vapours are evolved, and on cooling, the whole becomes a mass of crystals, which are perfectly pure after one crystallisation from alcohol. According to De Aguiar, the pure compound melts at 61° , which is some degrees higher than the melting point found by Laurent, viz. 43° .

Dinitronaphthalene.—Fuming nitric acid and naphthalene, boiled together for some hours, yield this compound in two modifications, α and β , in nearly equal quantities. On cooling, a crystalline mass separates, usually containing only traces of trinitronaphthalene. This mass is washed and dried, and then boiled with glacial acetic acid (about 2½ times its weight). Pure α -dinitronaphthalene remains undissolved, and may be crystallised from a large quantity of fresh acid. The β modification is much more soluble than the α , and is readily obtained pure by a few fractional crystallisations of the product obtained from the dissolved part. The two bodies differ in their crystalline forms and melting points, the α modification melting at 216° and the β at 170° . A small quantity of what appears to be a third modification is also obtained, but cannot readily be purified, as its solubility is nearly the same as that of β -dinitronaphthalene.

Trinitronaphthalene.—Two modifications of this derivative exist, and may be obtained by the action of nitric acid on naphthalene; their separation and purification are however difficult. Much better results are obtained by nitrating α - and β -dinitronaphthalene in sealed tubes at 120° – 130° , or in a retort with inverted condenser. α -dinitronaphthalene, thus treated, gives a product which after precipitation by water and crystallisation from alcohol, benzene, glacial acetic acid, or chloroform (the last being the best), yields fine crystals of α -trinitronaphthalene, melting at 128° and solidifying at 90° . β -dinitronaphthalene yields in like manner β -trinitronaphthalene melting at 218° ; the latter is much less soluble in alcohol and chloroform than the former, but may be crystallised from these solvents.

Beilstein a. Kuhlberg (*Deut. Chem. Ges. Ber.* v. 480), by treating dinitronaphthalene (m.p. 212°) with a mixture of nitric and sulphuric acids, have likewise obtained two trinitronaphthalenes, one probably identical with Laurent's, melting at 208° , the other at 147° .

Tetranitronaphthalene.—If the action of the nitric acid in preparing trinitronaphthalene be carried on for two days, tetranitrated bodies are formed. α -tetranitronaphthalene obtained from α -dinitronaphthalene is almost insoluble in alcohol, cannot be crystallised from acetic acid, but crystallises readily from chloroform, the crystals melting at 259° and solidifying at 225° . β -tetranitronaphthalene melts at 200° (De Aguiar).

NAPHTHALENE COLOURS (Ballò, *Dingl. pol. J.* xciv. 82). A mixture of fuchsine and monobromonaphthalene forms when heated a violet colouring matter similar in every respect to Hofmann's violet. The saturated alcoholic solution of this dye-stuff has a deep violet colour almost black; in the solid state the substance resembles fuchsine. On adding a small quantity of hydrochloric acid, the colour of the alcoholic solution changes to blue and on further addition to green. The addition of an alkali, or even of alcohol, brings about the same changes of colour in the reverse order.

NAPHTHALENE-CARBOXYLIC ACID. Syn. with NAPHTHOIC ACID.

NAPHTHALENE-POTASSIUM, $C^{10}H^8K^2$. The substance formed by fusing naphthalene with potassium (*1st Suppl.* 844) is converted by heating with ethyl bromide into a hydrocarbon, $C^{20}H^{12}$ (? dinaphthyl) (Abeljan, *Deut. Chem. Ges. Ber.* v. 102).

NAPHTHALENE-SULPHONIC ACID. According to Merz a. Weith (*Deut. Chem. Ges. Ber.* iii. 195), the action of sulphuric acid upon naphthalene at comparatively high temperatures (160° – 170°) yields chiefly the β modification of naphthalene-monosulphonic acid, $C^{10}H^7SO^3H$, whereas at lower temperatures (80° – 100°) the product consists chiefly of the α modification (*1st Suppl.* 860). In mixtures containing a considerable proportion of the α -acid, the separation of the two is best effected by converting them into calcium salts, the α -salt being the more soluble of the two. The α -sulphonic acid is partially converted into the β modification when its lead salt is heated to 100° with moderately concentrated sulphuric acid.

By treating naphthalene with *sulphuryl hydrozylchloride*, $SO^2.OH.Cl$, both modifications of the monosulphonic acid appear to be produced. With 2 mol. of the hydrozylchloride to 1 mol. naphthalene, the disulphonic acid, $C^{10}H^6(SO^3H)^2$, is obtained (Armstrong, *Chem. Soc. J.* [2], ix. 173).

NAPHTHAQUINONE, $C^{10}H^6O^2$. This compound, which Hermann obtained in small quantity by the dry distillation of potassium chloronaphthasulphoquinonate (*1st Suppl.* 852), has lately been obtained more abundantly and in greater purity by C. E. Groves (*Chem. Soc. J.* [2], xi. 209) by the application of Graebe a. Liebermann's method of preparing quinones—namely, by oxidising naphthalene with a solution of chromic anhydride in glacial acetic acid. For this purpose a solution of naphthalene in warm glacial acetic acid was treated with an almost saturated solution of chromic anhydride in the same solvent, whereby great heat was evolved, the solution turning green and depositing a green chromium salt on the sides of the vessel. As soon as the reaction was complete, the product was diluted with water, which dissolved the chromium salt, and at the same time produced an orange-coloured precipitate containing the impure naphthaquinone. This, when collected, washed, and dried, was of a deep-yellow colour, and had a strong odour, arising from the naphthalene which had escaped the action of the chromic anhydride. As the naphthaquinone in this precipitate was accompanied by a certain amount of black tarry matter, very difficult to separate by crystallisation, it was found advantageous to purify it partially by distillation in the vapour of water, in which it volatilises easily, although not so readily as naphthalene. The long, bright-yellow crystals which adhered to the sides of the condensing tube, consisting almost entirely of naphthaquinone and naphthalene, were either at once purified from the latter by alternate crystallisation from light petroleum oil, carbon bisulphide, and alcohol; or the greater part of the naphthalene was previously removed by allowing the mixture to remain freely exposed to the air for some time in a warm place.

Naphthaquinone identical with the above is produced by oxidising the hydrochloride of amidacetonaphthalide, $C^{10}H^8\{NH(COCH^3)\}_2$, with a 1 p.c. solution of chromic acid ($NH^2.HCl$) (Liebermann a. Dittler, *Deut. Chem. Ges. Ber.* vi. 945).

Naphthaquinone, prepared by either of these processes, is a bright-yellow crystalline substance, which melts at about 125°, and begins to sublime below 100°. Although but slightly soluble in cold water, it is readily volatile in vapour of water at 100°, communicating to it a pungent odour, like that which is so characteristic of ordinary quinone. It is but slightly soluble in light petroleum oil, readily in benzene, carbon bisulphide, chloroform, and other, especially when hot, and crystallises by spontaneous evaporation from its solution in the latter in well-formed rhomboidal plates. It is very soluble in boiling alcohol, but crystallises out in great part on cooling. It dissolves in concentrated sulphuric acid, and in glacial acetic acid, being again precipitated on the addition of water; also in alkalis, forming a reddish-brown solution, in which acids cause a precipitate of a bright-red colour, the nature of which has not yet been examined. When the quinone is boiled with concentrated hydrochloric acid, it is apparently converted into hydromonochloronaphthaquinone in a manner similar to that in which hydrochloroquinone is formed from ordinary quinone (Groves). When boiled with pure nitric acid, it is oxidised to phthalic acid (Liebermann a. Dittler).

Hydronaphthaquinone, $C^{10}H^8O = C^{10}H^7(OH)^2$.—A cold aqueous solution of sulphurous anhydride is almost without action on naphthaquinone, but when the latter is boiled with strong hydriodic acid and amorphous phosphorus, it dissolves, forming a colourless solution which deposits long needles of the hydronaphthaquinone on cooling. This compound crystallises in colourless needles which melt at about 176° and dissolve with comparative readiness in boiling water, crystallising out again, in great part, on cooling. It is readily soluble in alcohol and ether, even in the cold, also in glacial acetic acid, slightly soluble in hot benzene, crystallising out again on cooling in tufts of colourless needles, and almost insoluble in carbon bisulphide and light petroleum oil. When treated with oxidising agents, such as chromic acid, &c., it is reconverted into the quinone.

On boiling an aqueous solution containing a molecular weight of hydronaphthaquinone with a molecular weight of naphthaquinone, the latter dissolved, yielding a pale-brown solution which, as it cooled, deposited the dark-purple crystalline naphthaquinhydrone, $C^{20}H^{14}O^4$, analogous to the quinhydrone or green hydroquinone of the benzene series. The same purple quinhydrone was obtained when naphthaquinone was boiled with amorphous phosphorus and a weak solution of hydriodic acid. It is readily converted, by treatment with strong hydriodic acid, into colourless hydronaphthaquinone on the one hand, and by oxidising agents into naphthaquinone on the other (Groves).

Oxynaphthaquinones. *Monooxynaphthaquinone* or *Naphthalic acid*, $C^{10}H^6O^3 = C^{10}H^4(OH)\left\{ \begin{smallmatrix} O \\ O \end{smallmatrix} \right\}$, is most easily formed by heating the hydrochloride of di-imidonaphthol (p. 841) to 120° with *dilute* hydrochloric or sulphuric acid:

It dissolves sparingly in water, easily in alcohol and in ether. Reducing agents convert it into dioxynaphthol; zinc-dust, with the aid of heat, into naphthalene. It exhibits the characters of a strong acid. Its *ammonium salt* is a red, crystalline, easily soluble mass. The *silver salt* crystallises in cinnabar-red needles. The *ammonium salt* forms with ferric chloride a red-brown precipitate, with cupric sulphate a brownish red, with mercury salts an orange-coloured, and with barium chloride a red precipitate (Graebe a. Ludwig, *Ann. Ch. Pharm.* cliv. 303).

Dioxynaphthaquinone or *Naphtazarin*, $C^{10}H^4O^4 = C^{10}H^2(OH)^2\left\{ \begin{smallmatrix} O \\ O \end{smallmatrix} \right\}$

This substance was first obtained by Roussin (iv. 18) by the action of strong sulphuric acid and zinc on dinitronaphthalene. It sublimes in small red-brown crystals, or in long needles having a bright green metallic lustre. With baryta- and lime-water it gives fine violet-blue precipitates; with magnesia, a crimson; with basic lead acetate, a blue; and with ferric salts a black precipitate. Ammonia dissolves naphtazarin with a sky-blue colour, which by long standing changes to a reddish-violet; concentrated sulphuric acid gives in the cold a beautiful magenta-coloured solution from which water precipitates red flocks. It dissolves slowly in boiling water, more easily in alcohol, and crystallises therefrom. By heating with zinc-dust it is reduced to naphthalene (Liebermann, *Deut. Chem. Ges. Ber.* iii. 706).

De Aguiar a. Baeyer (*ibid.* iv. 251, 438) find that naphtazarin is formed from the modification of dinitronaphthane (melting at 214°). To prepare it, the dinitronaph-

lene was added to sulphuric acid heated to 200° , and then zinc in small portions; the temperature was kept constant for about twenty minutes, and then the mixture was allowed to cool; when cold it was treated with boiling water and left at rest for 48 hours. The precipitate was then filtered off, slightly washed with cold water, and treated with strong aqueous potash, any traces of unaltered dinitronaphthalene being removed by filtration. The beautifully coloured blue liquid was now supersaturated with dilute sulphuric acid, whereby the crude naphthazarin was slowly precipitated; it was then filtered off and dried at 100° . As thus prepared it contains a black substance, which cannot be separated by sublimation, as a large portion of the naphthazarin becomes carbonised at the same time. The purification may, however, be effected by dissolving the crude naphthazarin in warm glacial acetic acid, filtering from the undissolved black substance, and distilling at a temperature a little above 130° . The naphthazarin is thereby obtained as a crystalline substance having a metallic lustre.

The same result is obtained by heating α -dinitronaphthalene with sulphuric acid without the aid of zinc. In this case it is not necessary, as stated by Persoz (*Compt. rend.* lii. 1178), to raise the temperature above 200° , but the heating must be continued three times as long as when zinc is employed. When 4 grams of dinitronaphthalene were heated with sulphuric acid to 200° till the whole was converted into naphthazarin, 450 c.c. of gas were obtained, containing in 100 volumes $86\cdot15$ vol. SO_2 , 701 N., and $6\cdot54$ CO_2 .

In the blue liquid above mentioned, from which naphthazarin separates on boiling, the formation of that substance likewise goes on in the cold, inasmuch as the blue colour gradually changes to red. Nevertheless, the blue solution does not contain naphthazarin ready formed, and it contains only a small portion of ammonia, the quantity of which is, however, considerably increased by boiling. If the sulphuric acid be removed by barium carbonate, a bluish-violet liquid is obtained, which, after removal of the carbonate, still contains barium. It turns blue when acidulated, and red when heated, ammonia being then formed and naphthazarin becoming recognisable. From the acidulated liquid containing barium, and likewise from the original blue-violet liquid, there is deposited, on standing, a second compound distinguished from naphthazarin both by the violet colour of its solutions and by its different chemical behaviour. This body likewise yields naphthazarin, with separation of ammonia, but the transformation is somewhat slower than that which takes place in the solution. This last-mentioned compound is usually present in naphthazarin prepared by Roussin's process. The greater part of it carbonises when heated (De Aguiar a. Bayer).

Trioxynaphthaquinone, $\text{C}^{10}\text{H}^6\text{O}^3 = \text{C}^8\text{H}^4(\text{OH})^2 \left\{ \begin{smallmatrix} \text{O} \\ \diagup \quad \diagdown \\ \text{O} \end{smallmatrix} \right.$ This is the

chief constituent of the black substance above mentioned. To prepare it the cooled product of the action of sulphuric acid on dinitronaphthalene is mixed with water, and the black precipitate filtered off from the blue-violet solution is repeatedly boiled with water acidulated with sulphuric acid; much ammonia then passes into solution. The product is dissolved in soda-solution, again precipitated by sulphuric acid, the precipitate well washed with hot water, and then dried at 100° . The product thus purified has the composition of trioxynaphthaquinone. The same body is obtained by the action of sulphuric acid on pure naphthazarin, its formation, in this case, being possibly in accordance with the equation:

Thus prepared it is amorphous with a reddish metallic gloss, cannot be sublimed, dissolves in alkalis with a dirty blue-violet colour, and tinges hot water pale-red. On reduction with zinc-dust it yields naphthalene.

In an operation in which the heating had been carried too far, a body was obtained which, after purification in the same manner, gave on analysis less C and H than the above, and appeared to consist of a mixture of tri- and tetra-oxynaphthaquinone (De Aguiar a. Bayer).

NAPHTHOIC ACID, $\text{C}^{10}\text{H}^8\text{O}^3 = \text{C}^{10}\text{H}^7\text{COOH}$. Respecting the formation, properties, reactions, and salts of this acid, see 1st Suppl. p. 861.

α -Naphthoic acid, oxidised with potassium permanganate, is converted into an acid which, after purification, crystallises in slender needles, yields an easily soluble potassium salt, and flocculent, nearly insoluble lead and barium salts (Carstanjen a. Schertel, *J. pr. Chem.* [2], iv. 49).

Nitronaphthoic acids.— α -Mononitronaphthoic acid, $\text{C}^{10}\text{H}^7(\text{NO}^2)\text{O}^3$, is prepared by adding a mixture of α -naphthoic acid and potassium nitrate to sulphuric acid, and heating over the water-bath. When purified by sublimation it forms shining radiate

tufts of slender needles, having a faint yellowish colour; melts at 194° . β -Nitronaphthoic acid is prepared in like manner from β -naphthoic acid, the mixture being, however, finally heated over the open fire to complete the action. It resembles the α -acid, but melts at 288° . Both these nitro-acids dissolve sparingly in water, more freely in alcohol. Their alkali-salts have a yellow to orange-yellow colour; the barium and silver salts are faintly yellowish flocculent precipitates, slightly soluble in cold, more soluble in hot water. The lead and copper salts are precipitates only sparingly soluble even in hot water (O. Küchenmeister, *Deut. Chem. Ges. Ber.* iii. 739).

When β -nitronaphthoic acid is treated with tin and hydrochloric acid, a violent action takes place, and on boiling the product with ammonium carbonate and filtering, the liquid, on cooling, deposits a substance which, when recrystallised from weak alcohol, has the composition $C^{11}H^6NO$ or $C^{22}H^{12}N^2O^2$, and probably the constitutional formula:

The same compound is obtained by the action of iron and acetic acid on β -nitronaphthoic acid.

This substance does not combine either with acids or with bases, and is not precipitated from its solution in hot water by the addition of metallic salts. It is scarcely soluble in cold water, but more soluble in that liquid when hot, and is deposited, on cooling, in microscopic flexible needles. Ether and alcohol dissolve it readily, and the latter deposits it in tolerably long prisms. It melts at 174° , solidifies at 165° , and begins to sublime in small needles at 125° . Concentrated sulphuric acid dissolves it, and it is precipitated from the solution on the addition of water. When potassium bichromate is added to its solution in sulphuric acid, the liquid becomes dark blue, and the addition of water causes the separation of violet flocks.

β -Nitronaphthoic acid, treated with ammonium sulphide, yields, not amidonaphthoic acid, but a small quantity of azonaphthoic acid, $CO^2H - C^6H^4 - N = N - C^6H^4 - CO^2H$ (P. v. Rakowski, *Deut. Chem. Ges. Ber.* v. 1020).

Oxynaphthoic Acids, $C^{11}H^6O^2 = C^6H^4(OH.CO^2OH)$.—These acids are produced by fusing the potassium salts of the corresponding sulphonaphthoates with potassium hydrate. The α -acid dissolves freely in alcohol and with moderate facility in boiling water, and crystallises from a hot aqueous solution in long interlaced needles, melting at 234° – 237° , and subliming, when carefully heated, in feathery crystals. On boiling down the aqueous solutions of its salts, the liquid darkens and a dark amorphous mass separates out.

The β -acid crystallises from boiling water in long needles, melting at 212° – 213° . Its salts are as unstable as the α -oxynaphthoates (J. P. Battershall, *Ann. Ch. Pharm.* clxviii. 114).

Sulphonaphthoic Acids, $C^{11}H^6SO^3 = C^6H^4 \begin{cases} CO.OH \\ SO^2OH \end{cases}$ (Battershall. *loc. cit.*; also *Zeitschr. f. Chem.* [2], vii. 673).—Fuming sulphuric acid converts naphthoic acid into a mixture of at least two sulpho-acids, both of which yield crystallisable barium salts, $C^6H^4(SO^2)(CO^2)Ba$. On neutralising the mixture of the sulpho-acids with barium carbonate, the α -salt crystallises out first, and this when decomposed by sulphuric acid yields α -sulphonaphthoic acid. This acid dissolves readily in water and crystallises therefrom in colourless needles, melting with slight decomposition at 230° – 240° .

Its barium salt, $C^6H^4(SO^2)(CO^2)Ba + 4H^2O$, forms well-defined, glistening, transparent, and compact monoclinic crystals. The calcium salt, $C^6H^4(SO^2)CO^2Ca + 3H^2O$, is moderately soluble in water, and crystallises in thin plates. The potassium salt, $C^6H^4(SO^2K)(CO^2K) + 2H^2O$, forms thin tables and is freely soluble in water. The cupric salt, $C^6H^4(SO^2)(CO^2)Cu$, is a bluish-green precipitate, sparingly soluble in boiling water.

β -Sulphonaphthoic acid is produced by dissolving β -naphthoic acid in fuming sulphuric acid. It forms a very characteristic acid barium salt, $(C^{11}H^6SO^2)Ba + 7H^2O$, which is almost insoluble in cold water, and crystallises from a boiling solution in brilliant large plates. The neutral salt, $C^{11}H^6SO^2Ba + H^2O$, is readily soluble in water, and forms oblique crystals.

NAPHTHOIC ALDEHYDE, $C^{11}H^6O$ (Battershall, *Zeitschr. f. Chem.* [2], vii. 292, 673). β -Naphthoic aldehyde is produced by distilling an intimate mixture of calcium naphthoate and calcium formate at a high temperature. The distillate contains naphthalene together with the aldehyde, which may be purified by shaking it with

sodium bisulphite, washing the resulting crystalline mass with ether till it becomes colourless, and distilling the crystals with dilute solution of sodium carbonate. The aldehyde then passes over with the vapour of water, and solidifies in the condensing tube in dazzling white crystals. It is very nearly insoluble in cold water, somewhat soluble in boiling water, very soluble in alcohol and ether. It crystallises from boiling water in very bulky, thin, shining laminae, and is obtained in the same form by spontaneous evaporation of its alcoholic solution. It melts at $59^{\circ}5'$. Potassium permanganate oxidises it readily when heated with it, forming potassium β -naphthoate, with separation of hydrated manganic oxide. Strong nitric acid dissolves it at a gentle heat, forming a crystalline non-acid compound which separates on the surface of the liquid. Nascent hydrogen converts it into uncrystallisable compounds difficult to purify. It dissolves easily in alcoholic ammonia, and is thereby converted into β -hydronaphthamide.

α -Naphthoic aldehyde.—A mixture of calcium formate and pure calcium α -naphthoate yields by distillation scarcely anything but naphthalene, only the merest traces of the aldehyde being formed, if any. The cause of this negative result is doubtless that calcium α -naphthoate is resolved into naphthalene and calcium carbonate at a temperature lower than that which is required to bring about its reaction with the formate. When, however, a mixture α -naphthoate containing β -naphthoate is used, a distillate is obtained which, when purified as above with sodium bisulphite, yields liquid α -naphthoic acid containing a certain portion of the β compound, which after a while separates in crystals.

α -Naphthoic aldehyde is a somewhat thick liquid having a peculiar faint smell, and becoming coloured on exposure to the air. It is heavier than water, boils at about 280° , but cannot be distilled without forming a small quantity of condensation-products of higher boiling point; with steam, however, it volatilises readily and without alteration.

NAPHTHOLS, $C^{10}H^8O = C^{10}H^7(OH)$. *Reactions of α -Naphthols with Polybasic acids, their Anhydrides and Chlorides* (J. Grabowski. *Deut. Chem. Ges. Ber.* iv. 661, 725; vi. 1065).— α -Naphthol, like other phenolic bodies, unites with many polybasic acids (or their anhydrides), with elimination of water, when the two bodies are heated together in presence of glycerin or sulphuric acid. The resulting compounds, which belong to the class of Baeyer's phenolic colouring matters, are not true ethers, but either compounds which retain the phenolic character of the naphthol, and dissolve in potash with a deep colour which disappears on reduction, or indifferent substances which may be regarded as the anhydrides of the former. The coloured compounds are designated, according to Baeyer's nomenclature, by names ending in *ein*, the reduced compounds by names ending in *in*.

All these compounds are formed in such a manner that the OH-group of the acid unites with an atom of hydrogen from the naphthalene nucleus, forming water, which is eliminated, and the two residues unite together forming a ketonic compound. Thus carbonic acid forms with naphthol a compound having the formula, $C^{10}H^{12}O^2$:

Phthalic acid yields two compounds, viz.—

Reaction with Phthalic Anhydride.—When α -naphthol is boiled with phthalic anhydride, the liquid acquires a dark green colour, and on exhausting the cooled mass with alcohol, there remains a white substance, $C^{20}H^{18}O^3$, which is the *anhydride* of naphthol-phthalcin (1):

This compound separates from hot benzene in faintly yellowish crystals having a splendid vitreous lustre. It is insoluble in aqueous potash, and is converted by alcoholic potash into a green substance. Heated with sulphuric acid, it yields a red substance, which appears to have the composition $C^{20}H^{18}O^4$.

With Phthalic Chloride.—On heating a mixture of these two bodies on the water-bath, abundance of hydrogen chloride is evolved, and a green mass remains, partially soluble in cold dilute potash. The dissolved substance is purified by repeated fractional precipitation with hydrochloric acid and recrystallisation from benzene. The

small brown crystals so obtained dissolve in potash, with production of a fine blue colour; their composition, when dried at 100° – 110° , is $C^{22}H^{12}O^4 + \frac{1}{2}Aq$ (2). Leaving the half-molecule of water out of consideration, the formation of this body, called *phthalein- α -dinaphthol*, may be represented by the equation:

With Oxalic Acid.—On heating a mixture of oxalic acid, naphthol and sulphuric acid for two hours at 100° – 115° , a dark mass is obtained only partially soluble in alkali; the portion insoluble is dissolved by hot benzene, and crystallises on cooling in colourless, warty groups. These are a mixture of various substances, but after oft-repeated recrystallisation they are converted into beautiful, colourless, glistening crystals of *carbonein- α -naphtholanhydride*, $C^{21}H^{12}O^2$ (3). This body bears exactly the same relation to carbonic anhydride as the previously described phthalic compound does to phthalic anhydride:

The behaviour of the two substances is also identical (Grabowski, *loc. cit.*)

With Pyromellitic Acid.—The reaction between this acid and α -naphthol is very complex, giving rise to a large number of compounds, the most important of which, from its analogy to the phthalic and carbonic acid compounds, is *pyromellitein-tetra- α -naphtholanhydride* (4):

This compound is formed when one molecule of pyromellitic acid is heated with four molecules of α -naphthol in an oil-bath to 300° . The product after being exhausted with boiling acetone and purified by fractional crystallisation from phenol, yields microscopic crystals, which have the composition $C^{20}H^{20}O^6 \cdot C^8H^4OH$, and lose their phenol when heated to 260° . From the mother-liquors the compounds are obtained, the first, $2C^{20}H^{20}O^7 \cdot C^8H^4OH$, in thin plates, the second in very slender needles; they lose their phenol when dried at 260° , and are reduced to α - and β -*pyromellitein-tetra- α -naphtholhemianhydride*, $C^{20}H^{20}O^7$. In the acetone solution the compound γ -*pyromellitein-tetra- α -naphtholhemianhydride* is found. It melts at 265° , and when dried at 150° has the composition $C^{20}H^{20}O^7$. On heating one molecule of pyromellitic acid with three of α -naphthol to 250° as long as water escapes, and removing the excess of naphthol by distillation in a current of aqueous vapour, a brownish-black mass is left. This, when purified by repeated solution in potash, precipitation by acid, and solution in ether, forms a brown powder, *tri- α -naphtholpyromelliteic acid* (6), which has the composition $C^{16}H^{12}O^8$, and is readily soluble in alcohol, ether, and acetone. It dissolves in alkalis with a deep green colour.

Tri- α -naphtholhemianhydropyromelliteic acid, $C^{40}H^{22}O^7$ (7), is produced, together with the last-mentioned compound, when a mixture of one molecule of pyromellitic acid and three of α -naphthol is heated to 280° – 300° . It is a yellowish-brown powder, soluble with difficulty in cold alcohol or ether. It yields a fine blue solution with alkalis.

Pyromellitic anhydride and α -naphthol fused together form a black resinous mass, which, when purified by solution in potash and fractional precipitation, yields *di- α -naphtholpyromelliteic acid* (8), $C^{30}H^{20}O^8$.

The formation of these several compounds is represented by the following equations:—

(1). Phthalein-di- α -naphtholanhydride:

(2). Phthalein-di- α -naphthol:

(3). Carbonein- α -naphtholanhydride:

(4). Pyromellitein-tetra- α -naphtholanhydride:

(5). α -, β -, and γ -Pyromellitein-tetra- α -naphtholhemianhydride:

(6). Tri- α -naphtholpyromelliteic acid:

- (7). Tri-
- α
- naphtholhemianhydridepyromellitic acid:

- (8). Di-
- α
- naphtholpyromellitic acid:

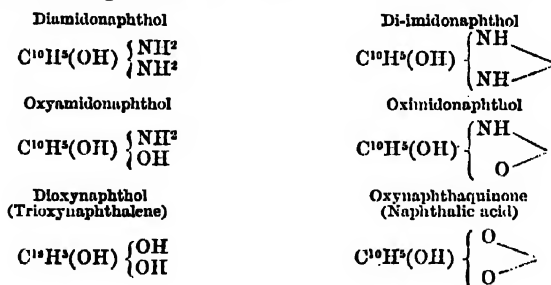

Dinitronaphthols. *Dinitro- α -naphthol*, $C^{10}H^7(NO^2)^2OH$, is formed by treating Dusart's nitroxynaphtholic acid (iv. 117) with dilute nitric acid, whence it may be inferred that Dusart's compound, to which he assigned the formula $C^{10}H^7N^2O^4$, is really mononitro- α -naphthol, $C^{10}H^7NO^3 = C^{10}H^6(NO^2)OH$. The latter melts at 151° – 152° , not at 100° , as stated by Dusart (Darmstädter u. Nathan, *Deut. Chem. Ges. Ber.* 943).

Dinitro- β -naphthol.—A solution of β -naphthol in a large quantity of alcohol is heated with dilute nitric acid, and the product, separated by water after the greater part of the alcohol has been removed by distillation, is purified by solution in dilute sodium carbonate, separation by hydrochloric acid, solution in alcohol, boiling with animal charcoal, reprecipitation by water, and finally by repeated crystallisation from chloroform.

Dinitro- β -naphthol, $C^{10}H^7(NO^2)^2OH$, thus produced, crystallises in highly lustrous light yellow needles, which appear under the microscope as truncated prisms, and melt with brown coloration at 195° . It is very sparingly soluble in water, more soluble in alcohol, very soluble in ether and in chloroform. These solutions, as well as the salts, dye deep yellow. The ammonium salt crystallises in shining red needles, which decompose partially in contact with the air. The silver salt is a scarlet flocculent precipitate; the barium salt forms yellow needles which turn red at 100° . All these salts are very slightly soluble in water (Wallach u. Wichelhaus, *ibid.* 846).

Amido- and Imido-naphthols. These compounds, which were first obtained from dinitronaphthol by Martius u. Griess (1st *Suppl.* 857), have been further studied, together with some of their derivatives, by Græbe u. Ludwig (*Ann. Ch. Pharm.* cliv. 803), who infer from their results that these bodies have a quinonic constitution as indicated by the following formulæ:—

1. *Diamidonaphthol*, $C^{10}H^{10}N^2O$.—The free base has not been prepared. The *stannochloride*, $C^{10}H^{10}N^2O \cdot 2HCl \cdot SnCl^2 + 2H^2O$, is obtained by heating 1 part of dinitronaphthol with 2 parts of tin and 7.5 parts of hydrochloric acid, and crystallises from its aqueous solution by spontaneous evaporation in large monoclinic prisms. Another *stannochloride*, having the formula $2(C^{10}H^{10}N^2O \cdot 2HCl) \cdot SnCl^2 + 4H^2O$, is converted into the former by heating with stannous chloride. The *sulphate*, $C^{10}H^{10}N^2O \cdot H^2SO^4 + H^2O$, is formed when the solution of the base in hydrochloric acid is mixed with sulphuric acid. It dissolves easily in alcohol and in hot water, less easily in cold water. By the action of the air or of ferric chloride it becomes deep red, from formation of di-imidonaphthol.

2. *Di-imidonaphthol*, $C^{10}H^8N^2O$.—This base is best prepared by precipitating the solution of its hydrochloride with ammonia. It forms small needles, insoluble in cold water, easily soluble in alcohol. Heated with alcohol or water it gives off ammonia, and is converted into oximidonaphthol; reducing agents reconvert it into diamidonaphthol. It unites with acids, and is converted, by boiling with alkalis or by heating to 120° with dilute hydrochloric or sulphuric acid, into oxynaphthaquinone. The *hydrochloride*, $C^{10}H^8N^2O$, is prepared from the stannochloride of diamidonaphthol by precipitating the tin with zinc, adding ferric chloride, washing the hydrochloride of di-imidonaphthol thereby precipitated with dilute hydrochloric acid, and recrystallising it from water.

This salt is nearly insoluble in strong hydrochloric acid, but dissolves easily in

water and in alcohol, and separates from the aqueous solution by spontaneous evaporation in monoclinic prisms, which are dark red by transmitted light, and exhibit a green metallic lustre by reflected light. The *platinochloride* has the composition $2(C^{10}H^7N^2O.HCl).PtCl^4$. The *sulphate*, $C^{10}H^7N^2O.SO^4H^2$, forms red prisms having a metallic lustre.

3. *Oximidonaphthol*, $C^{10}H^7NO^2$, is obtained by boiling a hydrochloric solution of di-imidonaphthol, made alkaline with ammonia, as long as ammonia resulting from the decomposition of the di-imidonaphthol continues to escape. It forms yellowish-red needles quite insoluble in ether, nearly insoluble in cold water, slightly soluble in hot water, easily in alcohol. By boiling hydrochloric acid, boiling alkalis, or strong sulphuric acid, it is converted into naphthalic acid (oxynaphthaquinone); by reducing agents into oxyamidonaphthol.

4. *Oxamidonaphthol*.—The *hydrochloride*, $C^{10}H^7NO^2.HCl$, is formed by treating oximidonaphthol with tin and hydrochloric acid, and crystallises from the stanniferous solution in well-defined, very soluble tables; the solution alters quickly in contact with the air.

5. *Oxynaphthaquinone* or *Naphthalic acid*, $C^{10}H^6O^4$, is formed by heating di-imidonaphthol hydrochloride to 120° , with dilute hydrochloric or sulphuric acid (see NAPHTHAQUINONE, p. 836).

6. *Dioxynaphthol* or *Trioxynaphthalene*, $C^{10}H^6O^2$, is formed by reducing oxynaphthaquinone with tin and hydrochloric acid, and may be extracted from the liquid by ether after separation of the tin. It crystallises in yellow needles, is extremely oxidable, reduces silver and mercury salts, and alkaline cupric solution.

Dinaphthols, $C^{20}H^{14}O^2 = (C^{10}H^7)^2O^2$ (Dianin, *Deut. Chem. Ges. Ber.* vi. 1252; vii. 125, 487). These compounds are produced by the action of ferric chloride on the aqueous solution of α - or β -naphthol, ferrous chloride being formed at the same time, the solution assuming a rose-colour, and the dinaphthol separating in the solid state—

α -*Dinaphthol* forms small silvery rhombic plates melting at 300° . It strikes a red colour with ferric chloride and forms a violet precipitate with nitric acid. Treated with *benzoyl chloride* it yields dibenzoyl-dinaphthol, $C^{20}H^{12}(C^7H^5O)^2O^2$, which is insoluble in water and in alcohol, dissolves with difficulty in benzene, and crystallises out in warty masses made up of small rhombs. An alcoholic solution of caustic soda decomposes it completely into benzoic acid and α -dinaphthol.

β -*Dinaphthol* crystallises from alcohol in broad four-sided, pointed prisms, melting at 218° . It gives with ferric chloride a greenish colour, which on heating becomes red and brown; nitric acid colours it dark-green. On passing its vapour, mixed with air, through hot tubes, a yellow body, probably a naphthaquinone, is formed. With *benzoyl chloride* it forms the two compounds, $C^{20}H^{12}(C^7H^5O)O^2$ and $C^{20}H^{12}(C^7H^5O)^2O^2$, the first crystallising in rhombic laminæ melting at 204° , the second in four-sided prisms which melt at 180° . Both are resolved by alcoholic potash into benzoic acid and β -dinaphthol. The formation of these two benzoic derivatives shows that the β compound from which they are derived, and therefore also the corresponding α compound, is really a dinaphthol, $C^{20}H^{14}O^2$.

The two dinaphthols are insoluble in water, sparingly soluble in benzene and chloroform, freely in alcohol and ether. They also dissolve in alkalis, forming unstable salts. They are not changed by the action of tin and hydrochloric acid, but are converted into the mononaphthols when distilled.

NAPHTHOPHTHALIC ACID, $C^{12}H^8O^4 = C^{10}H^7(CO^2H)^2$. *Naphthalene dicarboxylic acid*.—This acid, which Darmstädter & Wichelhaus obtained by boiling dicyanonaphthalene with potash (1st Suppl. 852), is likewise produced by boiling acenaphthene with chromic acid mixture. It sublimes in broad, serrated plates, melting at 286° , and is precipitated by acids from its alkaline solution in slender needles, melting at the same temperature. Its *potassium salt*, $C^{12}H^7K^2O^4 + 2H^2O$, is precipitated by alcohol in small pearly plates. The *barium salt*, $C^{12}H^6Ba^2O^4 + H^2O (2H^2O)$, according to D. and W., is a precipitate consisting of small compact shining plates. The acid, heated to 140° – 150° , is converted without melting into the anhydride, $C^{12}H^6O^3$. The calcium salt distilled with slaked lime yields naphthalene (Behr & van Dorp, *Deut. Chem. Ges. Ber.* vi. 80).

NAPHTHYL, $C^{10}H^7 = C^{10}H^7.C^0H^1$. Of this radicle in the free state two modifications are known, distinguished as *dinaphthyl* and *isodinaphthyl*. The former, discovered by F. Lossen, is produced by oxidising naphthalene with a mixture of manganese dioxide and dilute sulphuric acid (1st Suppl. 856). The latter, discovered

by Watson Smith (*Chem. Soc. J.* [2], ix, 1184), is obtained, together with hydrogen, by passing the vapour of naphthalene through an iron tube heated to bright redness:

The naphthalene collected in the receiver has a dark-brown colour, and, when re-distilled, from a retort, always leaves a minute quantity of liquid boiling at a temperature above 360° ; and by repeating the distillation a certain number of times, a quantity of this substance—which consists of impure isodinaphthyl—may be obtained sufficient for further treatment. It is purified by first distilling off the small quantity of naphthalene which it contains, and then distilling over the body itself, the temperature rapidly rising from 220° , below which the naphthalene comes over, to above 360° . A minute quantity of pitch is left in the retort. The solid, hard, yellowish substance is now crushed in a mortar with shale-spirit, and made into a thin homogeneous paste, then washed repeatedly on a filter with the spirit, drained, pressed in blotting-paper, and dried at a temperature fully sufficient to volatilise the spirit. By this washing it is freed from a small quantity of a resinous body, and from a lemon yellow substance. These wash-liquors all exhibit blue fluorescence. The dried substance is finally sublimed at as low a temperature as possible, and is then obtained as a faintly yellowish-white inodorous powder. This sublimate, by very careful and slow sublimation, may also be obtained in small, delicate plates. When possessing the faintest yellow tint, it imparts a beautiful and delicate-blue fluorescence to any liquid in which it is dissolved. When a very high temperature has been applied (a white heat), the substance obtained is always more largely contaminated with the resinous and lemon-yellow bodies, and on careful sublimation the first portions subliming are almost colourless, but the further the sublimation is carried on, the deeper is the yellow tint of the product. A small quantity of the latter portions of a sublimation-product of a sulphur-yellow colour, when warmed with concentrated sulphuric acid, yield a very fine purple solution, passing on further heating into an indigo and then to a dull green tint. This reaction is mentioned by Liebermann as characteristic of *chrysene*; probably, therefore, this yellow substance contains chrysono.

With a quantity of the pure re-sublimed substance the following results were obtained:—

No red or brown compound is formed with a benzol-solution of picric acid. The more thoroughly the substance is purified, the less is the fluorescence imparted to solvents.

Isodinaphthyl sublimes at a temperature considerably below its boiling point. Treated with two parts of potassium dichromate and sulphuric acid, it is oxidised at once with extreme energy. From the oxidation-product obtained, no colour, nor any substance bearing any resemblance to alizarin, could be obtained.

Sulphuric acid does not act on isodinaphthyl in the cold, but dissolves it when heated, forming, if the isodinaphthyl be quite pure, a very faint purplish-tinted solution; if, however, it contains a trace of the yellow body before mentioned, a violet or purple solution is formed, becoming green and then reddish-brown on further heating. The product is a sulpho-acid which forms a soluble barium salt. The sodium salt formed from it by double decomposition is very soluble in water, yielding a fluorescent solution.

Hot nitric acid oxidises isodinaphthyl with liberation of nitrous fumes, and forming in the hot liquid heavy oily drops; these on further heating dissolve in the acid, and a clear solution is obtained. On pouring this liquid into water, the nitro-compound is precipitated abundantly in a light yellow floccular form. Chlorine has no action upon it, when passed over it in a glass tube, and even on warming. When it is treated with bromine in the cold, a brominated compound is formed with very energetic action.

Chlorine passed over isodinaphthyl contained in a glass tube does not act upon it, even on application of heat; but when dry chlorine is passed through a solution of the substance in carbon sulphide, it is absorbed, with evolution of hydrochloric acid, and if, when the absorption is complete, the liquid be agitated with caustic soda solution, a gummy liquid is obtained which solidifies to a resinous mass soluble in ether and alcohol, and is precipitated from its alcoholic solution by water. The white precipitate washed and dried at 100° has the composition of tetrachlorisodinaphthyl, $C_{10}H_6Cl_4$.

Bromine acts violently on isodinaphthyl, with evolution of hydrobromic acid; and the product dissolved in carbon sulphide and purified as above exhibits the composition of heptabromisodinaphthyl, $C^{10}H^6Br^7$ (Watson Smith & Poynting, *Chem. Soc. J.* [2], xii, 855).

The chief differences between dinaphthyl and isodinaphthyl are exhibited in the following table.

Comparative behaviour of Dinaphthyl and Isodinaphthyl with Solvents, &c.

Solvents	Loosen's Dinaphthyl	Isodinaphthyl	
	Solubility, Crystalline form, &c.	Solubility	Crystalline form, &c.
Proof spirit	—	Scarcely at all soluble, even on boiling with excess	On cooling, a few plates separate out
Ether	More soluble than in alcohol	Very slightly; less than in alcohol	In plates
Absolute alcohol	Less soluble than in ether; separates in moss-like clusters	Slightly in the cold; soluble on boiling	Beautiful rhomboïdal plates, which, on drying, overlap, and present a beautiful silky appearance. They have a very faint delicate greenish colour
Methylated spirit	—	Rather more soluble	Rhomboidal plates
Wood spirit	From ether-alcohol mixture; crystallises in octahedrons	—	
Light petroleum spirit, sp. gr. = 710	—	Still more soluble than in the above	Rhomboidal plates
Light shale spirit, sp. gr. = 737	—	Rather more soluble than in petroleum spirit	
Carbon tetrachloride	—	Not quite so soluble as in benzene	Fine large fluorescent plates having when dry a silky laminated appearance
Benzol	About the same as in alcohol	Sparsely in the cold, freely in the hot fluid	
Carbon disulphide	Easily soluble	Easily soluble, even in the cold	In plates
Oil of turpentine	—	Very easily soluble	Delicate white lance-shaped crystals
Chlorine	Forms $C^{20}H^{10}Cl^4$	Forms $C^{20}H^{10}Cl^4$	
Bromine	" $C^{20}H^{10}Br^2$ and $C^{20}H^{10}Br^4$	" $C^{20}H^{10}Br^2$	
Melting point	154°	204°	
Boiling point	above 360°	above 360°	

NAPHTHYL ALCOHOLS. See NAPHTHOLS (p. 830).

NAPHTHYL CYANATE, $CONC^{10}H^7$, formerly obtained in small quantity by heating dinaphthylcarbamide with phosphoric anhydride (iv. 19), is more easily produced by similar treatment of naphthyl-urethane, $CO \{NH(C^{10}H^7)\}_2$. It is a colourless liquid, having a faint odour and boiling at 280°–270°. It reacts energetically with water, alcohols, and amines, and solidifies instantly with triethylphosphine (Hofmann, *Proc. Roy. Soc.* xix. 108).

NAPHTHYL SULPHIDES (H. E. Armstrong, *Deut. Chem. Ges. Ber.* vii. 407): α -naphthyl sulphide, $(C^{10}H^7)^2S$, is obtained on distilling a dry mixture of potassium sulphocyanate and α -naphthalene-sulphonate. It crystallises in long white needles, difficultly soluble in alcohol, but very soluble in carbon sulphide and glacial acetic acid. It melts at about 100°. The corresponding β -naphthyl sulphide appears to be formed when β -naphthalene is distilled with potassium sulphocyanate. It has a higher melting point and is less soluble than α -naphthyl sulphide.

NAPHTHYLACETAMIDE or **ACETONAPHTHYLAMINE**, $C^{10}H^7NH(C^2H^3O)$ (Rother, *Deut. Chem. Ges. Ber.* iv. 850; Tommasi, *Compt. rend.* lxxvi. 1287). This compound is produced by treating naphthylamine with acetyl chloride, acetic anhydride, or glacial acetic acid, most conveniently with the last (Tommasi); by heating naphthylamine with glacial acetic acid for several days (Rother). It crystallises in white silky needles melting at 152° and subliming at 160° (Tommasi); melts at 150° (Rother). It is only slightly soluble in boiling water, but dissolves easily in alcohol and in dilute acids (Tommasi).

Naphthylchloracetamide, $C^{10}H^7NH(C^2H^2ClO)$, prepared by the action of chloroacetyl chloride on naphthylamine, crystallises in colourless silky needles melting at 121° , soluble in alcohol and in acetic acid (Tommasi).

Bromonaphthylacetamide, $C^{10}H^6BrNH(C^2H^3O)$, formed by passing bromine through naphthylacetamide suspended in carbon sulphide, is a heavy amorphous substance melting at 94° . By boiling with strong potash-ley it is converted into monobromonaphthylamine, $C^{10}H^6BrNH_2$; and on converting the latter into the corresponding diazo-compound, and heating this diazo-compound with alcohol, a monobromonaphthalene is obtained which, from its boiling-point (277°), melting point, and the crystalline forms of its derivatives, appears to be identical with the bromonaphthalene obtained by the direct action of bromine upon naphthalene (Rother).

Dinitronaphthylacetamide, $C^{10}H^6(NO_2)_2NH(C^2H^3O)$, is precipitated as a yellow mass from a solution of naphthylacetamide in cold fuming nitric acid (Rother).

NAPHTHYLAMINE, $C^{10}H^7N = C^{10}H^7NH_2$. For the preparation of this base from nitronaphthane, Ballö (*Deut. Chem. Ges. Ber.* iii. 288, 673) recommends Réchamy's method of reduction with iron and acetic acid at a moderate heat, with this difference, however, that the product, after reduction, is to be supersaturated with soda-ley and distilled with steam, with the aid of good condensation.

For Böttger's mode of preparation with zinc and hydrochloric acid, see 1st Suppl. 861.

Naphthylamine, heated to boiling with dry ethyl oxalate, yields ethyl naphthyl-oxamate; but when heated to 90° with the same ether in presence of alcohol, it is converted into naphthylammonium naphthylloxamate. See NAPHTHYLOXAMIC ACID (p. 848).

Naphthylamine Bisulphite, $C^{10}H^7N.H^2SO_3$, is prepared by passing a stream of sulphur dioxide into water containing naphthylamine in suspension, assisting the action by a gentle heat and frequent agitation. The base then slowly dissolves, and the solution, on cooling, leaves the bisulphite in white rosettes having a nacreous lustre. This salt does not become coloured on exposure to light so readily as other salts of naphthylamine; neither does it decompose if kept in the solution saturated with sulphurous acid, but if taken out and quickly dried, it gives up its sulphurous acid and leaves pure naphthylamine. This decomposition may perhaps afford an easy method of obtaining the base pure and white.

Naphthylamine bisulphite unites with aldehydes, forming compounds analogous to those of the aldehydes with the bisulphites of aniline, phenylamine, &c. (1st Suppl. 79, 920).

Benzoyl-bisulphite of Naphthylamine, $C^{10}H^7N.H^2SO_3.C^7H^5O$, is formed on pouring benzoic aldehyde into a hot aqueous solution of naphthylamine bisulphite, and separates, on cooling, in ramified groups of small crystals which, if dried and placed in a well-closed vessel, may be kept for a long time without sensible alteration. It dissolves in alcohol, but not in ether or in water. This compound, when gently heated, gives off the whole of its sulphurous acid, leaving a resinous, very fusible compound, very soluble in ether, moderately soluble in absolute alcohol, insoluble in water. The ethereal solution, mixed with alcohol of ordinary strength, deposits the compound as a whitish-yellow crystalline powder having the composition $C^{10}H^7N.C^7H^5$. Its formation may be represented by the equation:

It does not unite with acids or with platinum chloride.

Naphthylamine bisulphite unites also with *cumic*, *cinnamic*, *salicylic*, and *anisic aldehydes*, forming crystalline compounds analogous to the benzoic compound above described.

With the aldehydes of the fatty series, on the contrary, similar compounds are not obtained. *Acetic aldehyde* acts very strongly on naphthylamine bisulphite, producing resin of aldehyde. *Butyric*, *valeric*, and *amanthyl* aldehydes form resinous garnet-red compounds, liquid at first, but afterwards solidifying to very friable crystalline masses, very soluble in ether and absolute alcohol.

The cenanthylic compound thus obtained gave by analysis 82.79 and 83.2 p.c. carbon, 9.1 and 9.8 hydrogen, agreeing approximately with the formula $C^{10}H^{12}N$, or $N\{(C^1H^1)^7\}$, which requires 85.37 C. and 8.79 N. It appeared to be contaminated with a small quantity of a sulphuretted compound. The same compound is formed with separation of water, when a solution of naphthylamine in anhydrous ether is mixed with cenanthol:

It does not possess basic properties.

Acetone does not act on naphthylamine bisulphite (G. Papasogli, *Gazzetta chimica italiana*, iii. 394).

Substitution-derivatives of Naphthylamine.

Girard a. Vogt (*Bull. Soc. Chim.* [2], xviii. 67) have obtained several secondary monamines containing naphthyl by heating a primary monamine with hydrochloride of naphthylamine to 280° – 300° in a closed vessel for 30 hours.

Phenyl-naphthylamine, $(C^6H^5)(C^{10}H^7)NH$, is thus produced from aniline:—

From the products of the reaction, the phenyl-naphthylamine is isolated by treatment with water, which leaves the base as an oily liquid which soon solidifies; by washing, pressure between bibulous paper, and crystallisation from alcohol, it is obtained in small crystals fusible at 60° , and soluble in alcohol, benzene, and ether, its solutions exhibiting dichroism; it distils unchanged at about 315° under 528 mm. pressure.

Its hydrochloride is obtained in small crystals by passing hydrochloric acid gas into a solution of the base in benzene; by ebullition of the benzene liquid it is mostly decomposed; alcohol also partly decomposes it, whilst water resolves it wholly into hydrogen chloride and the free base.

Cresyl-naphthylamine, $(C^6H^7)(C^{10}H^7)NH$, is similarly obtained by the action of toluidine on naphthylamine hydrochloride at 280° for 36 hours; it melts at 79° and distils at 290° under 528 mm. pressure, and at 236° under 15 mm. pressure. Its hydrochloride is obtained by the same means as those used for phenyl-naphthylamine, and is also decomposed by water.

A base isomeric with cresyl-naphthylamine is formed by treating naphthylamine with benzyl chloride in presence of a small quantity of zinc-dust. It has a deep brown colour, and is uncrystallisable, but may be obtained in scales like those of potassium ferriate tartrate. With fuming nitric acid it forms a yellow nitro-derivative (Froté a. Tommasi, *Compt. rend.* lxxvii. 57).

Xylynaphthylamine, $\begin{matrix} C^8H^7 \\ H \end{matrix} \} N$, has not been obtained solid, but in the form of a viscous liquid, rapidly becoming brown, and boiling at 243° – 245° (15 mm. bar.) It is no doubt a mixture of isomeric bodies, arising from the isomeric xylenes contained in the hydrocarbon boiling at 130° .

Dinaphthylamine, $\begin{matrix} C^{10}H^7 \\ H \end{matrix} \} N$, prepared by heating naphthylamine hydrochloride with naphthylamine, forms crystals, apparently quadratic, with truncated edges. It melts at 113° , and boils at about 310° – 315° (15 mm. bar.)

NAPHTHYLAMINE VIOLET. A. Kiellmayer (*Dingl. polyt. J.* cxvii. 67) prepares this colouring matter for calico-printing by boiling together 456 grams of starch, 1.1 litre of water, and 118 grams of dry naphthylamine dissolved in 1.5 litre of water and 70 grams of hydrochloric acid of sp. gr. 1.12, and adding to the liquid, after cooling, 13.5 grams of potassium chlorate dissolved in 0.3 litre of water. The printed goods are hung for three days in the oxidising room, then drawn through a soda-bath, and finally through a soap-bath, whereby their grey colour is developed into the pure violet shade; this, however, is much influenced by the temperature of the oxidation-room, and of the dry rollers, &c. Naphthylamine violet does not appear to be the final product of a chemical process, like aniline-black, but merely a transition-stage.

According to A. Scheurer (*ibid.* cxvii. 443), the dirty-gray violet with which the fabrics issue from the oxidising-room is changed by alkalis into a purer violet, partially decolorised by tin-salt, and turned gray by a boiling solution of tin-salt, and by sulphurous acid. Dilute acetic acid does not affect the colour; potassium chromate and solution of chloride of lime turn it brown. The oxidation goes on most regularly when the oxidising-chamber is kept cold and contains vapours of acetic acid. Scheurer

likewise regards the violet as only an intermediate stage of the oxidation, and attributes the beneficial action of the acetic acid to retardation of the oxidation which it effects.

Blumer-Zweifel (*ibid.* cxcvi. 66) produces naphthylamine violet directly on the fibre, by printing linen or cotton stuffs with a solution containing, in a litre of suitable thickening material, 30 grams of naphthylamine hydrochloride and 15 grams of cupric chloride solution of 15 B. For dyeing, the thickening material is omitted, and the quantity of cupric chloride reduced by a fourth. If only 15 grams of naphthylamine salt are used in the mixture, light shades are produced; 45 grams, on the other hand, produce dark shades. The printed or dyed stuffs are left for two or three days in the oxidising-chamber at a temperature of 25 C., and the colours are fixed by washing with soap-water. Alkaline baths render the colour reddish; acid baths make it bluish.

NAPHTHYLENE-DIAMINES, $C^{10}H^8N^2 = C^{10}H^8(NH^2)^2$ (A. de Aguiar, *Dent. Chem. Ges. Ber.* iii. 27). These bases, α and β , are formed by the action of phosphorus iodide on the corresponding dinitronaphthalenes. The dinitronaphthalene must be pulverised, and only a small quantity of water added; the reaction then goes on quickly, and the resulting naphthylene-diamine, which is almost insoluble in the acid liquid, is precipitated in the form of small crystals:

The di-hydriodide of β -naphthylene-diamine, $C^{10}H^8(NH^2)^2 \cdot 2HI$, is not a very stable compound. When gently heated it gives off hydriodic acid, and is converted into the mono-hydriodide. According to Costa, it crystallises in the rhombic system, exhibiting the combination $OP \cdot \infty Pn \cdot \infty P \cdot \infty P \infty$. The crystals are small prisms with rectangular base, the longer sides of which are slightly truncated; they are transparent with a faint fatty lustre and white colour inclining to straw-yellow; cleavable parallel to the faces of a rhombic prism. When well-defined and neutral they dissolve readily in water, but the solution turns red when heated and decomposes after a while. Free hydriodic acid diminishes the solubility, but increases the stability of the compound. The salt dissolves freely in alcohol, and may be obtained, by evaporation of the aqueous or alcoholic solution, in finely-developed but somewhat coloured crystals. When dry it changes colour by keeping, or under the influence of light, to yellow and red, and finally to black, but may for the most part be regenerated by treatment with hydriodic acid. The dry salt is decomposed by heat, giving off iodine and hydrogen iodide, while a sublimate and a brown oil distil over, and a carbonaceous residue is left behind. It reduces silver and platinum salts. Alkalis form with it a whitish precipitate which becomes coloured in contact with the air and melts to globules when heated. Oxalic acid produces no reaction in cold dilute solutions, but on evaporating to a certain degree of condensation, a red precipitate is obtained which becomes fiery-red on exposure to the air (this reaction is characteristic of the β base). *Sulphate of β -naphthylene-diamine* separates, when a strong solution of the preceding salt is mixed with sulphuric acid, in small white crystals, which may be purified by washing with dilute sulphuric acid, then with alcohol and ether. The salt is soluble in water, and is precipitated from its solution by the fixed alkalis, the precipitate redissolving in ammonia. It is precipitated without alteration by strong nitric, hydrochloric, and sulphuric acid. Fuming nitric acid blackens the liquid and forms a black precipitate. Potassium hypochlorite forms a blue precipitate turning red in contact with the air. Potassium nitrite forms immediately a cinnabar-coloured precipitate insoluble in hot water, soluble with yellow-red colour in alcohol or ether. The *hydrochloride of β -naphthylene-diamine*, $C^{10}H^8(NH^2)^2 \cdot 2HCl$, may be prepared by decomposing the sulphate with barium chloride, or better by precipitating the hydriodide with fuming hydrochloric acid, and purified by crystallisation, or by washing with dilute hydrochloric acid, and drying on a porous tile. It is more stable than the hydriodide; when heated in the dry state, it gives off hydrogen chloride, and yields a sublimate, with a residue of difficultly combustible charcoal. In other respects it resembles the preceding salts, excepting that potassium hypochlorite immediately produces with it a black precipitate, and slight reddening of the liquid, whereas with the sulphate this reaction takes place only after acidulation with hydrochloric acid.

α -Naphthylene-diamine hydriodide is prepared like the β -salt, but crystallises better from water than from alcohol. In most of its properties it closely resembles the β -salt. According to Costa the crystals are monoclinic, having the angle of the inclined axes equal to 80° , and exhibiting the combination $OP \cdot \infty P \cdot \infty P \infty \cdot (\infty P \infty)$. The crystals form small thin tables, appearing under the microscope as oblique prisms with rhombic or rhomboidal base, the plane angles of which differ but little from 90° . They are semi-transparent and brittle. The *sulphate*, prepared like the β -salt, crystallises in thin white needles. In its aqueous solution potassium hypochlorite produces

848 NAPHTHYLOXAMIC ACID—NAPHTHYL-URETHANE.

a fine violet coloration, changed to red by excess of the reagent, while red flocks are deposited. On addition of hydrochloric acid the liquid resumes its former colour; the precipitate which is then formed becomes darker on exposure to the air. Fuming nitric acid produces a red colour; potassium nitrite produces the same effect in dilute solutions, but in concentrated solutions still containing crystals it produces a violet colour and a violet precipitate which becomes darker on exposure to the air. The hydrochloride of α -naphthyleno-diamine crystallises in prisms and exhibits the same reactions as the sulphate, excepting that it gives an immediate violet precipitate with potassium hypochlorite and likewise with chlorine-water.

NAPHTHYLOXAMIC ACID, $\text{C}^{\text{O}}_2 \begin{Bmatrix} \text{NHC}^{\text{O}}\text{H}^{\text{O}} \\ \text{OH} \end{Bmatrix}$ (Ballò, *Deut. Chem. Ges.*

Ber. vi. 247). Ethers of this acid are produced by the action of ethyl oxalate on naphthylamine, the action being different according as it takes place between the dry substances or in presence of alcohol.

When 1 mol. of ethyl oxalate is heated to 90° with 1 mol. (or better with 2 mol.) of naphthylamine and a little 90 p.c. alcohol in a sealed tube for two or three hours, the product is naphthylammonium naphthylloxamate, formed according to the equation:

Naphthylammonium naphthylloxamate crystallises from alcohol, and better from hot water, in dry, fine, white needles, which melt at 154° , undergoing rapid decomposition. It is soluble in chloroform, carbon sulphide, and ether. Warm dilute hydrochloric acid dissolves and decomposes it, setting free naphthylloxamic acid. The aqueous solution gives with calcium chloride a precipitate of calcium naphthylloxamate.

When, on the other hand, naphthylamine is heated to boiling for some time with excess of dry ethyl oxalate, and the product, after cooling, is exhausted with boiling alcohol, the solution thus formed deposits crystals of ethyl naphthylloxamate, whilst the undissolved residue consists of a white pulverulent substance nearly insoluble in ordinary solvents, melting at 231° , and subliming at a somewhat higher temperature in delicate, white, often iridescent, crystals. The reaction in this case is represented by the equation:

Ethyl naphthylloxamate crystallises from alcohol in needles. It melts at 106° . It appears to be insoluble in water, but dissolves easily in chloroform and carbon sulphide, sparingly in ether.

Free naphthylloxamic acid, $\text{C}^{\text{O}}_2 \begin{Bmatrix} \text{NHC}^{\text{O}}\text{H}^{\text{O}} \\ \text{OH} \end{Bmatrix}$, is obtained by dissolving the foregoing naphthylammonium salt in hot weak hydrochloric acid, from which solution it crystallises in tufts of fine white needles. It dissolves easily in alcohol, less freely in ether, and with difficulty in water. It melts at 180° , undergoing decomposition. Its salts decompose when heated, evolving vapours which smell strongly of naphthylamine, and leaving a residue of carbon. The potassium salt is obtained by dissolving the acid in hot solution of potassium hydrate, not too strong. It is deposited, on cooling, in beautiful anhydrous crystals. The barium salt, obtained by saponifying the ethyl-compound with baryta-water, is a white crystalline powder, insoluble in water. The calcium salt is obtained by adding calcium chloride to a solution of the naphthylammonium salt.

When alcoholic solutions of 1 mol. of methyl oxalate and 2 mol. of naphthylamine are mixed at ordinary temperatures, a mass of crystals is formed consisting, not of a derivative of oxamic acid, but of naphthylamine oxalate. The crystals when heated give off carbon oxide and dioxide, and naphthylamine, whilst Zinin's oxanaphthalide and formamide are produced. The reaction between methyl oxalate and naphthylamine is represented by the equation:

NAPHTHYL-PHENYLAMINE. See PHENYL-NAPHTHYLAMINE (p. 846).

NAPHTHYL-PHENYL-GUANIDINE. See GUANIDINE (p. 583).

NAPHTHYL-PHENYL KETONE. See PHENYL KETONES.

NAPHTHYL-PURPURIC ACID. See PURPURIC ACID.

NAPHTHYL-URETHANE. See CARBAMATES (p. 263).

NARCEINE. On the detection of this alkaloid in chemo-legal investigations, see F. Salomon (*Zeitschr. anal. Chem.* x. 454; *Chem. Soc. J.* [2], x. 331).

NARCOTINE. See OPIUM ALKALOIDS.

NATALOIN. The aloin of Natal aloes (p. 53).

NEPHERITE. Recent analyses of this mineral from various localities lead to the conclusion that all nephrites consist essentially of a calcium-magnesium silicate (granatitic or tremolite), the variations in the analytical results being due to the presence of small quantities of other minerals (Fellenberg, *Jahrbuch. f. Mineralogie*, 1871, 173; Konngott, *ibid.* 293; *Chem. Soc. J.* [2], ix. 324, 673).

NICKEL. *Atomic Weight.*—R. H. Leo (*Sill. Am. J.* [3], ii. 44) has determined the atomic weight of this metal by the analysis of its crystalline double cyanides with strychnine and brucine. These compounds, prepared in the same way as the corresponding cobalt salts (p. 362), have the formulae $\text{Ni}^{2+}\text{C}_2\text{N}_2^{2-}(\text{C}^{2+}\text{H}^{2+}\text{N}^{2+}\text{O}^{2-})\text{H}^{+} + 10\text{H}_2\text{O}$ and $\text{Ni}^{2+}\text{C}_2\text{N}_2^{2-}(\text{C}^{2+}\text{H}^{2+}\text{N}^{2+}\text{O}^{2-})\text{H}^{+} + 8\text{H}_2\text{O}$. Six analyses of the brucine salt gave, for the atomic weight of nickel, numbers between 57.79 and 58.20; mean 57.98; and six analyses of the strychnine salt gave 57.72–58.21; mean 58.04. The mean of the whole is 58.01, or very nearly 58, which is considerably below the number determined by Russell (*1st Suppl.* 865), viz., 58.70.

Occurrence.—Nickel-linnæite, or Siegenite (iv. 44), containing 30 p.c. nickel, has been found in the mine of La Motte in Missouri, already known for its richness in copper, lead, and iron ores.

Reaction of Nickel and its Oxides with the Oxides of Carbon.—Nickel monoxide heated in carbon monoxide is reduced, with separation of carbon, to a compound whose proportion of oxygen agrees with the formula Ni^2O . In this respect nickel acts like iron (p. 259). Nickel sesquioxide is reduced to metallic nickel, with separation of a large quantity of carbon. Metallic nickel, heated in carbon monoxide, separates only a small quantity of carbon, and remains for the most part unaltered. Spongy metallic nickel, heated for 40 minutes to low redness in carbon dioxide, gave off 40 a.c. gas, 90 p.c. of which consisted of the monoxide. In the gases evolved by the decomposition of oxalic acid this kind of nickel remained unaltered (L. Bell, *Chem. News*, xliii. 258).

Reaction with Ammonium Sulphide.—Nickel immersed in yellow ammonium sulphide combines with the sulphur and colours the alkaline sulphide, eventually turning it deep black. Cobalt, on the other hand, is but very slightly acted on, even after several months' immersion (E. Priwoznik, *Ann. Ch. Pharm.* clxiv. 46).

Fatination and Separation.—On the estimation of nickel by electrolytic precipitation, see Merrick (*Chem. News*, xxiv. 100; *Chem. Soc. J.* [2], ix. 1091).

The several methods proposed for the separation of nickel from zinc have been examined by Klayo a. Deus (*Zeitschr. anal. Chem.* 1871, 190; *Chem. Soc. J.* [2], ix. 955). They give the preference to the method of Smith a. Brunner (*Dingl. pol. J.* cl. 369), which consists in passing sulphuretted hydrogen through a very dilute solution of the two metals in hydrochloric or nitric acid (1 gram of the oxides to at least 500 grains of liquid), nearly saturated with sodium carbonate; and when a large portion of the zinc is precipitated, adding a few drops of a very dilute solution of sodium acetate, which precipitates the whole of the zinc sulphide; filtering after 10–12 hours; and finally precipitating the nickel with potash after expelling the sulphuretted hydrogen. Klayo a. Deus observe that the saturation of the free acid in the solution of the two metals must be very carefully performed, so that only a trace of free acid may remain, as otherwise the precipitation of the zinc will not be complete; care must also be taken to add only a very small quantity of sodium acetate, as the least excess of this salt gives rise to precipitation of the nickel on subsequently passing sulphuretted hydrogen through the liquid.

On the distinction of nickel from manganese, zinc and cobalt by means of sodium sulphocyanate and potassium ferrocyanide, see COBALT, p. 362.

Electrolytic Deposition of Nickel.—To precipitate nickel in dense layers capable of receiving a good polish, Isaak Adams (*Compt. rend.* lxx. 123, 137) uses a bath containing only sulphate or chloride of nickel and ammonium, and free from every trace of fixed alkalis, as the presence of these latter gives rise to the formation of nickel peroxide. According to E. and Ch. Becquerel, on the other hand (*ibid.* 124, 137, 181), the formation of peroxide may be prevented by continual addition of ammonia, to neutralise the acid as fast as it is set free by deposition of the nickel, in which case the double sulphate of nickel and potassium will also give a dense metallic precipitate. E. Gaiffe, on the contrary (*ibid.* 181), defends Adams's view, observing that, to keep the bath in a proper degree of concentration by means of an anode of nickel, it is

necessary that only ammonium double salts be present. The use of metallic nickel as anode is also recommended by Jacobi (*ibid.* 1886) and Remington (*Dingl. polyt. J.* exev. 374).

The following method for the electrolytic deposition of nickel on wrought iron, cast iron, steel, copper, brass, zinc, and lead is given by F. Stolba (*Dingl. pol. J.* ccl. 145). A saturated solution of zinc chloride is mixed in any convenient vessel, best in a copper kettle, with about twice its volume of water; the solution is heated to boiling, and any turbidity that may arise is removed by addition of hydrochloric acid. The objects to be coated with nickel, after being carefully cleansed, are immersed in the zinc solution, and on adding to the boiling solution a little pulverised zinc, they become coated with a thin layer of zinc, to which the nickel adheres well. Nickel sulphate or potassium-nickel sulphate in the solid state or in solution is then added to the boiling liquid till it exhibits a green colour, a few cuttings of zinc are added, and the boiling is continued. If care be taken that the liquid remains clear, a closely adhering yellow deposit of nickel is obtained, shining or dull according as the metal surface on which it is deposited is polished or unpolished.

Cobalt may be precipitated upon metals in the same manner, but the deposit is not so beautiful as that of nickel, and is more easily attacked by the air.

An apparatus for coating the inside of metal tubes with nickel is described by Towle (*Engineering*, May 1871, p. 369).

Alloys. The following alloys of nickel have been analysed by A. Rüssler (*Chem. News*, xxi. 218).

	1	2	3	4	5	6
Copper . .	88.00	65.0	43.8	40.4	55.0	50.0
Nickel . .	8.75	16.8	15.6	31.6	20.0	25.0
Zinc . .	—	13.0	40.6	25.4	25.0	25.0
Iron . .	1.75	3.4	—	2.6	—	—

No. 1 is so-called *white copper*, which has been prepared in Suhl for about 100 years. No. 2 is an alloy from Paris distinguished by its capacity for polishing and gilding. Nos. 3 and 4 are Chinese *packfongs*. No. 5 is used for knife-handles, and 6 for forks. In many countries alloys containing nickel are used for small coins. Thus the Swiss pieces of 20, 10, and 5 centimes contain nickel and zinc in the proportion of 1 : 1.25, together with copper and silver. In the United States small coins are used containing 88 p.c. copper to 12 p.c. nickel.

Small crystals lining the cavities of a mass which had collected on the hearth of a nickel-smelting furnace, used for the roasting of magnetic pyrites containing 2 p.c. nickel and cobalt, were found by J. Wharton (*Sill. Am. J.* [2] xlix. 365) to have the composition A; the granular ground-mass had the composition B.

	Cu	Ni and Co	Fe	S
A.	1.85	25.22	64.10	8.00
B.	1.74	28.20	62.50	7.60

Some of the crystals were cubes, others were octohedrons grouped in spikes or dendrites.

Oxides and Hydrates. According to H. Teichmann (*Ann. Ch. Pharm.* clvi. 77) the nickel hydrate precipitated by caustic soda from the chloride or sulphate, obstinately retains small portions of acid; to obtain the hydrate quite pure it must be precipitated from the nitrate with caustic soda quite free from carbonate, and washed first with cold water till all alkaline reaction has disappeared, then with ammoniacal water, and finally with boiling water to remove any fixed alkali still adhering to it.

According to W. Wernicke (*Pogg. Ann.* cxli. 109) nickel peroxide precipitated by electrolysis from a neutral or alkaline solution, is a hydrate having the composition, $\text{Ni}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$, and specific gravity = 2.744.

On the *Chromates of Nickel*, see CHROMIUM (p. 335).

Sulphides (K. Liebe, *Jahrbuch f. Mineralogie*, 1871, 840).—Two sulphides of nickel have lately been obtained from a mine in the Westerwald, viz. millerite, or capillary pyrites, NiS (iv. 42), and beyrichite, a mineral not previously known.

Beyrichite forms radiate groups of macle crystals, made up of prisms about 70 mm. long and 8 mm. thick, some of which have a helicoidal curvature. The prismatic groups have mostly a single end-face, inclined at 81° to the vertical axis. A second but somewhat rarely occurring end-face, forms with the first a dome-like combination, with an angle of 144° corresponding with the angle of the terminal edges of millerite. Cleavage moderately distinct, parallel to the first-mentioned end-face.

The mineral belongs to the family of the glances rather than to that of the pyrites. It is very tough, but moderately impressionable to the point of a knife. Hardness

about 3.2 to 3.3. Sp. gr. 4.7. Colour, red-grey, with faint metallic lustre, stronger on the cleavage-faces. When heated in a tube, it decrepitates, and at a dull red heat, gives off sulphur, without fusion, and is thereby converted into a pyrites, having a dark pinchbeck-brown tarnish on the surface, spesis-yellow to brass-yellow internally, harder and more brittle than the original mineral. On charcoal, beyrichite melts easily and quietly, with evolution of sulphurous acid, to a strongly magnetic bead, having a brass-yellow colour internally. It gives the nickel reaction with borax and phosphorus salt, and dissolves easily in hydrochloric acid, especially on addition of nitric acid, forming an emerald-green solution. Pure specimens yield by analysis 42.86 p.c. sulphur, 2.70 iron, and 54.23 nickel. If the iron be supposed to replace an equivalent quantity of nickel, these numbers lead to the formula Ni^{25}S^7 or $3\text{NiS}.2\text{NiS}^2$ (calc. 43.21 S, and 56.79 Ni). The presence of the iron may, however, be due to the admixture of iron pyrites, and in that case the composition of beyrichite may be represented by the formula $2\text{NiS}.2\text{NiS}^2$.

The crystals of beyrichite are coated by millerite in extremely thin yellow laminae, or more rarely in dendritic or thin crystalline forms, often penetrating them in the direction of the cleavage-planes, in the form of sharply separated lamellae, sometimes to the complete displacement of the beyrichite. The millerite has a sp. gr. of 5.7 to 5.9, hardness between 3.6 and 3.8, and contains 35.27 p.c. S, 1.16 Fe, and 63.41 Ni.

Beyrichite, as appears from the facility with which it gives off sulphur when heated, is very easily converted into millerite, a circumstance which may perhaps account for the great variations in the statements respecting the specific gravity and other properties of the latter (i. 42). These diversities may be due either to the presence of beyrichite enclosed in the capillary pyrites, or to the different conditions under which the transformation of beyrichite into millerite takes place. Beyrichite is, in fact, converted into millerite by taking up nickel from the vein-water, and the more compact and less porous the structure of the beyrichite, the denser and heavier will be the millerite formed from it.

Nickel-gyauite or *Genthite*.—This mineral was originally found as a yellow-green incrustation on chromo-iron ore at Texas, Lancaster Co., Pennsylvania, and was examined by Genth (*Kenngott's Uebersicht*, 1852, 45), who found it to have a sp. gr. of 2.49, and to contain—

SiO^2	NiO	MgO	FeO	CaO	H^2O
35.36	30.64	14.60	0.24	0.26	19.09 = 100.19

agreeing approximately with the formula—

A different composition has been deduced by P. F. Dunnington (*Chem. News*, xxv. 290) from the analysis of a specimen from the neighbourhood of Webster (sp. gr. 2.48), which gave—

SiO^2	NiO	MgO	FeO	H^2O
49.89	22.35	16.60	0.06	12.36 = 101.26

numbers which are most nearly represented by the formula—

NICOTINE, $\text{C}^4\text{H}^7\text{N}$. *Occurrence in Tobacco*.—According to Vohl a. Eulenberg (*Arch. Pharm.* [2], cxlvii. 130; *Chem. Soc. J.* [2], ix. 1075), snuff contains not more than 0.0392 to 0.062 p.c. nicotine. The strongest tobacco for chewing was found to contain only a trace, and other specimens none at all, so that nothing like nicotine-poisoning can result from the use of such tobacco. Vohl a. Eulenberg also confirm the observations of Zeise, made in 1843, that nicotine is not present in the smoke of tobacco (see *Tobacco*).

Double salts of nicotine with zinc chloride and cadmium chloride have been prepared by H. Vohl (*J. pr. Chem.* [2], ii. 331). The *zinc salt*, $(\text{C}^4\text{H}^7\text{N.HCl})^2.\text{ZnCl}^2 + 4\text{H}^2\text{O}$, is obtained by mixing a neutral alcoholic solution of zinc chloride with an alcoholic solution of nicotine, and dissolving the precipitate in hydrochloric acid, avoiding an excess. The salt is then deposited in shining tables or prisms, and may be advantageously recrystallised from boiling alcohol of 80 p.c. It is permanent in the air, easily soluble in water, almost insoluble in absolute alcohol and in ether, smells faintly of nicotine, and has a faint acid reaction. When left over sulphuric acid, or heated to 100° , it gives off all its water of crystallisation; in the latter case also part of its nicotine. The *cadmium salt*, $(\text{C}^4\text{H}^7\text{N.HCl})^2.\text{CdCl}^2 + 2\text{H}^2\text{O}$, prepared like the zinc-salt, crystallises in beautiful concentric groups of needles and prisms. It is easily soluble in water and in alcohol of 80 p.c., insoluble in ether; gradually turns brown when exposed to the air.

NIGELLA SEEDS or BLACK CUMMIN. The seeds of *Nigella arvensis*, a ranunculaceous plant growing on the Mediterranean coasts, and in Egypt, Trans-Caucasia, and India, were found by Reinsch, in 1841, to yield 35.8 p.c. of fat oil, 0.8 p.c. of volatile oil, and only 0.6 p.c. of ash. He gave the name of *Nigellin* to a bitter extract resembling turpentine, yet soluble in water as well as in alcohol, though not in ether.

By submitting 25 lbs. of fresh seed to distillation, Flückiger (*Pharm. J. Trans.* [2], ii. 161) has obtained a nearly colourless essential oil in even smaller quantity than Reinsch. It has a slight odour, somewhat resembling that of parsley oil, with a magnificent bluish fluorescence, as already remarked by Reinsch. In a column 50 mm. long this oil deviates the ray of polarised light 9.8° to the left. Its specific gravity is 0.8909. The chief part of it, when distilled with chloride of calcium in a current of dry carbonic acid, comes over at 256° . It contains: carbon 83.3, and hydrogen 11.8 p.c., corresponding with the formula $2C^{10}H^{15}.H^{2}O$.

The residual portion, which was almost entirely devoid of rotatory power, yielded carbon 87.89, and hydrogen 11.72 p.c., after having been rectified by means of sodium. This part of the oil consequently belongs to the terpenes $C^{10}H^{16}$.

The fat oil, extracted by means of boiling ether from seed grown in Germany, previously finely powdered (necessarily including some essential oil which imparted to the other its fluorescence) amounted to 25.6 p.c. It is a fluid fat which does not congeal at 15° ; it was found to consist chiefly of olein, besides which it yielded a considerable amount of a solid fatty acid, the crystals of which, after reiterated purification, melted at 55° . The melting point did not rise by recrystallisation, the acid being probably a mixture of palmitic and myristic acids.

Nigella seeds, powdered and dried over sulphuric acid, yielded 3.3195 p.c. of nitrogen, answering to about $21\frac{1}{2}$ p.c. of albuminous matter.

It is stated in the *Pharmacopœia of India* that *Nigella* seeds are carminative, and they were formerly so regarded in Europe. In the East generally they are used as a condiment to food, and in Greece, Turkey, and Egypt they are frequently strewed over the surface of bread and cakes in the same manner as anise or sesame. The fixed oil of the seeds is also expressed for use.

NIGHTSHADE. On the variations in the quantity of atropine in the leaves and root of the Deadly Nightshade in different seasons, see *ATROPA* (p. 117).

NIIN. This name is given to the fatty product of an insect found in Yucatan. It is a yellowish-brown fatty mass, which has a neutral reaction, absorbs oxygen from the air, melts at 48.9° , and resolidifies between 26.7° and 24.9° ; dissolves easily in ether, benzene, chloroform, and oil of turpentine, but is insoluble in alcohol; saponifies with difficulty, yielding a pungent-smelling acid called *niic acid*, and a volatile oil, together with palmitic and stearic acids. Ammonia colours it red. Its solution in turpentine-oil is converted, by exposure to the air, into a resinous syrup (A. Schott, *Chem. News*, xxii. 110).

NIOBUM. Elaborate investigations of the composition of natural niobates and tantalates have been published by Rammelsberg (see *TANTALATES*).

For R. Hermann's investigations on the compounds of niobium and the supposed element *Umenium*, and the method of separating the two, see *J. pr. Chem.* [2], iii. 373, iv. 178; *Bull. Soc. Chim.* [2], xvi. 256; *Jahresb. f. Chem.* 1871, 287–292.

NITROCARBOL. Syn. with NITROMETHANE.

NITRO-COMPOUNDS OF THE FATTY SERIES. See NITROPARAFFINS under PARAFFIN.

NITROGEN. On the quantivalence of this element, see Sestini (*Cimento*, 1871–72, p. 274; *Chem. Soc. J.* [2], x. 962).

On the constitution of the Pentatomic Compounds of Nitrogen, see Blomstrand (*J. pr. Chem.* [2], iii. 186).

Preparation.—Pure nitrogen may be obtained from atmospheric air by introducing into a flask of 10 to 14 litres capacity about 200 grams of copper-turnings free from other metals, and partly covering them with aqueous ammonia, the flask being then closed by a cork fitted with a safety-tube and a gas delivery-tube stopped at the end with a caoutchouc-cap. If the flask be shaken from time to time, the whole of the oxygen, even that which may enter by the safety-tube in consequence of changes of atmospheric pressure, will be completely absorbed in a day or two. The nitrogen gas then be transferred to another vessel by pouring in water previously freed from oxygen by means of copper and ammonia, and washed with strong sulphuric acid (Berthelot *Bull. Soc. Chim.* [2], xiii. 314).

NITROGEN OXIDES. Monoxide, N_2O . T. Willis (*Chem. Soc. J.* [2], xi. 21) has succeeded in solidifying this compound by means of the cold arising from it.

own evaporation when in the liquid state, the evaporation being aided by a strong current of air. A very fine steel tube is directed into the axis of a thin brass cone, having a small opening, about the eighth of an inch at its apex. On causing a stream of the liquid to issue from the jet, it is retained in the cone for a moment, and then forcibly blown out at the apex, together with a strong stream of air. The solid is in this way formed in some quantity, and may be collected in a dish lined with filter-paper, or other suitable vessel.

The appearance of the solid is more compact than that of the well-known carbonic snow, probably because larger particles of the liquid are frozen, this freezing taking place with carbonic acid immediately the jet of liquid leaves the tube, and while it is yet in the state of fine spray, but in the case of nitrogen monoxide, only after it has to some extent been collected into larger drops. Unlike solid carbonic acid, nitrogen monoxide will melt and boil, if gently warmed before assuming the gaseous condition. Hence, if touched with the fingers, or placed in contact with the skin, it melts, producing a painful blister. The temperature of its freezing or melting point is -120° F., or -99° C., as observed with an alcohol thermometer. The boiling point, usually said to be -88° C., seems to be really -109° F. or -92° C. The proximity of the boiling and freezing points renders it possible to freeze the liquid by simply blowing a stream of air through it.

The specific gravity of liquid nitrogen monoxide is about 0.9004; it is not miscible with water.

Salts of Nitrogen Monoxide, NOM or $N^{\circ}O.M^{\circ}O$. *Hyponitrites* (Divers, *Proc. Roy. Soc.* xix, 425).—When a solution of nitrate of sodium or other alkali-metal is mixed with a quantity of sodium-amalgam, more than sufficient to reduce it to nitrite, red vapours are produced with effervescence. If the liquid be then cooled and more of the amalgam added very gradually, the evolution of red vapours recommences briskly after 2 atoms of sodium have been added, and ceases after the addition of 4 atoms of sodium. The liquid then contains, though in comparatively small quantity, a hyponitrite of sodium. The corresponding *silver salt*, $NOAg$ or $Ag^{\circ}O.N^{\circ}O$, is prepared by neutralising with acetic acid, precipitating with silver nitrate, washing the yellow precipitate, and drying at 100° . If the precipitate should be black, as sometimes arises from the presence of a body formed from the sodium, rock-oil, and silver acetate, it may be purified by dissolving it, after washing, in very weak nitric acid, filtering carefully, adding ammonia to alkaline reaction, and then adding acetic acid.

The precipitate is stable at temperatures a little above 100° and nearly as difficult of solution in water as silver chloride. It is not affected by light, is insoluble in acetic acid, but soluble in ammonia and in dilute sulphuric and nitric acids, and may be separated unaltered from these solutions. Strong nitric acid oxidises it immediately with evolution of red vapours; moderately concentrated acids decompose it, with formation of nitrogen, nitrous acid, and nitric acid. It is also decomposed by soluble chlorides and by hydrogen sulphide.

The original solution of the sodium hyponitrite, mixed with acetic acid till silver nitrate no longer forms with it a brown precipitate, gives insoluble precipitates with most metals. With potassium iodide it gives no sensible reaction, but a solution containing free iodine is immediately decolorised by it, both in neutral and in acid solution. Heated with acetic acid it gives off nitrogen monoxide:

Trioxide or Nitrous Anhydride, $N^{\circ}O^{\circ}$. This oxide is formed by the direct combination of nitrogen dioxide and oxygen in the proportion by volume of 4 : 1 ($= N^{\circ}O^{\circ} : O$), also by the combination of the dioxide and tetroxide when the two gases in equal volumes ($NO : NO^{\circ}$) are passed through a red-hot tube. The latter is indeed a very convenient method of preparing the pure trioxide, which, as thus obtained, is a liquid having at ordinary temperatures a dark blue colour, changing at -10° to a splendid indigo-blue; it does not solidify at -30° (Hasenbach, *J. pr. Chem.* [2], iv, 1).

Nitrogen trioxide may also be prepared by decomposing the so-called lead-chamber crystals with water. To prepare a concentrated solution of these crystals, dry sulphurous anhydride is passed into well-cooled fuming nitric acid, till the liquid becomes oily and evolves much gas on the addition of water. This solution is placed in a flask provided with a double-bored cork, dropping funnel, &c., and the current of gas is regulated by the quantity of water added (H. Streiff, *Deut. Chem. Ges. Ber.* v, 285).

Reactions.—1. The reaction of nitrous anhydride with water varies according to the proportion in which the two are mixed. With a relatively small quantity of water, nitrous anhydride, or the compound $2SO^{\circ}.N^{\circ}O^{\circ}.H^{\circ}O$, gives nitric acid and absolutely pure nitrogen dioxide. In a large excess of cold water, on the other hand, nitrous

anhydride dissolves without decomposition. The solution thus formed may be kept unaltered for several days, and when boiled gives off, though not immediately, tri- and dioxide of nitrogen. 2. When indifferent pulverulent bodies, such as sand, gypsum, and especially charcoal, are introduced into the solution of nitrous acid, it is immediately decomposed into nitric acid and nitrogen dioxide. Nitrous acid is a strong reducing agent, and acts in this manner on auric chlorido and potassium permanganate. 3. *Sulphurous acid* forms with nitrous acid at ordinary temperatures several nitrosulphuric acids; when heated it yields the products of decomposition of these acids—viz., nitrogen dioxide, ammoniac, and even nitrogen monoxide. The action of sulphurous acid on the compound of nitrous acid and sulphuric acid gives rise to the evolution of a large quantity of nitrogen dioxide. When the mixed solution of sulphurous and nitrous acid is warmed, nitrogen monoxide is evolved, wherein, according to Frémy, may perhaps be found the cause of the great loss of nitric acid which takes place in the manufacture of sulphuric acid; in fact, nitric acid when heated with sulphurous acid likewise gives off nitrogen monoxide. By many reducing agents, nitrous acid, nitric acid, and their salts are reduced, with formation of ammoniac and a small quantity of hydroxylamine, NH_2O (Frémy, *Compt. rend.* lxx. 61).

Detection and Estimation of Nitrous Acid.—The following modes of detection are given by Chataud (*Chem. News*, xxiv. 225). 1. The liquid to be tested for nitrous acid is mixed with *potassium ferrocyanide* and *acetic acid* and boiled, then left to cool and treated with ammonium sulphide; if nitrous acid is present the liquid turns blue. 2. The liquid to be tested is evaporated nearly to dryness and the residue triturated with two drops of solution of *aniline sulphate*, whereupon, if nitrous acid is present, a distinct odour of phenol is emitted. This reaction is regarded by Chataud as the most delicate of all tests for nitrous acid; moreover it affords a certain distinction between nitrous and nitric acid, which latter gives with aniline only a yellow coloration, but no odour of phenol.

3. For the detection of nitrous acid in spring, rain, and river water, P. Griess (*Ann. Chim. Phys.* cliv. 333) uses a solution of *diamidobenzoic sulphate* (iv. 294), which, with a large quantity of nitrous acid, produces a brown-red amorphous precipitate; with a small quantity, a more or less strong yellow coloration. This reaction is capable of indicating the presence of 1 pt. nitrous acid in 5,000,000 parts of water, i.e. of $\frac{1}{5}$ milligram in a litre. For quantitative estimation an aqueous solution of nitrous acid of known strength is added to a solution of diamidobenzoic acid till a shade of colour is produced identical with that which is developed by the same solution in the liquid under examination. For this estimation the following liquids are required: (1). A solution of diamidobenzoic sulphate saturated in the cold; if coloured it must, before use, be treated with animal charcoal. (2). A normal solution of silver nitrite prepared by dissolving 0.328 gram of the salt in a litre of water; each cubic centimeter of this solution is equivalent to $\frac{1}{10}$ milligram nitrous acid. (3). Colourless sulphuric acid free from nitric acid. (4). Perfectly colourless distilled water.

The water to be examined must, if coloured, be decolorised by addition of a few drops of aluminium sulphate solution, and subsequent addition of sodium carbonate; the precipitate thereby formed does not carry nitrous acid down with it. After the water thus decolorised has been passed through a filter previously freed from adhering nitrous acid by washing with water containing sulphuric acid, a tall glass cylinder about an inch in diameter is filled with it to a mark of 100 c.c., about $\frac{1}{2}$ c.c. solution of diamidobenzoic acid solution is added, together with a few drops of sulphuric acid, and the liquid is left at rest for about a quarter of an hour, by which time the colour is fully developed. A second cylinder of the same diameter is then filled to the mark of 100 c.c. with distilled water, diamidobenzoic and sulphuric acid added as before, and then a quantity of the normal solution of silver nitrite sufficient to produce the same depth of colour as in the first cylinder. The colours of the two liquids must be compared together after a quarter of an hour, best near a window. The quantity of the normal solution of nitrous acid used gives directly the amount of nitrous acid in the water under examination.

Respecting the estimation of nitrous acid in nitrous sulphuric acid, see G. E. Davies (*Chem. News*, xxiv. 257, xxv. 25; *Chem. Soc. J.* [2], x. 173), and W. Crowder (*Chem. News*, xxiv. 237 and 240; *Chem. Soc. J.* [2], x. 174).

Nitrites. *Ammonium nitrite*.—On the simultaneous formation of ammonium nitrite, hydrogen dioxide, and ozone, in the combustion of hydrogen in the air, see HYDROGEN (p. 660).

Cobalt nitrites (S. P. Sadtler, *Sill. Am. J.* [2], xlix. 189).—Erdmann found that when cobalt salts are precipitated by potassium nitrite, various products are formed accordingly as the cobalt solution is acid or neutral, and that the 'neutral salt', $3\text{CoK}^+(\text{NO}_2)^+ + \text{H}_2\text{O}$, is likewise formed in an atmosphere of carbon dioxide (*J. pr. Chem.* xlvii. 385). The salt examined by Sadtler was prepared by mixing a solution

of cobalt chloride, strongly acidulated with acetic acid, with a concentrated solution of potassium nitrite. This salt, after washing with potassium acetate and then with alcohol, has the composition of tripotassio-cobaltic nitrite, $\text{Co}^2\text{O}^3 \cdot 3\text{N}^2\text{O}^3 + 3(\text{K}^2\text{O} \cdot \text{N}^2\text{O}^3)$, or $\text{Co}^2(\text{NO}^2)^3 \cdot 6\text{KNO}^2$. According to the concentration of the solutions employed, it contains 4, 3, 2, 1 mol. H^2O , or is anhydrous, the colour varying at the same time from light yellow to dark greenish-yellow. Hence it appears that mixtures of salts containing different amounts of crystallisation-water are very apt to form, so that it is difficult to give a definite process for the preparation of either of them.

When a solution of cobalt chloride, kept constantly acid with acetic acid, is mixed with sodium nitrite, brown disodiocobaltic nitrite, $\text{Co}^2(\text{NO}^2)^3 \cdot 4\text{NaNO}^2 + \text{H}^2\text{O}$, is precipitated, and on further addition of sodium nitrite, yellow trisodiocobaltic nitrite, $\text{Co}^2(\text{NO}^2)^3 \cdot 6\text{NaNO}^2 + \text{H}^2\text{O}$. The solution of the latter salt yields, on addition of luteo-cobaltic chloride, a crystalline yellow salt, in which the sodium is replaced by luteo-cobalt, giving the formula $\text{Co}^2(\text{NO}^2)^3 + \text{Co}^2 \cdot 12\text{NH}^3(\text{NO}^2)^3 + \text{H}^2\text{O}$. In like manner are obtained the corresponding roseo-cobaltic salt, $\text{Co}^2(\text{NO}^2)^3 + \text{Co}^2 \cdot 10(\text{NH}^3 \cdot \text{NO}^2)^3 + \text{H}^2\text{O}$, and a xantho-cobaltic salt not yet analysed. The ammonium salts corresponding with the sodium salts, viz. diammonio-cobaltic nitrite, $\text{Co}^2(\text{NO}^2)^3 \cdot 4(\text{NH}^3 \cdot \text{NO}^2) + 2\text{H}^2\text{O}$, and triammonio-cobaltic nitrite, $\text{Co}^2(\text{NO}^2)^3 \cdot 6(\text{NH}^3 \cdot \text{NO}^2) + 2\text{H}^2\text{O}$, have also been prepared; but the conditions of their formation have not been determined further than that the formation of the triammonium salt is favoured by the use of concentrated solutions.

The addition of potassium nitrite to a warm dilute neutral solution of cobaltous chloride produces first a black or green precipitate of potassio-dicobaltous nitrite, $2\text{Co}(\text{NO}^2)^2 \cdot 2\text{KNO}^2 + \text{H}^2\text{O}$, and afterwards a yellow slightly crystalline or amorphous precipitate of potassio-monocobaltous nitrite, $\text{Co}(\text{NO}^2)^2 \cdot 2\text{KNO}^2 + \text{H}^2\text{O}$.

Respecting the Nitrites of Platinum-bases, see PLATINUM-BASES, AMMONIACAL.

Silver nitrite, AgNO^2 , heated in an open crucible or a watch-glass, is decomposed according to the equation—

in a well-covered crucible, on the contrary, the decomposition takes place in the manner represented by the equation—

And, lastly, when the salt is heated for a long time to 98° – 140° in dry air, or in aqueous vapour, it is decomposed almost completely, according to the equation—

(Divers, *Chem. Soc. J.* [2], ix. 85).

Tetroxide, NO^2 or N^2O^4 . This oxide is produced by the action of nitryl chloride on silver nitrite:

This reaction tends to the conclusion that the rational formula of the tetroxide is $\text{NO}^2 \} \text{O}$ (A. Exner, *Chem. Centr.* 1872, 273).

Nitrogen tetroxide is also formed by the direct combination of oxygen with the trioxide, which is easily effected by passing a stream of oxygen or air into the mixture of nitrogen trioxide and tetroxide evolved by the action of fuming nitric acid on arsenious acid. The liquid tetroxide thus obtained is pure enough for most purposes after one rectification (Hasenbach, *J. pr. Chem.* [2]. iv. 1).

Reactions.—1. Nitrogen tetroxide unites at high temperatures with the *dioxide*, producing the trioxide: $\text{NO}^2 + \text{NO} = \text{N}^2\text{O}^3$ (p. 853). This seems to show that the molecule of the tetroxide at ordinary temperatures contains N^2O^4 , and that it is split up at high temperatures into 2 molecules of NO^2 . At comparatively low temperatures the affinity of the dioxide for the group NO^2 does not appear to be strong enough to split up the molecule N^2O^4 ; but as soon as this separation is effected by the action of heat, the NO^2 thus set free unites with NO , producing N^2O^3 .

In like manner, the combination of NO^2 with Cl, Br, and Cy, may be effected by the action of chlorine, &c. on the heated tetroxide. Nitryl chloride, NO^2Cl , is easily obtained in this manner. The bromide is formed in like manner, but is partly resolved into its constituents by distillation; the iodide is not formed by the action of iodine on the heated tetroxide. By passing cyanogen and nitrogen tetroxide through a red-hot tube, white silky needles are obtained, which explode with fearful violence without any assignable cause, even at low temperatures; in consequence of this, their composition could not be determined, but they probably consist of nitryl cyanide, NO^2Cy .

Nitrogen tetroxide acts on *sulphuric anhydride*, forming the compound $\text{N}^2\text{O}^5\text{SO}^4$.

With *sulphurous anhydride*, nitrogen tetroxide unites to a white solid mass, probably having the composition $\text{SO}^2(\text{NO}^2)^2$. *Carbon monoxide* is partly oxidised by nitrogen tetroxide at ordinary temperatures, and partly combines with it, forming a very volatile liquid, which is decomposed, with effervescence, by water. *Benzene* is acted upon by nitrogen tetroxide, yielding nitrobenzene and oxalic acid. When sulphuric acid is added to a mixture of benzene and nitrogen tetroxide, nitrobenzene is formed, probably according to the equation—

Pentoxide. Nitric Anhydride, N^2O^5 . *Preparation.*—R. Weber (*Pogg. Ann.* cxlvii. 113) prepares this compound by the action of phosphoric anhydride on nitric acid. The strongest nitric acid, freed as completely as possible from nitrous acid and cooled by ice, is treated with phosphoric anhydride added slowly and by small quantities at a time. The syrupy liquid is distilled as long as anything comes over at a blood-heat, and condenses in oily drops in the neck of the retort; and the two layers of the distillate are separated by decantation, the lower consisting mainly of nitric hemihydrate, $2\text{N}^2\text{O}^5 \cdot \text{H}^2\text{O}$. The upper layer, which consists of nitric anhydride, nitrous acid, and some of the hydrate, is cooled by ice-water, which renders it turbid, and causes a small quantity of a clear coloured liquid to separate. This liquid, which consists of nitric anhydride and nitrous acid, is further cooled by ice or a freezing-mixture, when some of the nitric anhydride crystallises in well-formed, transparent, yellowish prisms, leaving a liquid compound of nitric anhydride and nitrous acid, which appears to be richer in the former than nitroso-nitric acid. Lastly, the anhydride is purified by cautiously fusing it, again crystallising it by cold, and draining off the mother-liquor.

Berthelot (*J. Pharm.* [4], xix. 182) cools the nitric acid by a freezing-mixture, so as to prevent the temperature from rising above zero, and after all the phosphoric anhydride has been added, transfers the pasty mass quickly to a tubulated retort capable of containing five or six times the quantity, and distils very slowly, collecting the product in stoppered bottles surrounded with ice.

Nitric anhydride melts at about 30° ; its specific gravity in the solid state is above 1.64, in the liquid state less than 1.636.

It is very unstable, particularly in the fused state, but can be preserved for several days at 10° in a dry atmosphere. It is volatile at ordinary temperatures, and its vapour condenses in beautiful crystals in the cooler part of the tube containing it. In a freezing mixture it is almost colourless (Weber).

It is not explosive either in the solid or in the gaseous state, but as it gradually decomposes even at ordinary temperatures into oxygen and the tetroxide, it should be preserved in stoppered bottles, not in sealed tubes (Berthelot).

Nitric anhydride acts with great violence on sulphur, forming a compound of sulphuric anhydride and nitrous acid. It also acts with great energy on phosphorus, potassium, and sodium, setting them on fire. Upon organic substances it also acts with great intensity. It does not act upon charcoal, but this substance when previously kindled burns with great brilliancy in its vapour. It acts on zinc, cadmium, mercury, and arsenic, and slightly on magnesium and thallium, but has no action on most other metals (Weber).

Nitric Hemihydrate, $2\text{N}^2\text{O}^5 \cdot \text{H}^2\text{O}$. This hydrate crystallises out on cooling the lower layer of the distillate from nitric acid and phosphoric anhydride in a freezing mixture. It can also be prepared by adding nitric anhydride to nitric acid. The anhydride dissolves, with development of heat, until the hemihydrate is produced, but any further quantity of it remains insoluble. The pure hemihydrate is obtained by crystallising it out in a freezing-mixture, draining it from the mother-liquor, allowing it to melt, and again crystallising it. In its chemical properties the hydrate resembles the anhydride. It is liquid at ordinary temperatures, but less so than the ordinary monohydrate, and more or less yellow-coloured; solid at about -5° . Its specific gravity at 18° is 1.642. It decomposes slowly at ordinary temperatures. When heated it partly distils unchanged, but nitric anhydride is also formed, so that the distillate consists of two layers, the upper being the anhydride. In this decomposition it resembles fuming sulphuric acid (Weber).

Nitric Monohydrate, Nitric Acid, $\text{N}^2\text{O}^5 \cdot \text{H}^2\text{O}$ or NO^2H . *Occurrence.*—Goppelsröder (*Zeitschr. anal. Chem.* x. 259, xi. 16) has determined the quantities of nitric acid and ammonium nitrate in rain-water and snow (at Basel), for the twelve months from October 1870 to September 1871. The results are given in the following table:—

Months 1870-71	Total amount of rain and snow-water	Minimum		Maximum	
		Amount contained in 1,000,000 parts of the collected rain or snow-water			
		N ^o O ^s	NH ⁴ .NO ^s	N ^o O ^s	NH ⁴ .NO ^s
October, 1870 .	101.2 mm.	trace	trace	13.6	20.1
November " .	123.9 "	.5	.7	1.2	1.8
December " .	91.2 "	.4	.6	5.3	7.8
January, 1871 .	37.4 "	3.1	4.6	6.3	7.8
February " .	38.5 "	2.2	3.2	4.4	6.5
March " .	27.5 "	2.6	3.8	12.3	18.2
April " .	107.4 "	2.2	3.2	4.6	6.8
May " .	41.3 "	2.2	3.2	10.	14.8
June " .	114.5 "	2.3	3.2	6.2	9.1
July " .	141.4 "	6.41	0.6	1.1	0.63
August " .	26.9 "	0.08	0.11	0.98	1.4
September " .	41.6 "	0.6	0.87	1.0	1.46

Former observers, among whom are Barral, Bobierre, Boussingault, Bineau, and Knop, found from 0.1 to 16 parts of nitric acid in a million parts of atmospheric deposit.

According to Chabrier (*Compt. rend.*) rain-water which falls when the air is tranquil contains more nitrous than nitric acid, but in storms the nitric acid predominates, especially if the rain is collected in the middle of the storm.

C. Ekin (*Chem. Soc. J.* [2], ix. 64) found in the spring-water of an uncultivated hill near Bath, not exposed to any contamination with organic matters, 65 grains of nitric acid in a gallon. The rocks and fossils of this hill were found to contain the following proportions of nitrogen in a million parts.

Grey chalk marl	1.1
Bath oolite	1.3
Fossils from the green-sand	2.23
" " lias	3.6 to 4
" " Fuller's-earth	3.0
Inferior oolite	6.9 to 7.6

Formation.—When hydrogen is burnt in oxygen in a large flask to which air is at the same time admitted, the flask becomes filled with red vapours, and the water which condenses contains a considerable quantity of nitric acid (Hofmann, *Deut. Chem. Ges. Ber.* iii. 658).

Decomposition by Heat.—It is well known that nitric acid is decomposed by heat into oxygen, water, and nitrogen tetroxide, the decomposition beginning at the boiling point of the acid and being complete at a red heat. To ascertain with greater accuracy the nature of the products, the gradual increase of the decomposition with the temperature, and the point at which it becomes complete, Carius (*Deut. Chem. Ges. Ber.* iv. 828) has made the following determinations of the specific gravities of the gas produced at different temperatures.

Temperature of the decomposition	Specific gravity of the Mixed Gases		
	Air = 1	Difference	H = 1
0			
86	2.05	—	29.6
100	2.02	—	29.1
130	1.92	0.10	27.6
160	1.79	0.13	25.8
190	1.59	0.20	23.0
220	1.42	0.17	20.4
250	1.29	0.13	18.6
266	1.25	—	17.9
265	1.24	—	17.8
312	1.23	—	—

These numbers show that the specific gravity of the gases produced by the decomposition of nitric acid remains constant from about 256° to 312° , whence also it appears that from 256° upwards no further change takes place in the composition of these gases. Moreover their specific gravity, which is nearly 18 ($H = 1$), is $\frac{4}{5}$ of 31.5 the sp. gr. of nitric acid vapour, which is just what it should be if the decomposition takes place as shown by the equation:

The result negatives the supposition—improbable also for other reasons—that the vapours contain nitrous acid.

To ascertain approximately the quantities of oxygen set free at different temperatures, nitric acid enclosed together with air in a sealed tube was heated, and the increase of volume of the air on opening the tube under water was measured; this gave the volume of the oxygen set free by the decomposition. The results are given in the following table:—

1 gram of Nitric acid yields of Oxygen gas:—

	In presence of air:			
	15 c.c.	250 c.c.	1200 c.c.	Calculated
°	c.c.	c.c.	c.c.	c.c.
130	13.08	15.47	16.89	17.26
180	22.70	33.30	38.45	37.26
200	23.39	—	50.80	52.05

The quantity of oxygen increases up to a certain point with the quantity of air present and the temperature of decomposition; above 200° there were found, for equal quantities of air added, nearly equal quantities of oxygen. Lastly, on calculating the quantities of oxygen set free, from the specific gravities of the mixed vapours, these quantities below 200° are found to be nearly equal to those obtained in presence of large quantities of air.

The specific gravities of the mixed vapours afford the means of calculating the amounts per cent. of nitric acid decomposed, according to the preceding equation, at different temperatures below 256° , and the quantities of oxygen thereby formed. The results are as follows:—

Temperature of decomposition	Sp. gr. $H = 1$	Decomposition per cent.	Oxygen from 1 gram HNO_3
°			c.c.
86	20.6	9.53	8.43
100	29.1	11.77	10.41
130	27.6	18.78	16.62
160	25.8	28.96	26.22
190	23.0	49.34	43.69
220	20.4	72.07	63.77
250	18.6	93.03	82.30
256	18.0	100.00	88.47

On the Electrolysis of Nitric Acid, see Bourgoin (*Compt. rend.* lxx. 811; *J. Pharm. Chim.* [4], xii. 110, xiii. 266; *Chem. Soc. J.* [2], ix. 886).

Estimation.—For the estimation of nitric acid in well-water, Marx in 1868 proposed a volumetric method based on the decoloration of indigo by nitric acid. The water is mixed with twice its volume of strong sulphuric acid, whereby its temperature is raised to about 120° , and a standard solution of indigo (4 c.c. = 1 mgrm. nitric acid) is poured into it till a distinct green colour is produced (*Zeitschr. anal. Chem.* vii. 412). Several modifications of this method, with the view of rendering it more accurate, have been proposed by Goppelsröder (*ibid.* ix. 1), Trommsdorff (*ibid.* ix. 167), Bemmelen (*ibid.* xi. 186; *Chem. Soc. J.* [2], xi. 90), and F. Fischer (*J. pr. Chem.* [2], vii. 57; *Chem. Soc. J.* [2], xi. 1054).

An apparatus for the performance of Schlösing's method of estimating nitric acid

based on the reducing action of boiling hydrochloric acid and ferrous chloride on nitrates (iv. 88), together with certain modifications in the method, is described by E. Reichardt (*Zeitschr. anal. Chem.* ix. 24; *Chem. Soc. J.* [2], ix. 439). Another modification of the method is described by E. Fleischer (*Zeitschr. anal. Chem.* xi. 309; *Chem. Soc. J.* [2], xi. 529).

For the estimation of nitric acid in saltpetre, A. Wagner (*Dingl. pol. J.* cc. 120, cci. 423; *Chem. Soc. J.* [2], ix. 753, x. 323) makes use of the oxidising action of nitric acid on chromic oxide:

0.3 to 0.4 gram of the saltpetre is heated with 3 grams of chromic oxide and 1 gram of sodium carbonate in a tube from which the air has been previously expelled by a stream of carbon dioxide, which is also slowly kept up during the ignition to expel the nitrogen dioxide evolved. After cooling, the contents of the tube are dissolved in water, the chromic acid precipitated by mercurous nitrate, the precipitate washed with a dilute solution of the same salt, then ignited, and the resulting chromic oxide weighed. 1 part of CrO^3 is equivalent to 0.7068 N^2O^5 .

The estimation may also be made by collecting the evolved nitrogen dioxide over mercury in a tube containing oxygen gas and a standard solution of caustic soda, whereby the nitrogen dioxide is converted into nitric acid, which combines with the soda. When no more oxygen is absorbed on shaking the tube, an aliquot part of the soda-solution is titrated back with standard sulphuric acid.

The presence of organic matter vitiates the results of this method. In applying it to the estimation of nitrates in potable waters, Wagner first evaporates the water with sodium carbonate and potassium permanganate.

A method of estimating nitric acid in potable waters, based on Schulze's method of reduction with aluminium, and titration of the ammonia thereby produced, is given by T. P. Blunt (*Chem. News*, xxv. 205; *Chem. Soc. J.* [2], x. 922).

Metallic Nitrates. On the Heat of Formation of Nitrates, see HEAT (p. 626).

Aluminium nitrate, prepared by dissolving recently precipitated alumina in dilute nitric acid, crystallises in rhombic pyramids truncated by horizontal prisms, dissolves easily in water and alcohol, is very hygroscopic, and has a strong acid reaction (E. Thorey, *Russ. Zeitschr. Pharm.* x. 321).

Ammonium nitrate.—This salt is capable of condensing considerable quantities of ammonia gas, forming a liquid the properties of which have been studied by E. Divers (*Proc. Roy. Soc.* xxi. 107).

Ammoniated ammonium nitrate varies in composition according to the temperature and pressure. At a temperature of 23° and the pressure of the atmosphere, it consists of about 4 parts of nitrate to one of ammonia by weight; but under greater pressure or at lower temperatures, much more ammonia can be condensed by the nitrate. At 0° and the pressure of the atmosphere, 2 parts of nitrate can condense 1 part of ammonia. Like an aqueous solution, the liquid boils when heated, and, when nearly saturated with the nitrate, deposits crystals of it when cooled. It can also, like an aqueous solution, be heated above its boiling point without boiling, and become supersaturated with the salt without crystallising. During its decomposition cold is manifested, and during its formation heat is evolved, but not to a great extent, because the heat given out by the liquefaction of the ammonia is nearly all used up in the liquefaction of the nitrate.

The specific gravity of the liquid varies with its composition. When it consists of two of nitrate to one of ammonia, it has a specific gravity of 1.0725; when it consists of four of nitrate to one of ammonia, it has a specific gravity of nearly 1.200. Its specific gravity can be calculated from its composition by taking 1.5245 as the specific gravity of the nitrate, and 0.671 as that of the ammonia.

In its rate of expansion by heat, the liquid resembles others which exist as such at ordinary temperatures, rather than those which, like ammonia itself, are retained as such only by great pressure. Its expansivity increases with the quantity of ammonia present.

Its action upon a great number of substances, principally inorganic, resembles for the most part the actions of dry ammonia and ammonia nitrate conjoined. The nitrate appears to undergo double decomposition with most salts, and the ammonia to unite with nearly all, including the salts of magnesium, aluminium, iron, and manganese. The ammoniated compounds which do not dissolve in the liquid are very bulky. Nitrates, chlorides, iodides, and bromides, are either soluble or are decomposed into soluble chlorides, &c., of ammonium, and insoluble ammoniated compounds of the metals. Sulphates, oxalates, chromates, and arsenites are insoluble, and phosphates are nearly so. Phosphoric and chromic anhydrides do not act upon the liquid with

the energy that might be expected, but combine with the ammonia. Iodine dissolves freely. Bromine generates nitrogen. Lead salts, including sulphate, chloride, iodide, and oxide, are freely soluble as ammoniated compounds. Platinous chloride dissolves freely as tetrammonio-platinous chloride. Potassium salts are very sparingly soluble. Alkalies and their carbonates decompose the nitrate; so do litharge, lime, and baryta. Calomel is converted into metallic mercury and a soluble ammoniated mercuric compound. Potassium, sodium, zinc, and cadmium dissolve without liberating gas, by reducing the nitrate to nitrite, potassium taking fire. Magnesium slowly dissolves, liberating a little hydrogen, reducing the nitrate, and becoming partly converted into Beetz's black suboxide of magnesium. Methyl iodide is decomposed; butyric ether and chloroform dissolve sparingly without decomposition. Ether is insoluble, but by its contact causes the liquid to break up into its two constituents.

Ammoniated ammonia nitrate is a good electrolyte, ammonia and hydrogen appearing at the negative electrode, and nitrogen and ammonia nitrate at the positive electrode. Positive electrodes of silver, lead, copper, zinc, and magnesium, are dissolved by the liquid as (ammoniated) nitrates. A positive electrode of mercury is converted into a compound almost insoluble in the liquid. When the electrode is acted upon, the generation of nitrogen does not take place.

Cerium nitrates (p. 274).

Manganous nitrate.—According to Schulz-Sellack, the solution of this salt in strong nitric acid evaporates to a thin syrup, which deposits crystals consisting of the hydrate $\text{Mn}^{2+}\text{O}^{2-}\cdot 3\text{H}^2\text{O}$, that is to say, with half the quantity of water of the ordinary salt (iv. 95).

Silver nitrate, AgNO_3 .—On the action of Hydrogen on this salt, see HYDROGEN (p. 660).

The compounds of silver nitrate with *silver iodide* (iv. 105) have been further examined by C. Stürenberg (*Arch. Pharm.* [2], cxliii. 12). When silver iodide is dissolved in a boiling moderately concentrated solution of the nitrate, the salt, $2\text{AgNO}_3 \cdot \text{AgI}$, crystallises out on cooling; but on saturating the solution completely with silver iodide, another double salt is obtained to which Stürenberg assigns the formula $2\text{AgNO}_3 \cdot 2\text{AgI}$. When this latter is treated with a concentrated solution of silver nitrate, it dissolves and is converted into $2\text{AgNO}_3 \cdot \text{AgI}$. This salt can be obtained as a finely crystalline precipitate by treating its solution with alcohol. When the salt $2\text{AgNO}_3 \cdot 2\text{AgI}$ is treated with water, silver iodide separates out, but redissolves partly on boiling, the salt $2\text{AgNO}_3 \cdot \text{AgI}$ being thereby produced.

When a boiling solution of silver nitrate is incompletely saturated with *lead iodide*, the hot-filtered solution deposits, on cooling, the salt $8\text{AgNO}_3 \cdot 4\text{AgI} \cdot \text{Pb}(\text{NO}_3)_2$ in well-defined colourless prisms belonging to the quadratic system, with the faces ∞P and P . It is decomposed by water into silver iodide and the nitrates of silver and lead. By prolonged boiling with lead iodide it is converted into the salt $4\text{AgNO}_3 \cdot 4\text{AgI} \cdot 2\text{Pb}(\text{NO}_3)_2$, which, however, cannot be obtained pure in this manner. It may be prepared in the pure state by mixing the solution containing the two salts with alcohol, whereupon the salt containing the smaller proportion of lead is precipitated, while that which contains the larger proportion crystallises from the liquid in beautiful well-defined hexagonal prisms with the faces ∞P and P . This salt is decomposed by silver nitrate with formation of $2\text{AgNO}_3 \cdot \text{AgI}$.

Silver-lead nitrate, $2\text{AgNO}_3 \cdot \text{Pb}(\text{NO}_3)_2$, is obtained by evaporating a solution of the mixed nitrates to the crystallising point. The crystals belong to the hexagonal system.

Similar double salts of silver nitrate with mercuric nitrate appear to exist. An experiment similar to those by which the lead salts above described were prepared led to the formation of the salt $32\text{AgNO}_3 \cdot 16\text{AgI} \cdot \text{Hg}(\text{NO}_3)_2$.

Uranium nitrate.—According to Schulz-Sellack (*Zeitschr. f. Chem.* [2], vi. 646) a solution of uranic nitrate, evaporated with a large excess of nitric acid, deposits, on cooling, beautifully fluorescent needles of the salt $(\text{UO}_2)(\text{NO}_3)_2 \cdot 3\text{H}^2\text{O}$ [$\text{U}^{VI} = 240$], whereas, according to Drenckmann (*Jahresb.* 1861, 256), the ordinary salt $(\text{UO}_2)(\text{NO}_3)_2 \cdot 6\text{H}^2\text{O}$ crystallises from acid as well as from neutral solutions. Good crystals of the hydrate $(\text{UO}_2)(\text{NO}_3)_2 \cdot 3\text{H}^2\text{O}$ are obtained by evaporating the acid solution over sulphuric acid and potash; they do not effloresce in a vacuum, but deliquesce in the air, and melt at 120° , whereas the ordinary hydrate melts, according to Ordway, at 59° . According to Pelliot the ordinary hydrate gives off half its water in a vacuum (v. 107), leaving therefore a mass having the composition of the tri-hydrate.

Yttrium nitrate, $\text{Y}(\text{NO}_3)_3 \cdot 4\text{H}^2\text{O}$, forms large colourless crystals easily soluble in water, alcohol, and ether. It is unalterable in the air, but gives off 2 mols. of water when dried at 100° (P. T. Cleve, *Bull. Soc. Chim.* [2], xx. 193).

Nitric Ethers. According to P. Champion (*Compt. rend.* lxxiii. 571, 578) the

nitrates of *ethyl*, *amyl*, *hexyl*, and *cetyl*, may be obtained by treating the corresponding alcohols with a mixture of nitric and sulphuric acid.

Cetyl nitrate, $C^{18}H^{35}NO_2$, prepared by adding pulverised cetyl alcohol to the mixed acids, washing the separated oil with water (best after solution in ether), and drying in a vacuum, is a colourless liquid solidifying between 12° and 10° , and crystallising by slow cooling in long flattened needles. It is slightly soluble in cold alcohol, more soluble in warm alcohol, still more in ether, chloroform, and carbon sulphide, slightly soluble in amyl alcohol and methyl alcohol. Sp. gr. = 0.91. It is decomposed by heat, with separation of charcoal, burns with difficulty, assumes the spheroidal condition when poured upon a hot plate, and then burns with a smoky flame. It is decomposed by strong sulphuric acid.

NITROGLYCERIN. On the heat developed in the formation of this compound, see HEAT (p. 626).

On the Explosive force of Nitroglycerin, see EXPLOSION (p. 498).

NITROMANNITAN. See MANNITE (p. 775).

NITROMETHANE, CH_3NO_2 . See NITROPARAFFINS, under PARAFFINS.

NITROMETHYLBENZOPHENONE, $C^{11}H^{11}(NO_2)O = C^6H^5NO_2 - CO - C^5H_5 - CH_3$. A body formed by the action of nitric acid of sp. gr. 1.4 on benzyl-toluene at the heat of the water-bath. It crystallises from hot dilute alcohol in long flat needles or silky plates melting at 127° and subliming without decomposition in shining plates. When treated with tin and hydrochloric acid, it yields an amido-compound, forming amorphous salts, from which it is precipitated by soda-solution as a light white powder (Zincke, *Deut. Chem. Ges. Ber.* v. 683).

NITROPROPANE, $C^3H^7NO_2$. See NITROPARAFFINS, under PARAFFINS.

NITROSODIETHYLAMINE, $C^4H^{10}N^2O = N \begin{Bmatrix} C^2H^5 \\ C^2H^5 \\ NO \end{Bmatrix}$. *Nitrosodiethylin*,

Nitrosoethylin.—This compound, formed by the action of potassium nitrite on diethylamine hydrochloride (iv. 114), is somewhat strongly acted upon by potash, soda, and other alkaline bases, either in aqueous or in alcoholic solution; when it is heated therewith in sealed tubes to 155° for about eight hours, the chief products are ammonia and ethylamine. With sodium amalgam, in presence of water, it yields diethylamine and nitrogen monoxide:

Dry hydrogen chloride transforms nitrosodiethylamine into a mass of crystals consisting of diethylammonium chloride, nitrosyl chloride being formed at the same time:

(Gauthier, *Jenaische Zeitschrift*. vii. 118).

NITRYL CHLORIDE, BROMIDE, IODIDE, and CYANIDE, NO^2Cl , &c. On the formation of these compounds by the action of chlorine, &c., on nitrogen tetroxide, see p. 855.

NOCTILUCIN. This name is given by T. L. Phipson (*Chem. News*, xxvi. 130) to the peculiar organic substance which causes the production of light in phosphorescent fish, the glow-worm, and probably all other phosphorescent animals; it appears also to be formed, under a variety of circumstances, at the expense of dead animals and vegetable tissue, and even by certain living plants (*Euphorbia*, *Agaricus*, &c.)

Animal noctilucin at the ordinary summer temperature is a semi-fluid, almost liquid substance, containing nitrogen; it is white, contains a considerable amount of water, and has a slight odour resembling that of caprylic acid; it is only slightly soluble in water, and insoluble in alcohol and ether. Sulphuric and nitric acid dissolve and decompose it; potash evolves ammonia from it. When moist it absorbs oxygen and evolves carbonic acid, and, when left to itself, dries up to thin, shining, transparent films, devoid of structure, and resembling the mucin of the garden snail.

When recently produced, it is highly phosphorescent, and the production of light is owing to oxidation. It is secreted in phosphorescent animals by a special organ, and appears to be consumed [? by oxidation] in producing light nearly as fast as it is formed. Its light is nearly monochromatic, and its spectrum principally de-

veloped between the lines E and F. In an impure state noctilucin can be obtained from the surface of various fish when highly phosphorescent, also from the glow-worm, by pressing the luminous matter collected by the scalpel through porous filtering-paper. It is secreted in a pure form by the luminous centipede (*Scolopendra electrica*).

NOHLITE. This mineral, from Nohl near Kongelf, Sweden, very nearly resembles the samarskite from the Ural, but is distinguished from it by a rather considerable percentage of water. It is compact, of a black-brown colour, and is opaque and brittle. The fracture is uneven and splintery, and the lustre highly vitreous. Hardness 4.5-5.0; specific gravity 5.04. Before the blowpipe it slowly melts at the edges to a dull glass, and feebly decrepitates through loss of water.

Analysis gave the following numbers:—

Nb ² O ⁵	ZrO ²	UO	YO	CeO	CaO	MgO, MnO	FeO	CuO	H ² O
50.43	2.96	14.43	1.36	0.25	4.67	0.28	8.09	0.11	4.62 = 100.20

agreeing approximately with the formula $2(\text{RO.Nb}^2\text{O}^5) + 3\text{H}^2\text{O}$. (A. E. Norden-skiöld, *Jahrbuch f. Mineralogie*, 1872, 552).

NONANE, C⁹H²⁰. See PARAFFINS.

NONYLIC ACID, C¹¹H²²O². See PELARGONIC ACID.

NUCLEIN. A substance resembling mucin existing in pus-corpuscles and in the nuclear structures of the yolk of the hen's egg. See F. Miescher, 'Ueber die Chemische Untersuchung der Eiterzellen' (*Med.-chem. Unters.* 1871, 411). 'Die Kerngebilde im Dotter des Hühnerereies' (*ibid.* 509). Hoppe-Seyler, 'Ueber die Chemische Zusammensetzung des Eiters' (*ibid.* 486); also *Chem. Soc. J.* [2], ix, 742-747. *Gmelin's Handbook*, English Edition, xviii, 467.

NUTMEG OIL (Wright, *Chem. Soc. J.* [2], xi, 549). The purest commercial oil of nutmeg is resolvable by fractional distillation into the following bodies: 1. A soft brown resin (about 2 p.c. of the oil) not volatile at 300°, and having the composition C¹⁰H¹⁶O⁴. 2. Liquids boiling at 260°-280° and 280°-290°, whose composition may be represented by the formula (C¹⁰H¹⁶O²)_n. 3. An oxidised oil, C¹⁰H¹⁶O, boiling at 212°-218°. 4. A mixture boiling at 173°-179° (about 15 p.c. of the original oil), of a terpene, C¹⁰H¹⁸, with a small quantity of cymene. 5. A hydrocarbon boiling at 163°-164°, consisting of a terpene with a trace of cymene, amounting to 70 p.c. of the original oil.

From these results it may be inferred that the hydrocarbon boiling at 167°, called by Gladstone myristicene (*Chem. Soc. J.* [2], x, 3), is a mixture of two or more terpenes with perhaps a little cymene.

The oxidised body, C¹⁰H¹⁶O, is myristicol (p. 833). It is converted by heat into an isomeric (or polymeric) modification boiling at a higher temperature, and subsequently into a resin having the same composition. Myristicol treated with dehydrating agents yields cymene, and when treated with phosphorus pentachloride it is converted into a compound C¹⁰H¹⁴Cl, which is resolved by prolonged boiling into hydrogen chloride and cymene.

The cymene contained in the portion of the nutmeg hydrocarbon which boils at 163°-164°, may be isolated by treating the mixture with sulphuric acid so as to polymerise the terpene present (the cymene is not altered by the treatment), then shaking with water and distilling in a current of steam. The cymene thus obtained is quite pure, and amounts to about 8 p.c. of the hydrocarbon boiling at 163°-164°.

The terpene of nutmeg-oil may be converted into cymene by combining it with bromine and distilling the resulting dibromide C¹⁰H¹⁶Br₂, whereby it is resolved into 2HBr and C¹⁰H¹⁴.

NUTRITION. For the most important contributions to the chemistry of Animal Nutrition since the publication of the *First Supplement* of this Dictionary, see the articles GASTRIC JUICE, GLYCOGEN, MUSCULAR TISSUE, RESPIRATION, and URINE, in the present volume.

O

OATS (Fr. *Avoine*, Ger. *Hafer*). Cultivated oats include *Avena sativa*, the common oat; *A. orientalis*, Tartar oats, also largely cultivated; and *A. brevis*, and other species grown for hay in some parts of the continent. The varieties, especially of the first-named species, are very numerous, and differ much from each other as to the colour of the husk, the weight per bushel of the grain, the length and character of the straw, &c. Oats having a high weight per bushel (44-46 lbs.), owe this quality in great measure to the thinness of their husk and skin; they yield the best proportion of meal, 60 p.c. and upwards. Oats with a low weight per bushel (some varieties 35-38 lbs.) have a thicker husk and skin, yield a smaller proportion of meal, and are used as food for horses. From this difference in the character of the husk, oats present a wide range in chemical composition. The following table shows the average composition and extent of variation of oat-grain and straw of good quality. The composition of oat-husk is taken from old analyses by Norton; the figures for oat-chaff are Wolff's average.

	Number of analyses	Water	Albuminoids	Fat	Carbo-hydrates	Fibre	Ash
Oats . . .	24	12.07 10.5-14.8	12.87 8.6-18.5	6.05 4.2-7.1	53.85	10.76 6.3-13.4	3.50 2.7-5.1
Oat-husk . .	—	11.09	1.67	1.07	80.21		5.96
Oat-chaff . .	—	14.30	4.00	1.50	28.2	34.00	18.00
Oat-straw . .	16	14.68 11.3-19.5	3.69 1.1-7.0	1.60 1.1-2.7	34.47	40.46 31.8-48.9	5.10 3.6-6.3

When the husk is removed from the oat, in making oatmeal, the proportion of fibre and of ash is greatly reduced, while the amount of albuminoids and carbo-hydrates rises. Thomson gives 15.61 p.c. as the average of albuminoids in oatmeal; Voelcker, 15.68; some chemists place it as high as 17; very few perfect analyses have been published. The fat in oatmeal is about 7 p.c., the ash 1.5. From its high contents in albuminoids and fat, oatmeal is probably the most concentrated food supplied by cereal grains. It is interesting to observe that, while the removal of the bran from wheat reduces the nitrogenous and fatty contents of the flour, the removal of the husk from oats has precisely the opposite effect, so that the finer the oatmeal the richer it is in these ingredients.

The embryo of the oat, as probably of all other seeds, is especially rich in nitrogen; Lenz (*Jahresh. Agri. Chem.* 1870-2, 4) found it to contain nitrogen equal to 26.7 p.c. of albuminoids.

The nature of the albuminoids in oats has been thoroughly studied by Krouser (*J. pr. Chem.* cvii. 17). The principal albuminoid is oat-legumin, the avenine of Johnston; it is obtained by acting on oatmeal with very weak solution of potash in the cold, precipitating the solution with acetic acid, and purifying the precipitate by resolution and precipitation, treatment with ether, and finally by boiling with 60 p.c. alcohol to remove gliadin. Thus purified it contains, ash deducted, C. 51.63, H. 7.40, N. 17.16, O. 22.93, S. .70. It agrees in most respects with the legumin of peas, but in its high percentage of sulphur, and some of its properties, more resembles the glutenin of Ritthausen. Oatmeal also yields by extraction with alcohol a small quantity of oat-gliadin, similar in properties and composition to the gliadin of wheat, but containing more hydrogen and sulphur; it is indeed the richest in sulphur of the vegetable albuminoids. The percentage composition of purified oat-gliadin, ash deducted, is C. 52.59, H. 7.65, N. 17.71, O. 20.39, S. 1.66.

For the composition of the fat of oats and oat-straw, see the article FAT in this volume.

Oat-straw has, on an average, a higher nutritive value than the straw of wheat or barley; it contains less woody fibre and a larger amount of soluble carbo-hydrates and albuminoids. The albuminoids vary greatly, being high when the straw is green, and diminishing rapidly in quantity as the straw ripens; for the sake of the improved quality of the straw oats are frequently harvested before ripening is completed. The straw at the time of harvest contains 30-40 p.c. of water even when fully ripe, and much more if cut earlier; the analyses quoted above refer to straw which has become dry in the stack.

Way found in six specimens of oats an average of 2.34 p.c. of sulphur, and in four specimens of straw an average of 1.68 p.c., both on the dry substance.

The average composition of the ash of oats, oat-straw, &c., is as follows:—

	Number of analyses	Per cent. ash in dry	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	SiO ²	Cl	Co ²
Oats, whole	22	3.3	15.7 { 9.8-24.3	2.5 { 8.2-2.3	3.7 { 8.4-1.3	7.2 { 0.7-4.9	.7 { 2.1-1.1	21.7 { 32.3-9.7	1.5 { 4.0-1.1	45.7 { 56.5-32.3	1.6-0	none

Whole plant when ripe:												
Bretschneider	1	5.4	19.1	5.3	5.4	5.0	.4	10.1	3.9	49.2	2.0	—
Arendt	1	5.2	34.5	.7	11.6	5.0	.5	11.2	4.2	28.6	4.6	—

The variations in the ash of oats are seen to be very considerable; they are mainly due to the varying proportion of husk. Oats with thin husk give an ash with high potash and low silica, but when the husk is thick the silica is high and the potash low. This is made evident by comparing the ash analysis of the husk with that of oats deprived of husk. The ash analyses of husked oats are by Norton and Johnston, and the ash analyses of the husk by Norton and Fromberg; the methods used for these analyses were very imperfect, but the general character of the ash is made evident. The ash analysis of *Avena nuda*, in which the husk is naturally separated from the grain, is by F. Schulz. The ash analyses of oat-chaff are by Way and Marchand, with one quoted by Anderson; they vary greatly. Norton found in seven specimens of oat-chaff a mean of 16.94 p.c. of ash in the dry, containing 60-80 p.c. of silica; he detected manganese in several specimens of grain and husk. The analyses of oat-straw with chaff are by Way and Ogston. The results of Bretschneider and Arendt are very different as regards potash, lime, silica, and chlorine; the explanation lies in the fact that Bretschneider operated on an average sample of an oat-crop, Arendt on selected vigorous and perfect plants. Arendt showed the great difference which the luxuriance of the plant makes in the composition of the ash by examining separately very vigorous, strong, and weak plants at different stages of growth; the analysis of the whole plants at the time of blossom gave:—

	Alkalies	Lime	Magnesia	Ferrio Oxide	Phosphoric acid	Sulphuric acid	Silica	Chlorine
Very luxuriant oat-plant . . .	45.3	6.1	2.9	.4	8.2	4.8	27.0	6.7
Strong oat-plant . . .	34.3	5.4	2.3	.5	8.5	4.1	39.9	5.8
Weak oat-plant . . .	30.4	5.2	2.3	1.0	8.8	5.0	42.0	4.7

Luxuriant plants always contain a greater amount of soluble ash constituents than they actually require.

Arendt found that in the stem and leaves of the oat all the sulphates and chlorides, and nearly all the phosphates, existed in a soluble condition, but that nearly all the silica, save in the lower part of the stem, was in an insoluble state. By determining sulphates in the green plant, he ascertained that the distribution of sulphates and of sulphur was very different. Thus, immediately after blossom, the lower part of the stem contained no sulphates, while they were abundant in the upper leaves; both parts, however, contained sulphur in considerable quantity.

The composition of the different parts of the oat plant at different stages of its growth has been thoroughly studied by Norton (*Amer. Jour. Sci.* [2], iii. 223, 318), by Bretschneider (*J. pr. Chem.* lxxvi. 193), by Arendt (*Wachsthum der Haferpflanzen*, and *Jahresb. Agri. Chem.* 1858-9, 124), and by Fittbogen (*Jahresb. Agri. Chem.* 1864, 128). From this abundance of material we select Bretschneider's figures dealing with the oat crop as a whole, and Arendt's results for the various parts of the plant.

Bretschneider analysed the stem, leaves, and seed of an oat-crop in five stages of growth—I. June 19, 58 days after sowing; the fourth and fifth leaf generally developed. II. June 29; the ear had left its sheath. III. July 8; full bloom. IV. July 28; commencement of ripening. V. August 6; fully ripe. The results for the second period were imperfect.

Composition of an Oat Crop in various Stages of Growth.

Contents in 100 parts of the dry crop					Contents in kilos. per hectare			
	I.	III.	IV.	V.	I.	III.	IV.	V.

Composition of the Ash.

In 100 parts					In kilos. per hectare			
	I.	III.	IV.	V.	I.	III.	IV.	V.
Potash	28.96	25.60	25.90	19.14	29.52	61.93	69.38	65.91
Soda	6.40	8.67	4.16	5.29	6.54	20.97	11.17	18.19
Lime	5.66	6.46	5.19	5.43	5.77	15.62	13.90	18.69
Magnesia	5.34	5.25	4.98	5.02	5.44	12.70	13.34	17.29
Ferric oxide	1.22	.39	.31	.39	1.24	1.04	.83	1.34
Phosphoric acid . . .	7.95	9.17	9.61	10.13	8.10	22.18	25.74	34.88
Sulphuric acid . . .	5.57	2.46	1.99	3.89	5.67	5.95	5.33	13.39
Silica	36.28	40.00	45.57	49.17	36.97	96.77	122.07	169.28
Chlorine	3.38	2.68	2.94	2.00	3.45	6.25	7.90	6.68

From these figures it appears that the crop attains its maximum weight at the time of blossoming, after which the amount of water rapidly diminishes, while the organic matter and ash continue to increase. Assimilation is most rapid shortly before blooming. The organic matter of the crop increases far more quickly than the ash, the percentage of which at first rapidly, and then more slowly, diminishes. The individual organic elements are assimilated in different proportions at the various stages of growth, which will be most clearly seen by the following statement, showing the proportion of each taken up for 100 of carbon assimilated.

Period	I.	Carbon	Nitrogen	Hydrogen	Oxygen
"	III.	100	7.81	13.4	73.6
"	IV.	100	4.92	13.3	72.5
"	V.	100	6.15	12.3	100.3
"		100	2.61	10.6	106.5

It is evident that the formation of albuminoids takes place chiefly in the earlier part of the plant's life, while carbo-hydrates are the principal formation in the later stages. The low proportion of hydrogen assimilated at the close seems to point to the formation of lignose.

Among the ash constituents of the oat-crop it appears that but little potash or lime is assimilated after the time of blossom, while of magnesia, and especially of phosphoric acid and of silica, more considerable quantities are taken up during the later stages of growth.

Arendt, as already mentioned, selected vigorous and perfect oat-plants, and determined the composition of various parts of the plant in five stages of growth; his results are given in the table, p. 866. At Period I. the plants were 0.31 meter high; three leaves were unfolded. At Period II. the height was 0.63 m.; the ear was half protruded. At Period III. the height was 0.84 m.; blossoming had just finished. At Period IV. the height was unchanged; ripening had commenced. At Period V. perfect ripeness was attained. Arendt's crop was sown later and reaped earlier than that of Bretschneider, and the plants taken for analysis were clearly far more luxuriant than those

operated on by the last-named investigator. Only a few points in the table can be referred to.

The amount of woody fibre apparently reaches its maximum at the time of blossoming, after which other carbo-hydrates are developed. Fibre reaches its highest percentage in the dry matter of the stem, especially in the lower part. Fat is most abundant in the leaf, the lower leaves after blossoming containing 9-10 p.c. of fat and wax. Albuminoids in the young plant are most abundant in the leaf, in the ripe plant in the ear; a transference of nitrogen from the leaf to the ear is evident after blossoming. The leaf is the part richest in ash; after blooming the upper leaves contain much more ash than the lower ones. Norton even found that the upper half of an oat-leaf contained more ash than the lower half. The ash of the stem is exceedingly rich in potash, that of the leaf contains less potash, but a much larger quantity of lime (compare Ulbricht's results with clover, FODDER PLANTS). The ash of the stem, contrary to popular notion, is poorest in silica of any part of the plant; the maximum of silica is in the leaf. Phosphoric acid and magnesia find their maximum in the ash of the ear; a transference of phosphoric acid from the leaf and stem to the ear is plainly seen. This relation of the ash constituents of the stem, leaf, and ear is abundantly confirmed by Bretschneider. In Arendt's 'ash' carbonic acid is deducted; the ash of the ripe stem must have contained a large quantity.

Fittbogen is the only experimenter on the oat-plant who has included the roots in his investigation; his plants were grown in glass pots and examined at three periods. From the time when three leaves were unfolded, the roots diminished in weight, and especially in ash constituents; the transference of matter from the root took place chiefly just before the time of blossoming. Hellriegel examined the plants grown by Fittbogen, and found that each oat-plant (growing at the rate of 32 in a cubic foot of soil) possessed an average of 150 feet of root fibre.

The influence of different classes of manures on the growth of oats, and their effect on the composition of the crop, are best illustrated by the results of Messrs. Lawes and Gilbert. The following figures, kindly communicated by the authors, show the average produce of black Tartarian oats grown for five successive years on the same land.

Produce of Tartar Oats with various Manures.

Manures per acre	Dressed corn	Straw and chaff	Total produce	Corn to 100 straw	Weight per bushel of dressed corn
	bushels	owts.	lbs.		lbs.
No manure	19½	10½	1988	72	33½
Mixed cinereal manure	24½	13½	2532	70	35
Ammonium salts, 400 lbs.	47	28½	5188	65	36½
Nitrate of sodium, 550 lbs.	47½	27½	5110	69	35½
Ammonium salts, 400 lbs. with } cinereals	50	41½	7100	58	37
Nitrate of sodium, 550 lbs. with } cinereals	57½	35	6347	67	35½

The mixed cinereal manure consists of superphosphate, with potassium, sodium, and magnesium salts. The ammonium salts are mixed chloride and sulphate; they supply the same quantity of nitrogen as the 550 lbs. of nitrate of sodium.

The results plainly show that the oat-plant, like other graminaceous crops, is unable to supply itself from the natural resources of the soil and atmosphere with an amount of nitrogen sufficient to produce a full crop, even when abundantly supplied with ash constituents. The best result in the experiments is obtained where nitrogenous and cinereal manures are applied together.

The effect of the above manures on the composition of the crop is seen in the following table, which shows that the dry matter in the corn is practically not altered by manuring, while in the straw the dry matter is a little lower in the more luxuriant crops. The amount of dry matter is, however, considerably affected by season, the variation being greatest in the straw. The percentage of ash in the corn exhibits considerable variation by manuring, but the variation is not so much connected with the supply of ash constituents to the plant as with the weight per bushel of the grain; where the grain is best developed, and contains the largest proportion of kernel to husk, there the ash is at a minimum, and the weight per bushel at a maximum; where the specific

Percentage Composition of Oat-corn variously manured.

gravity is lowest, and the proportion of husk greatest, the ash reaches its maximum. In the straw the percentage of ash varies even more than in the corn. The supply or non-supply of ash constituents has here clearly some effect on the result, especially in seasons of defective ripening, as seen in the column of highest percentages; but in favourable seasons the percentage is mainly affected by the bulk of the crop, the heavier crops containing least ash. The straw manured with nitrate of sodium contains distinctly less ash than that manured with sulphate and chloride of ammonium. The percentage of nitrogen both in grain and straw is but little affected by its supply, the effect of season is far more considerable; nitrogen is lowest in both grain and straw in seasons of favourable ripening, and high when ripening is incomplete.

An average out-crop of 45 bushels of grain, at 42 lbs. per bushel, and 2835 lbs. of straw (3 of straw to 2 of grain), will remove from the land in lbs. per acre about the following quantities:—

	Nitrogen	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	Cl	SiO ²	Total ash
Grain . . .	37.8	8.5	1.4	2.0	3.0	.4	11.8	.8	—	24.8	54.3
Straw . . .	14.2	29.6	5.0	9.8	5.3	2.1	7.1	4.8	5.5	69.3	139.7

R. W.

OBOLUS. Analyses of *Obolus* shells from the lower Silurian sandstone of Eathland have been made by A. Kupffer (*Jahresb. f. Chem.* 1870, 1337); they consist, mainly of a fluorapatite, having the composition $\text{CaF}_2 \cdot 3\text{CaP}_2\text{O}_8$.

OCTANE, C₈H₁₈. *Octyl Hydride*, Normal Octane, or dibutyl, prepared by the action of sodium on normal butyl iodide, obtained by Lieben a. Rossi's process from butyric acid, boils at 123°–125°, and has a specific gravity of 0.7032 at 17°. It appears, therefore, to be identical with the octane obtained from methyl-hexyl carbinol and from sebic acid, also with that which Zincke obtained from primary octyl alcohol (1st Suppl. 877).

OCTAMINE (or TETRAMINE) CHROMIUM-COMPOUNDS. See CHROMIUM (p. 386).

OCTAPO-TETRAMORPHINE. See MORPHINE (p. 823).

OCTENE, or OCTYLENE-COMPOUNDS.—The *chlorhydrin*, $C^8H^{14}(OH)Cl$, is formed by treating octene with aqueous hypochlorous acid not containing more than 0.75 p.c. $HClO$. The product freed from unaltered octylene by heating it to 125° , and passing a rapid stream of carbonic anhydride through it, is a mobile slightly yellowish liquid, having a camphorous odour and burning taste, insoluble in water, but soluble in ether and in alcohol, decomposed by boiling. Sp. gr. = 1.003 at 0° , and 0.987 at 31° . Heated to 180° in a digestion-tube with sticks of potash and a little water, it yields a liquid which boils at 145° , has a specific gravity of 0.831 at 15° , and yields by analysis 72.9 p.c. carbon and 11.7 hydrogen. Now octene oxide, $C^8H^{14}O$, requires 75.0 C. and 12.5 H., whereas heptene oxide, $C^7H^{12}O$, requires 73.7 C. and 12.3 H. Probably, therefore, the product consisted mainly of heptene oxide, resulting from the oxidising action of the hypochlorous acid on the octene chlorhydrin. When octene was treated with a 2 to 3 p.c. solution of hypochlorous acid, no octene chlorhydrin was obtained, the hypochlorous acid in the more concentrated state exerting an oxidising as well as a substituting action. The product yielded, by fractional distillation, a liquid boiling at 206° – 208° , and having the composition of heptene-chlorhydrin, $C^7H^{12}(OH)Cl$. The portion boiling above 208° contained a still larger proportion of chlorine (P. de Clermont, *Bull. Soc. Chim.* [2], xiii. 404).

Octene glycol, $C^8H^{14}(HO)^2$, boiled for ten hours with nitric acid containing rather more than $4H^2O$ to each N^2O^3 , yields a solution of oxalic acid on which there floats an oil containing, besides unattacked octene glycol, an acid which remains liquid at -10° . A barium salt prepared from it contained 22.95 p.c. metal, and could not therefore be either a suberate or a caprylate. In another oxidation not carried quite so far, a solid crystalline acid was formed, the barium salt of which contained from 38.8 to 38.7 p.c. metal (P. de Clermont, *loc. cit.*)

OCTETHYL-SILICIC ETHER. See SILICIC ETHERS.

OCTYL ALCOHOLS, $C^8H^{18}O$. Primary iso-octyl alcohol or isohexptyl carbinol, obtained by Zincke from the volatile oil of the seeds of *Heracleum sphondylium* (1st *Suppl.* 878), may also be obtained from the oil of *Heracleum giganteum*, which contains the corresponding acetic ether (Franchimont a. Zincke, *Deut. Chem. Ges. Ber.* iv. 420).

Secondary Octyl Alcohol or Methyl-hexyl Carbinol, $\begin{matrix} CH^3 \\ | \\ C^6H^{13} \end{matrix} CHOH$, is produced, together with methyl-hexyl ketone, by distilling sodium ricinoleate with excess of alkali hydrate; and Neison has lately shown, by a very careful investigation, that these are the sole products of the reaction (*Chem. Soc. J.* [2], xii. 837–851). The alcohol, when purified from the ketone as completely as possible, boils, according to Schorlemmer's latest determination, at 177° – 178° (*Chem. Soc. J.* [2], xii. 1029). Former determinations gave 181° , but Schorlemmer regards the recent determination as the more trustworthy, first because the pure alcohol had been prepared from a larger quantity of material, and secondly, because it appears to be a general law that a normal secondary alcohol containing the group $-CHOH-CH^3$, boils at the same temperature as the normal primary alcohol which contains 1 atom of carbon less. This may be seen from the following table, including only such alcohols as have been most minutely studied:—

	Bolling-point		Bolling-point
$C^6H^{12}.OH$. . .	97° – 98°	$C^8H^{18}.OH.CH^3$. . .	86° – 98°
$C^6H^{11}.OH$. . .	137°	$C^8H^{16}(OH).CH^3$. . .	136°
$C^6H^{10}.OH$. . .	116.5° – 177.5°	$C^8H^{14}(OH).CH^3$. . .	177° – 178°

CENANTHOL, or CENANTHYLIC ALDEHYDE, $C^8H^{14}O$. Preparation.—Schiff (*Zeitschr. f. Chem.* vi. 74) prepares this aldehyde by distilling half a litre of castor-oil in a 2½-litre vessel over a gas flame till the mass just begins to froth up. The distillation-vessel is then emptied, again charged with ½-litre of the previously warmed oil, and this operation is repeated till 10 kilograms of material have been treated. The products consist of 1.27 kilograms of purified cenanthol, 50 grams of less pure cenanthol, to be purified by combination with sodium bisulphite, &c., 100 grams of acrolein, and a quantity of oily bye-products. The viscid, spongy residue of the distillation may be completely liquefied by gentle heating, and ultimately distilled almost without residue. An addition of the oily bye-products above mentioned diminishes the frothing.

Reaction with Hydrochloric acid.—Williamson, by passing hydrochloric acid gas through an alcoholic solution of cenanthol, and treating the product with water, ob-

tained an oily liquid which he regarded as cenanthylic ether, $C^8H^{14}.O^2H^{14}O^2$ (iv. 178). Schiff, on the other hand (*Zeitschr. f. Chem.* vi. 74), finds that the chief product of this reaction is heptene-chlorethylin, or heptene-methyl chloride, $C^7H^{14}\{Cl\}OC^2H^3$. This compound is a light oil insoluble in water, easily soluble in alcohol and ether, gradually decomposed by contact with warm water. It could not be obtained pure, as it is completely decomposed by distillation. The decomposition, which is very complicated, may, according to Schiff, be approximately represented by the following equations:—

If the first distillation be interrupted at 320° , there remains a brown viscid residue consisting of hydrocarbons, $C^{14}H^{2n-2}$, and others, which residue, when heated, is resolved, as indicated by equation (4), into bodies of relatively lower boiling point. Hence, by continually separating from the resulting distillates the portions which go over below 320° , and again distilling the residues, the relative quantity of the lower-boiling hydrocarbons will continually increase at the expense of those of higher-boiling point. From a product thus obtained, the following compounds were isolated by repeated fractionation: (1.) Heptene, C^7H^{14} , from fractions 90° – 100° ; (2.) a yellow oil, $C^{14}H^{28}$, from fractions 245° – 260° ; (3.) a very viscid oil, $C^{14}H^{28}$, having the consistence of turpentine in the cold, from fractions 320° – 330° ; (4.) a pitch, $C^{14}H^{18}$, as residue of the distillation when carried on to 350° . The formulae assigned to these bodies are supported by closely agreeing analyses. The four bodies just mentioned constitute, however, only the smallest portion of the entire product of the decomposition, the principal portion consisting of mixtures which could not be separated into definite products.

The product of the first distillation of the heptene-chlorethylin contains an aldehydic body boiling at 240° , the separation of which succeeds only when the product is distilled by itself. It slightly reduces ammoniacal silver nitrate on boiling, and unites with sodium bisulphite to a scarcely crystalline mass. Its analysis gave numbers which agreed with the formula:

considering, however, the imperfect purity of the substance, the result might also be represented by the formula:

which requires the same amount of carbon and 1 p.c. less hydrogen (Schiff).

Cenanthol, treated in the cold with solid potassium hydrate, is converted into two polymeric modifications, one a crystalline solid, the other an oily liquid. Both yield, on distillation, cenanthol and condensation-products formed from it by abstraction of water (Borodin, *Deut. Chem. Ges. Ber.* v. 480).

CENANTHYLIC ACID, $C^8H^{14}O^2 = C^8H^{12}.CO^2H$. This acid, first obtained by Tilley in 1841 by oxidising castor-oil with nitric acid, is also produced by oxidation of cenanthol with nitric acid or with chromic acid; by the oxidising action of nitric acid on oleic acid and on Chinese wax; by that of chromic acid on heptylic alcohol from heptane; and by the action of potash on cenanthol (iv. 177). The boiling-points of the acid obtained by these several processes have been variously stated at 212° – 222° . Tilley's acid, which boiled at 148° , was doubtless impure. Franchimont (*Ann. Ch. Pharm.* clxv. 23), by converting hexyl alcohol from hircalium oil into the nitril, $C^8H^{14}N$, and decomposing this compound with caustic potash, obtained a heptylic or cenanthylic acid, which boiled at 223° – 224° , the whole column of mercury being in the vapour.

To obtain more precise data as to the identity or diversity of the acids from these several sources, a further examination of cenanthylic acid produced by oxidation of cenanthol has been made by Grimshaw & Schorlemmer (*Chem. Soc. J.* [2], xi. 1073).

To prepare the acid, 300 grams of cenanthol from castor-oil, boiling at 150° – 160° —not quite pure, but still containing some acrolein and other products—was gradually added to a warm solution of 300 grams of potassium dichromate, 400 sulphuric acid, and 900 water. After the action was over the flask was connected with a reversed condenser, and the liquid boiled for some hours. After cooling, the two layers of

liquid were separated, the lower one, containing some cenanthylic acid in solution, was distilled, and the distillate saturated with soda. The upper layer was well shaken with caustic soda, to remove chromic oxide, and the solution of the sodium salt evaporated. On adding sulphuric acid to the concentrated liquid, cenanthylic acid separated out as an oily layer, which was washed with water and dried over phosphorus pentoxide.

The acid thus obtained contains some acrylic acid, and begins therefore to boil a little above 140° ; the boiling point soon rises to 200° , and then more slowly to 230° ; at the same time the liquid blackens, and a dark residue is left in the flask. On rectifying the higher-boiling portion, it again leaves a dark residue, and water is formed; the distillates must therefore be dried over phosphorus pentoxide, and the fractional distillation continued, until the acid has a constant boiling point, does not act any longer on phosphorus pentoxide, and volatilises without leaving a residue.

Properties.—Pure cenanthylic acid is a limpid, oily liquid, boiling under a pressure of 763 mm. at 223° – 224° . The cold acid has a faint smell, like that of tallow, but on heating it becomes unpleasantly sour and pungent. In a freezing mixture it soon solidifies to plates, or large broad needles. It melts and solidifies at -10.5° . Franchimont's heptylic acid melted at -8° , but he adds that, from repeated experiments, the melting point seemed to be two degrees lower. Schorlemmer's heptylic acid from heptane did not solidify in a freezing mixture; but as the heptane from which it was prepared had to be separated by fractional distillation from an isomeric boiling at 7° lower, and from an octane boiling about 17° higher, it probably still retained some of these hydrocarbons, and would yield an heptylic acid contaminated with the corresponding acids.

The specific gravity of cenanthylic acid, compared with water at 4° , is 0.9350 at 0° , 0.9288 at 0° , and 0.9235 at 28° ; that of heptylic acid at 24° is 0.9212.

Ethyl Cenanthylate, $C^7H^{12}(C^2H^5O_2)^2$, prepared by mixing equal volumes of the acid and absolute alcohol with half a volume of strong sulphuric acid, and purified by washing with water and dilute soda-solution, drying over calcium chloride and finally over phosphorus pentoxide, and fractional distillation, boils at 187° – 188° , with the whole mercurial column immersed in the vapour. It has a specific gravity of 0.8735, and does not solidify at -20° . Ethyl heptylate boils at about the same temperature, has a specific gravity of 0.874, and does not solidify at -18° .

Metallic Cenanthylates. The *potassium salt* was obtained only as a transparent jelly. The *sodium salt* crystallises by slow cooling in slender rhmifid needles; from a strong solution quickly cooled it separates in a gelatinous mass in which distinct needles may be recognised by the microscope. Sodium heptylate from Franchimont's acid possesses similar properties.

Barium Cenanthylate, $Ba(C^7H^{12}O_2)^2$, crystallises in thin plates or flat needles, 1.700 grams of which dissolve in 100 c.c. of water. The barium salt of the acid from heptane has very similar properties: 100 c.c. of water dissolve 1.744 grams of it. The barium salt of Franchimont's acid also crystallises in anhydrous thin plates; its solubility was not determined.

Calcium Cenanthylate, $Ca(C^7H^{12}O_2)^2 + H_2O$, forms very thin, flat, fascicular needles which dry up to a silky mass. 100 c.c. of its solution saturated at 8.5° contain 0.17 gram CaO . The calcium salts of the acid from heptane and from Franchimont's acid exhibit similar properties and composition; 100 c.c. of the solution of the former contain also 0.17 gram CaO .

Zinc Cenanthylate, $Zn(C^7H^{12}O_2)^2$, obtained by adding zinc sulphate to the sodium salt, and crystallising the dried precipitate from absolute alcohol, separates in small needles or short four-sided prisms, accordingly as the solution is cooled quickly or slowly.

The crystals, which contain neither alcohol nor water, melt at 130° and decompose at higher temperatures. Franchimont's zinc heptylate crystallises also in short prisms melting at 131° – 132° ; they contain, however, 2 molecules of alcohol.

Lead Cenanthylate, $Pb(C^7H^{12}O_2)^2$, is a heavy precipitate not very freely soluble in boiling water, but it may be crystallised therefrom, and is thus obtained in thin, small, iridescent, rhombic prisms, or in stellate groups of flat needles. The precipitated salt softens at 79° – 80° , and melts to a transparent liquid at 90° . The crystallised salt begins to soften at 88° , liquefies completely at 94° – 96° , and resolidifies at 75° – 76° . Lead heptylate is a similar salt, melting, according to Franchimont, at 78° – 80° .

Copper Cenanthylate, $Cu(C^7H^{12}O_2)^2$, falls down as a soft mass, on adding copper sulphate to a solution of the sodium salt, but on standing the precipitate becomes granular. It is quite insoluble in boiling water, but dissolves readily in absolute

alcohol, and is obtained by spontaneous evaporation in green silky needles, or short prisms.

The copper salt of the acid from heptane, and Franchimont's copper heptylate, are similar precipitates. The former could not, however, be obtained in crystals, but separated from the alcoholic solution as a liquid, drying up to an amorphous mass. Franchimont's copper heptylate also is first obtained in drops, which afterwards solidify to groups of short prisms.

Silver Ceanthylate, $\text{AgC}^{14}\text{H}^{13}\text{O}_2$, is a white precipitate, crystallising from boiling water, in which it is but sparingly soluble, in small, woolly needles.

From the facts above detailed it appears most probable that the heptylic acid prepared from heptane is identical with ceanthylic acid from castor-oil, the barium and calcium salts of the two acids having the same properties, composition, and solubility. Heptylic acid prepared by Franchimont's method also bears the greatest resemblance to ceanthylic acid, only the copper and zinc salts exhibiting slight differences. Whether these are essential or not, can be decided only by preparing the salts under exactly the same conditions, and comparing them directly with each other.

There can be no doubt that ceanthylic acid and heptylic acid are both normal compounds; this, however, does not imply that they are really identical. It is not only possible, but even very probable, that the hexyl alcohol from hemeleum oil, as well as the heptylic acid obtained from it, are optically active, while ceanthylic acid probably does not possess this property.

OILS VOLATILE or ESSENTIAL. The essential oils of plants consist for the most part of mixtures of hydrocarbons with oxidised constituents, the latter being sometimes products of the direct oxidation of the hydrocarbon, in which case they are usually viscid resins, while in other cases the relation between the two constituents of the oil is not apparent.

Hydrocarbons (Gladstone, *Chem. Soc. J.* [2], x. i).—The specific gravities, boiling points, and optical properties of several of these hydrocarbons, were determined by Gladstone in 1864, and are given in the table on p. 188, vol. iv. of this Dictionary. Gladstone now proposes to distinguish them by the following names:

Hydrocarbon from Bay	Laurylene.
" " Calamus	Calamene.
" " Dill	Anetheno.
" " Elder	Sambuceno.
" " Eucalyptus amygdalina	Eucalypteno.
" " Myrtle	Myrteno.
" " Nutmeg	Myristiceno.
" " Rosewood	Rhodieno.

Polymeric Groups.—The hydrocarbons from essential oils may be arranged in three polymeric groups having the formulæ $\text{C}^{14}\text{H}^{14}$, $\text{C}^{16}\text{H}^{16}$, $\text{C}^{18}\text{H}^{18}$; the first comprising the great mass of these hydrocarbons—turpentine, orange, caraway, nutmeg, anise, thyme, myrtle, and twenty others; the second, those derived from cloves, rosewood, cubeba, calamus, cascarrilla, and patchouli; while the third group is represented only by colophene. It is probable, however, that paracajputene belongs to this last group, also that some of the substances named colophene, obtained from various sources, are not identical, but only isomeric, with colophene from turpentine.

These groups are distinguished from one another by several properties, especially by the vapour-density of the hydrocarbons belonging to them, that of the first being nearly equal to, though generally a little above, the theoretical density for $C^{10}H^{18}$, viz. 4.71. Among the bodies of the second group, which should have theoretical density 7.06, cedrene was found by Walter to have a vapour-density of 7.6, and the hydrocarbons from calamus and patchouli have, according to Gladstone's determinations, the vapour-densities 6.80 and 7.2 respectively. The experimental vapour-density given in Gmelin's Handbook for colophene exceeds that which would be required by the formula $C^{20}H^{32}$.

The following table gives a general view of the properties and reactions of the hydrocarbons of the three groups—

	10-Carbon group	16-Carbon group	20-Carbon group
Formula	$C^{10}H^{18}$	$C^{16}H^{24}$	$C^{20}H^{32}$
Vapour-density	4.7	7.1	—
Character of liquid	limpid	viscid	more viscid
Specific gravity at 0°	0.846-0.880	0.904-0.927	0.939
Refractive index for A, at 20°	1.457-1.467	1.488-1.497	1.5084
Dispersion	about 0.027	about 0.020	0.031
Sensitiveness	about 48	about 43	41
Boiling point	160°-176°	249°-280°	315
Action of sulphuric acid	polymerises	doubtful	none
Solubility in aqueous alcohol	freely soluble	sparingly soluble	insoluble
Combination with HCl	$C^{10}H^{18}.2HCl$ and $C^{10}H^{18}.HCl$	$C^{16}H^{24}.HCl$ and in smaller proportions	very small quantity

There is no difference in specific refractive energy between the several groups. The various members of the 10- and 16-carbon groups have powerful odours and rotate the plane of polarisation strongly, sometimes in one direction, sometimes in the other.

OILS CONTAINING OXYGEN.

* Menthol I. was prepared by fractional distillation; menthol II. from the compound with hydrogen sulphide.

Testing of Volatile Oils.—On the mode of distinguishing volatile oils one from the other by mixing them with strong sulphuric acid, or with sulphuric acid and carbon sulphide, whereby mixtures are produced varying in colour and transparency, see Hager (*Zeitschr. anal. Chem.* 1870, 534); Flückiger (*Arch. Pharm.* [2], cxliv, 144; also *Jahresb. f. Chem.* 1870, 1048). Hager finds that many of the more expensive oils are adulterated with sassafras-oil, which addition may easily be detected by the cherry-red colour produced on diluting the sulphuric acid mixture with alcohol.

To detect oil of turpentine in other essential oils, Zeller some years ago proposed the use of alcohol, the slight solubility of turpentine-oil in that liquid giving rise to a turbidity in the mixture. This test has hitherto been regarded by many who have tried it as applicable only when the turpentine is present in considerable quantity; but, according to Dragendorff (*N. Rep. Pharm.* xxii. 1), this want of delicacy arises from the use of alcohol in an undiluted state; for when the oil to be examined is miscible in all proportions with absolute alcohol, it forms with this liquid a mixture capable of dissolving a very considerable proportion of oil of turpentine. If, however, the alcohol be diluted until 2-4 volumes of it are required to dissolve 1 volume of the oil, it will be found that the presence of a small quantity of turpentine is indicated by the decreased solubility of the adulterated oil in the diluted alcohol.

To determine the solubility of an oil in alcohol, 2 c.c. of it are placed in a stoppered bottle, and the alcohol is gradually added from a burette, the mixture being well shaken after each addition. The termination of the experiment is known by the liquid becoming clear. A suspected sample being now similarly treated, it will be found that, if turpentine be present, a larger proportion of alcohol will be required.

In testing essential oils for turpentine by means of alcohol, it must be borne in mind that some other oils, such as those of juniper, savin, eucalyptus, and copaiba are but slightly soluble in dilute alcohol, and that they may, when mixed with other oils, give rise to appearances similar to those produced by oil of turpentine. Moreover, in some cases changes take place in oils which have been kept for a long time, and these must be considered in applying the alcohol test for turpentine.

For the details concerning each individual oil we must refer to the original paper, which also contains a table showing the solubility of turpentine-oil from various sources in spirit of various degrees of concentration.

For the detection of alcohol in essential oils, Hager (*Chem. Centr.* 1871, 821) adds to the oil a piece of solid tannin, which becomes moist and slimy if any spirit is present.

For the estimation of the alcohol, Böttger (*ibid.* 1872, 742) agitates the oil in a graduated tube with an equal volume of pure glycerin. On leaving the liquid to separate, the increase in the volume of the glycerin indicates the amount of alcohol present.

Essential oils, prepared by distillation with water, often retain some of that liquid even when they appear quite clear. The water may be detected by mixing the oil, with several times its volume of petroleum ether (the so-called benzine), whereby a turbidity is produced, owing to the separation of globules of water (G. Leuchs, *J. pr. Chem.* [2], vi. 159).

OLEFINES. On the Production of Olefines from Paraffin by Distillation under Pressure, see PARAFFIN.

OLIBANUM. By distilling this gum-resin with water in a cast-iron retort, an oil is obtained constituting about 7 p.c. of the resin taken; alcohol extracts from the residue about 72 p.c. of resin, and the remainder is gum. The crude oily distillate boils between 160° and 170°, and contains oxygen, as Stenhouse previously observed (*iv.* 198). By fractional distillation a hydrocarbon, olibene, boiling at 156°-158°, of turpentine-like odour, and sp. gr. 0.863 at 12°, is obtained, together with a small quantity of an oxidised substance boiling above 175°, and not yielding a hydrocarbon when treated with sodium. Olibene is soluble in alcohol and in ether, and is resinised by nitric acid; it absorbs 1 mol. of hydrogen chloride, giving, on standing, a crystalline camphor-like body, $C^{10}H^{12}.HCl$, which melts at 127°.

The resin, exhausted as above by alcohol, melts readily, and yields by dry distillation traces of an organic acid and an oil which boils above 360°, and contains less oxygen than the resin itself (Kurbatow, *Zeitschr. f. Chem.* [2], vii. 201).

OLIGOCLASE. See FALSIFAR (pp. 510-514).

OLIVE-OIL. This oil in its natural state contains in solution a yellowish substance which, when the oil is treated with acids or with caustic soda, gives rise to the well-known greenish coloration. By exposure to sunshine this colouring matter is essentially altered, the oil being thereby decolorised and no longer exhibiting a green-

ish colour when treated with the reagents above mentioned. Moreover, other changes take place at the same time in the constituents of the oil, the olein in particular being greatly altered, and acquiring the fundamental property of *elaidin*, namely, that of not solidifying in contact with nitrate of mercury mixed with nitrous products. At the same time free acids are formed, and the oil acquires a rancid taste and odour.

From these results it appears that the method suggested by some authors of distinguishing olive-oil from other oils by means of sulphuric acid, caustic soda, and nitrate of mercury, can be depended upon only when the oil is in its natural state, not altered by exposure to sunshine (L. Moschini, *Gazzetta chimica italiana*, i. 580).

On the detection of *Earthenut-oil* in Olive-oil, see p. 443.

OLIVIN. The olivin of the Pallas meteoric iron has been examined by N. v. Kokscharow (*Jahrb. f. Mineralogie*, 1870, 778), who, in addition to the forms discovered by G. Rose, has observed the following:— $\frac{1}{2}P$, $\frac{1}{4}P$, mPn , $\frac{1}{2}P\infty$, $\frac{1}{4}P\infty$, and $P\infty$, which, excepting the last two, are new for olivin. Numerous measurements gave, for the ratio of principal axis, macrodiagonal and brachydiagonal, 1.25928 : 2.14706 : 1. An examination of thin sections showed that the channels observed by G. Rose are empty, and run parallel to the principal axis. An analysis by N. v. Leuchtenberg gave:—

SiO ²	SnO ²	MgO	FeO	MnO	Al ² O ³	Sp. gr.
40.24	0.08	47.41	11.80	0.29	0.06 = 99.88	3.3398

The following analyses by Philipp of the olivin in the olivin-rock of the Dreiser Wogher Basalt, in the Eifel, is given by Rammelsberg (*Zeitschr. geol. Gesellschafts.* xx. 899):—

SiO ²	MgO	FeO	Sp. gr.
41.25	48.85	9.90 = 100.0	3.36

The analysis gives Fe : Mg = 1.0.

The olivin-rock above mentioned has been analysed by Rammelsberg with the following results: A. Decomposable portion; B. undecomposable; C. The decomposable portion calculated to 100 parts.

	SiO ²	Al ² O ³ , Cr ² O ³	MgO	CaO	FeO	Chrom-iron	
A. .	27.41	—	34.24	trace	6.85	—	= 68.50
B. .	15.57	1.74	8.35	2.29	1.74	1.00	= 30.69
C. .	40.02	—	49.98	trace	10.00	—	= 100

The numbers in C, compared with those in the analysis of olivin above given, show that the latter only is decomposed by acids, while the augitic substance, as shown by the mere trace of CaO, is scarcely attacked.

Kraubat, in Upper Styria, is mentioned by R. v. Drascho (*Min. Mitth.* 1871, 57) as a new locality of olivin rock.

F. Sandberger (*Jahrb. f. Mineralogie*, 1871, 622) mentions a patito as a hitherto overlooked constituent of olivin rock. In the rock of Lherz, A. Hilger found 0.096 to 0.112 p.c. P²O⁵. Traces of cobalt were also found in it.

OPAL. An elaborate investigation of numerous opals has been made by H. Behrens (*Wien. Acad. Ber.* 2te. Abth. lxiv. 519; *Jahrb. f. Mineralogie*, 1872, 316). The following minerals occur as admixtures with the opal mass: hydrophane (recognisable by impregnation with colouring matters), quartz, ferric oxide and hydrate, nontronite, green earth, serpentine, arsenic sulphide, and lime. Organic matter occurs but rarely and in small quantity.

Opals may be distinguished, according to their microscopic structure, as homogeneous and mixed opals. To the former belong fire-opal, glass-opal, noble opal, and hyalite; the latter sometimes exhibits an irregular, mostly stratified, occasionally also an oolitic structure, due in some cases to concretions of tridymite. The play of colours is attributed by Behrens to their reflecting lamellae, which appear to have been originally imbedded horizontally in the still soft opal mass, but afterwards to have become fissured and notched during the irregular desiccation of the mass. That an unequal contraction has taken place is shown by the strong double refraction. All noble opals are biaxial. The horizontally arranged cavities to which Brewster ascribed the play of colours, Behrens was unable to detect.

An opal from Waddela plain, Abyssinia, has been analysed by Maskelyne & Flight (*Chem. Soc. J.* [2], ix. 2). It is of a dark smoky green colour, with occasional layers of white opal, like the prase-opal of Faros, weathered on the exterior, and passing into yellowish-white cacholong:

SiO_2	H_2O	Fe^{+2}O	Mn^{+2}O	CaO	MgO	
sol.	insol.					
90.562	2.049	5.666	0.933	trace	0.137	0.311 = 99.648

Most, if not all, of the water, is given off at 100° .

Opal from S. Piero in Elba is described by G. vom Rath (*Zeitschr. geol. Gesellsch.* xxii. 643). It occurs in flat lumps collected in veins in a disintegrated serpentine bordering on granite. The fresh nearly colourless opal has a sp. gr. of 1.990 (at 21°), and loses 9.48 p.c. by ignition. After ignition its sp. gr. is 1.815. No microscopic tridymite was found in it. Black opal containing garnet, like that of Meronitz in Bohemia, also occurs in loose blocks at S. Piero. Sp. gr. before ignition, 2.062 (at 21°); after ignition, 1.953. Loss by ignition, 6.36.

OPIANIC ACID, $\text{C}^{10}\text{H}^{10}\text{O}^6$. By the action of sulphuric acid upon opianic acid, Anderson, in 1855, obtained a colouring matter which yielded with alumina and iron mordants, colours like those of madder, and was regarded by him as probably identical with alizarin (*Chem. Soc. Qu. J.* viii. 277). This colouring matter has been further investigated by Liebermann a. Chojnacki (*Deut. Chem. Ges. Ber.* iv. 194). To prepare it, opianic acid is heated to 180° with 30 times its weight of strong sulphuric acid, whereupon the liquid becomes violet-red. On pouring the cooled mass into water, the impure colouring matter separates in black flocks, which may be obtained of yellow-brown colour by repeated solution in caustic soda, filtration, and precipitation with acid. By dissolving them in ether and evaporating, yellowish-red crusts are obtained, which may be purified by several repetitions of the entire process.

This colouring matter distilled with zinc-dust yields a colourless sublimate which has not been analysed, but appears from its properties to be anthracene. The colouring matter dissolves in potash with the colour of purpurin, but is distinguished from this compound, as well as from alizarin, by the violet-red colour of its solution in strong sulphuric acid, which, on the other hand, exactly resembles that of rufgallic acid. This acid, however, dissolves in potash with blue colour, and is quickly precipitated from the solution in contact with air, a reaction not exhibited by the colouring matter from opianic acid. With lead and barium solutions coloured precipitates are obtained; mordants are dyed with colours resembling those produced by rufgallic acid more than those of alizarin. On subliming the colouring matter, the greater part of it is carbonised. The analysis of the unsublimed substance gave numbers agreeing nearly with the formula $\text{C}^{10}\text{H}^{10}\text{O}^6$, but Liebermann a. Chojnacki are of opinion that this formula does not express the true composition of the substance.

Hypogallic acid treated with sulphuric acid does not yield any colouring matter, but is decomposed, with evolution of gas.

Liebermann a. Chojnacki assign to opianic acid the constitutional formula

volatile oil having exactly the odour of methyl-pyrocatechin. Heated to 200° with dilute hydrochloric acid, it yields, with elimination of carbon dioxide, several well-crystallised acids of more simple constitution.

OPIUM. On the estimation of Morphine in Opium, see MORPHINE (p. 818).

In opium grown at Hancock, Vermont (U.S.) W. Procter (*Arch. Pharm.* [2] cxlii. 237) found 16.75 p.c. morphine, 2.00 narcotine, 5.25 meconic acid, 11.00 caoutchouc, fatty substances and resins, 22.00 insoluble matter, 38.50 substances soluble in water and different from the salts of morphine and narcotine, and 5.00 water.

In opium from the south coast of the Victoria Colony, J. S. Ward (*Pharm. J. Trans.* [3], i. 628), found 9 p.c. morphine, 4 narcotine, and 6 meconic acid.

OPIUM BASES. O. Hesse (*Ann. Ch. Pharm. Suppl.* band viii. 261; *Zeitschr. f. Chem.* [2], vii. 641; *Deut. Chem. Ges. Ber.* iv. 693). The papers here cited contain a continuation of Hesse's observations on the rarer opium bases (1st *Suppl.* p. 883).

In these later experiments Hesse has examined the mother-liquors obtained in the Robertson-Gregory process (iv. 1051) for extracting morphine (conversion into hydrochlorides by addition of calcium chloride to the opium extract, and crystallisation of the morphine, pseudomorphine, and codeine salts from the liquor). On addition of an excess of ammonia to the mother-liquor diluted with its own bulk of hot water, an inconsiderable resinous precipitate of lantopins is produced, the other bases remaining in solution. By agitation of the filtrate with ether, and of the ethereal extract with acetic acid, a mixture of acetates is obtained. Caustic soda added in excess precipitates papaverine, narcotine, thebaine, some cryptopine, and the three

new bases, protopine, laudanose, and hydrocotarnine, while the alkaline filtrate contains in solution lanthopine, laudanine, some cryptopine, meconidine (?) and codamine. These last are again converted into acetates by the ether process, and the liquid is neutralised with ammonia. A little lanthopine separates after twenty-four hours, and the filtrate yields, with ammonia, a precipitate soluble in boiling dilute alcohol. On cooling, crystals of a mixture of laudanine and cryptopine separate. The alcoholic filtrate was found to contain no meconidine, although this base should be here obtained, whence Hesse concludes that the meconidine is decomposed by the Robertson-Gregory process, though not by the process adopted in his former experiments. By evaporation of the alcoholic solution, and treatment with ether, a solution was formed, from which codamine was obtained, either by addition of fused calcium chloride, which causes water, colouring matters, and crystals of codamine to separate, or by conversion into acetate, thence into hydriodide, and purification of the latter.

The precipitate insoluble in caustic soda is digested with diluted alcohol, and acetic acid added till litmus-paper is faintly reddened by it. Addition of three times the volume of boiling water produces a crystalline precipitate of papaverine and narcotine (these bases not neutralising acetic acid). The filtrate freed from alcohol by evaporation, gives, on addition of strong hydrochloric acid, a precipitate of cryptopine hydrochloride; but this method is not to be recommended, as the acid converts some of the thebaine into thebaineine (a non-crystalline isomeride), which interferes with the separation of the other bases. A better plan is to add tartaric acid, which causes a copious crystallisation of thebaine bitartrate. The mother-liquor of this is neutralised by ammonia, and mixed with 3 p.c. of its weight of sodium bicarbonate made into a paste with water. After about a week, a black pitchy mass separates. The filtrate from this gives with ammonia a precipitate which is treated with boiling benzene, the filtrate being also extracted with benzene. Cryptopine and protopine then remain undissolved, while on shaking the benzene solution with a saturated aqueous solution of sodium bicarbonate, laudanose crystallises out; and the benzene filtrate from this, treated with gaseous hydrogen chloride, yields hydrochloride of hydrocotarnine.

Hesse describes narcotine as existing in the mother-liquors of the Robertson-Gregory process, but does not state how, or at what stage, it is separated from the other bases.

Pseudomorphine, $C^{17}H^{10}O^4$, is found only occasionally in opium, being observed only once in good Smyrna opium during four years. It gives crystals with H^2O and $4H^2O$. It forms a nitro-substitution product, which rapidly disappears in nitric acid. Reducing agents (sulphurous acid, sulphuretted hydrogen, nascent hydrogen) have no action on it.

Lanthopine, like pseudomorphine, narcotine, and papaverine, does not neutralise acetic acid. It gives no colour with ferric chloride.

Laudanine, $C^{20}H^{23}NO^4$, and *Cryptopine* are separated by dilute caustic soda, which dissolves the latter only sparingly. The filtrate is treated with sal-ammoniac, the precipitate thereby formed is dissolved in acetic acid, and potassium iodide added, whereby a hydriodide of laudanine, free from cryptopine, is obtained. Concentrated caustic potash solution gives a crystalline compound with laudanine. Hesse formerly found $C^{20}H^{23}NO^3$ as the formula of laudanine, but he now adopts $C^{20}H^{23}NO^4$. For cryptopine he gives the formula $C^{21}H^{23}NO^3$. The body analysed by T. and H. Smith, to which they attributed the formula $C^{21}H^{23}NO^3$, was contaminated with thebaine. The observation of these chemists, that the base forms two hydrochlorides, the one containing $C^{21}H^{23}NO^3 \cdot HCl \cdot 5H^2O$, the other, $C^{21}H^{23}NO^3 \cdot 2HCl \cdot 6H^2O$, is erroneous, only one, $C^{21}H^{23}NO^3 \cdot HCl \cdot 6H^2O$, being produced. Nitric acid of sp. gr. 1.06 forms nitro-cryptopine, which forms well characterised salts, the base being anhydrous, crystalline, and melting at 185° . Its formula is $C^{21}H^{22}(NO^2)NO^3$, which is the same as that of crystallised nitropapaverine, with which, however, it is not identical, the latter containing water of crystallisation = $C^{21}H^{22}(NO^2)NO^4 \cdot H^2O$.

Codamine, $C^{20}H^{23}NO^4$, melts at 126° when crystallised from benzene, and at 120° when from alcohol or ether; ferric chloride gives a fine dark-green colour, with separation of ferric oxide; it appears to form compounds with caustic alkalis. Hesse now adopts the formula $C^{20}H^{23}NO^4$, instead of the earlier one, $C^{20}H^{23}NO^3$.

Narcotine, $C^{20}H^{23}NO^3$.—Hesse corroborates the formula ascribed to this base by Matthiessen and Foster, in place of the older one, $C^{21}H^{23}NO^3$; the base is separated from papaverine by solution in boiling water containing one-third part of oxalic acid; on cooling, the acid papaverine oxalate crystallises out; this process is repeated several times, and, finally, the narcotine is precipitated by ammonia and crystallised from boiling alcohol. It melts at 176° , and decomposes at a few degrees higher. On

boiling with baryta-water, narcotine forms a base much resembling hydrocotarnine readily soluble in ether, which Hesse supposes to be formed by the reaction—

and he infers that narcotine is decomposed by water in the same way, and not in the manner stated by Matthiessen & Wright (*1st Suppl.* 863), viz:—

Papaverine, $\text{C}^{21}\text{H}^{21}\text{NO}^4$.—Hesse formerly showed that the pure base has this composition, and not that which was formerly attributed to it, viz., $\text{C}^{22}\text{H}^{22}\text{NO}^4$, and he considers that the supposed new derivative obtained from it by E. L. Mayer (*Deut. Chem. Ges. Ber.* iv. 128), by the action of zinc chloride, and considered by him to be formed by the reaction—

is nothing but papaverino, Mayer's numbers agreeing well with those required for the formula $\text{C}^{21}\text{H}^{21}\text{NO}^4\cdot\text{HCl}$.

Papaverino treated with nitric acid of sp. gr. 1.06 is converted into nitropapaverine, $\text{C}^{21}\text{H}^{20}(\text{NO}^2)\text{NO}^4 + \text{H}^2\text{O}$, which, when crystallised in the dark, is colourless, but becomes yellow in the light; the water of crystallisation is given off only at 163° , when the substance melts and becomes coloured.

Protopine, $\text{C}^{20}\text{H}^{19}\text{NO}^4$, is separated from cryptopine by precipitation of the solution of the mixed hydrochlorides with strong hydrochloric acid; the protopine salt is horny, and adheres to the sides of the vessel, and is easily freed from the cryptopine salt by a little washing with water: a quantity of material that gave 80 grams of cryptopine, gave only about $1\frac{1}{2}$ of protopine. It gives no colour with ferric chloride.

Laudanosine, $\text{C}^{21}\text{H}^{21}\text{NO}^4$, crystallises from alcohol, hot benzene, or ether; it melts at 89° , and gives no colour with ferric chloride.

Hydrocotarnine, $\text{C}^{12}\text{H}^{12}\text{NO}^3 + \frac{1}{2}\text{H}^2\text{O}$, dissolves readily, and without coloration, in alcohol, acetone, chloroform, benzene, and ether, and crystallises readily from the latter. The crystals melt at 50° , losing all their water of crystallisation at 57° . At 100° , a great loss of weight is perceptible, without any appreciable alteration in composition; it cannot, however, be distilled under the ordinary pressure.

Pure sulphuric acid gives, on warming, distinctive colorations with the opium alkaloids, the tints being much altered in many cases by traces of impurity of iron or oxides of nitrogen. By this means Hesse divides the opium alkaloids into groups:—

I. α . Morphine, Pseudomorphine, Codeine.	Dirty dark-green (morphine group).
β . Laudanine, Codamine, Laudanosino.	Dirty red-violet (laudanine group).
II. Thebaine, Cryptopine, Protopine.	Dirty green to brown-green (thebaine group).
III. α . Papaverine.	Dark violet (papaverine group).
β . Narceine, Lanthopine.	Black-brown to dark-brown (narceine group).
IV. Narcotine, Hydrocotarnine.	Dirty red-violet (different shade from that of I. β) (narcotine group).

Group I. β give a dark-violet tint with acid containing iron, while IV. give still a dirty-red violet, as with the pure acid.

OPIUM WAX. See CERYLIC ETHERS (p. 276).

ORANGE-PEEL OIL. (Wright & Piosse, *Chem. Soc. J.* [2], ix. 1186; Wright, *ibid.* xi. 552). It has been shown by Soubeiran & Capitaine, also by Gladstone, that the essential oil of orange-peel consists mainly of a hydrocarbon $\text{C}^{18}\text{H}^{14}$, called hesperidene, boiling at 174° . This result is confirmed by the experiments of the authors above cited. The pure oil begins to boil at 175° , and 97.8 p.c. goes over below 180° , the remainder consisting of a soft yellow resin, inodorous when quite free from hesperidene, having a bitter aromatic taste, and only slightly soluble in alcohol either cold or hot. It contains 75.6 p.c. carbon, and 9.7 hydrogen, agreeing with the formula $\text{C}^{18}\text{H}^{14}$. On distilling it, a few drops passed over between 180° and 280° ; the portion collected at 240° – 260° had the composition $\text{C}^{16}\text{H}^{12}\text{O}^2$. The small portion distilling over between 210° and 230° appeared to be identical with myristic oil, $\text{C}^{18}\text{H}^{16}\text{O}$.

* With reference to this, Wright observes that the experiments by himself and Matthiessen above quoted have distinctly shown that pure meconin may be obtained by heating narcotine with water in sealed tubes (*Chem. Soc. J.* [3], ix. 738).

Hesperidene does not contain cymene, for on agitating it with strong sulphuric acid (to polymerise the terpene), diluting with water after 24 hours, and distilling in a current of steam, a distillate is obtained which does not yield a trace of terephthalic acid when treated with chromic acid mixture. Nevertheless the heat developed by agitating hesperidene with sulphuric acid is sensibly less than that which is evolved by the action of sulphuric acid on an equal quantity of the nutmeg hydrocarbon boiling at 163° – 164° , although this latter contains a considerable quantity of cymene which is not acted on by the sulphuric acid (p. 862). A similar difference is observed when bromine is dropped into the two hydrocarbons, the nutmeg product developing much more heat than that from orange-oil, although the product in each case is a dibromide, $C^{10}H^{16}Br^2$. This difference in the quantities of heat evolved from the two isomeric hydrocarbons under similar circumstances is doubtless related to the diversities in their boiling-points and other physical properties.

Hesperidene dibromide is resolved by heat into hydrogen bromide and cymene: $C^{10}H^{16}Br^2 = 2HBr + C^{10}H^{14}$ (p. 419). When hesperidene is boiled for several days with a large excess of dilute chromic acid mixture, about 1 p.c. of it is oxidised to myristical $C^{10}H^{16}O$; the greater portion is, however, completely oxidised to carbonic acid and water; and, on distilling the product, a distillate is obtained containing acetic acid, with perhaps a trace of formic acid. No terephthalic acid is produced (Wright).

ORCIN, $C^7H^8O^2$. This compound may be formed synthetically from toluene. On heating chlorotoluene, $C^7H^5Cl.CH^3$, to 100° for some hours with sulphuric acid, two isomeric chlorocresylsulphurous acids, $C^7H^4Cl.SO^2H$, are produced, which may be separated by the fractional crystallisation of their barium salts. The less soluble salt, *barium α -chlorocresylsulphite*, $(C^7H^4ClSO^2)^2Ba + 2H^2O$, forms beautiful colourless rhombic plates, whilst the other, viz.: *barium β -chlorocresylsulphite* $(C^7H^4ClSO^2)^2Ba + 1\frac{1}{2}H^2O$, which is much more soluble, crystallises in mammellated tufts consisting of small crystalline grains. The *potassium α -chlorocresylsulphite*, obtained by double decomposition from the corresponding barium salt, forms nacreous plates, moderately soluble both in cold water and in boiling alcohol. When this salt is fused with twice its weight of potassium hydrate, it becomes brown, and gives off hydrogen, while orcin, salicylic acid, and cresol are produced. The aqueous solution of the fused mass is agitated, first with benzene to remove the salicylic acid and cresol, then with ether, which dissolves the orcin and leaves it in an impure state on evaporation. This orcin when purified is identical both in its properties and crystalline form with the orcin prepared from the lichens, which is therefore a toluenediphenol, $C^7H^4.HO.HO$.

Orcin is the principal product of this reaction, the cresol and salicylic acid formed at the same time resulting from the action of the potassium hydrate on the potassium cresylsulphite; the latter is produced from the potassium chlorocresylsulphite by the reducing action of the hydrogen formed during the fusion (Vogt u. Henninger, *Compt. rend.* lxxiv. 1107).

Chlor- and Brom-orcins. These compounds, some of which are described in vol. iv. pp. 213, 214, have lately been further examined by Stenhouse (*Proc. Roy. Soc.* xx. 72), who has also obtained the penta-compounds.

Pentachlororcine, $C^7H^2Cl^5O^2$, is formed when a solution of orcin is added to a pulpy mixture of chlorine hydrate and water, or to a mixture of potassium chlorate and hydrochloric acid, care being taken to keep the chlorinating mixture in excess. The crude product is then purified by crystallisation from carbon sulphide. It forms large colourless prisms, which melt at 120.5° . It is moderately soluble in carbon sulphide and benzene, readily in ether. It is but very slightly soluble in water, to which, however, it communicates an exceedingly disagreeable and persistent bitter metallic flavour. It appears to suffer decomposition when boiled either with alcohol or with water, trichlororcine being one of the products formed in the latter case.

Pentachlororcine hypochlorite, $C^7H^2Cl^5O^2 = C^7H^2Cl^5O^2.HClO$.—When orcin is treated with hydrochloric acid and a solution of calcium hypochlorite, the two latter being in excess, a turbid solution is obtained, which, after the lapse of 24 hours, deposits white crystals. These, when crystallised from benzene, form colourless transparent prisms of great dispersive power, which melt at 140.5° . This compound is very soluble in ether, but, unlike pentachlororcine, only sparingly soluble in carbon sulphide. It is decomposed by hydriodic acid and phosphorus, but the product has not yet been examined.

Trichlororcine, $C^7H^2Cl^3O^2$, is readily obtained by the reduction of pure pentachlororcine with hydriodic acid and amorphous phosphorus. It is moderately soluble in boiling water, and crystallises out on cooling in colourless transparent needles, which melt at 123° . It is but sparingly soluble in carbon sulphide, moderately in

petroleum oil and benene, and excessively soluble in ether and alcohol. It dissolves in hot glacial acetic acid, from which it crystallises in thin transparent plates which become white and opaque on the addition of water. Heated to 180° with hydriodic acid and phosphorus, it is reconverted into orcin (Stenhouse).

Pentabromorcin, $C^6H^3Br^5O^2$, is easily prepared by adding an aqueous solution of orcin, with constant agitation, to a mixture of bromine and water, taking care that the bromine is in slight excess. Its solution in carbon sulphide, in which it is moderately soluble, yields very large and almost colourless transparent crystals, melting at 126°. It is almost insoluble in water, very soluble in alcohol and ether, and moderately so in benzene. Pentabromorcin, when boiled with phosphorus and strong hydriodic acid, passes into solution, probably as orcin; but with very weak hydriodic acid, tribromorcin is formed, identical with that described by Stenhouse, and subsequently examined by Laurent and Gerhardt, and by Lamparter (iv. 213).

Pentabromorcin, heated to 150°-160°, gives off 2 at. bromine, leaving the compound $C^6H^3Br^3O^2$, which crystallises from chloroform in minute yellow scales. This com-

pound may be regarded as tribromorcinquinone, $C^6H^3Br^3 \begin{matrix} \diagup O \\ \diagdown O \end{matrix}$ (Liebmann & Dittler,

Ann. Ch. Pharm. cxlix. 252).

Iodorcin, $C^6H^3IO^2$, is prepared by dissolving 1 part of orcin and 2 of iodine in 6 parts of ether, and gradually adding 9 parts of finely-powdered litharge. The colour of the solution rapidly disappears, and heat is developed. On distilling off the ether, and exhausting the residue with hot benzene, the iodoricin separates in the crystalline state on cooling. When pure, it forms colourless prisms which melt at 86.5° and decompose, with evolution of violet vapours of iodine, when heated. It is only slightly soluble in cold water, but dissolves readily in hot water, the substance undergoing decomposition when the solution is boiled. It is very soluble in ether and alcohol, moderately so in benzene and in hot petroleum, slightly in carbon sulphide. It is quite destitute of the peculiar astringent sweet taste so characteristic of pure orcin. Mercuric oxide may be employed instead of lead oxide in its preparation, but, from the solubility of mercuric iodide in most liquids, it is not so advantageous (Stenhouse, *Proc. Roy. Soc.* xxii. 53).

Trinitro-orcinic acid, $C^6H^3(NO^2)^3O^2$ (Stenhouse, *Proc. Roy. Soc.* xix. 410). Orcin treated with nitric acid at ordinary temperatures yields nothing but resinous uncrystallisable substances and ultimately oxalic acid; but by proceeding in the following manner, a crystalline nitro-compound may be obtained.

Colourless orcin, prepared from ordinary orcin by distillation in a vacuum, is dissolved in a small quantity of water, and this solution is gradually added to strong nitric acid, cooled to -10°. The pale brown solution thus obtained is now added, with constant stirring, to concentrated sulphuric acid, also maintained at -10°, and the resulting pasty mass, after remaining in the freezing mixture for fifteen or twenty minutes, is poured into a mixture of water and crushed ice; the crude nitro-orcin is thus precipitated as an orange-coloured granular powder amounting to 150 p.c. of the weight of the orcin.

One or two recrystallisations from boiling water render the nitro-orcin pure. It then forms large yellow needles having the composition above stated, readily soluble in hot water, but slightly in cold, and still less so in dilute acids. It is soluble in alcohol, very soluble in hot benzene, and crystallises out in great part on cooling; less soluble in ether, and but moderately so in carbon sulphide. It dyes the skin yellow like picric acid, but is tasteless. It volatilises slightly at 100°, melts at 162°, and decomposes with slight explosion immediately afterwards. When heated with concentrated sulphuric acid, it dissolves, forming a deep yellow solution, which deposits crystals on cooling, and is immediately precipitated by water. It dissolves in hot, strong nitric acid, with evolution of nitrous fumes and formation of oxalic acid. It yields chloropicrin when treated with calcium hypochlorite at the ordinary temperature. Its aqueous solutions are coloured dark brown by ferric chloride, and completely precipitated by lead subacetate. It is a powerful acid much resembling picric acid.

The **potassium salt**, $C^6H^2(NO^2)^3 \begin{matrix} \diagup O \\ \diagdown O \end{matrix} K$, prepared from potassium carbonate and trinitro-orcinic acid, is very soluble in hot water, and crystallises in needles of a deep orange colour. The **sodium salt**, like the potassium salt, forms orange-coloured needles; the **ammonium salt** forms deep yellow silky needles, which are very soluble in water, but much less so in alcohol. The **barium salt**, $C^6H^2(NO^2)^3 \begin{matrix} \diagup O \\ \diagdown O \end{matrix} Ba$, $O^2 + 3H^2O$,

prepared by neutralising a boiling solution of 1 part of nitro-orein in 500 of water with barium carbonate, forms bright yellow needles, which lose their water of crystallisation at 100° , and become orange-red. The *calcium salt* forms yellow needles which are very soluble in hot water. The *magnesium salt* is very soluble in cold water, and crystallises in minute orange needles. The *lead salt*, $\text{C}^{\text{H}}(\text{NO}^2)^3\text{Pb}\text{O}_2$, prepared by precipitating a very dilute aqueous solution of nitro-oreinic acid with an acidulated solution of lead acetate, forms tufts of microscopic needles, which are almost insoluble in cold water, slightly in hot. It crystallises unaltered from acetic acid. The *copper salt* is very soluble in water and alcohol, and crystallises in reddish-brown needles; the *zinc salt* forms tufts of yellow needles, which are likewise very soluble. The *silver salt*, $\text{C}^{\text{H}}(\text{NO}^2)^3\text{Ag}_2\text{O}_2$, prepared from the acid and silver oxide, forms an orange-red, gelatinous mass, which exhibits no signs of crystallisation. It is slowly decomposed by long boiling.

Ethyl trinitro-oreinate, $\text{C}^{\text{H}}(\text{NO}^2)^3\text{(C}^2\text{H}_5\text{)}\text{O}_2$, prepared by boiling the silver salt with excess of ethyl iodide, crystallises from alcohol in bright yellow prismatic needles, which melt at 61.5° . *Methyl trinitro-oreinate* very closely resembles the ethyl compound, but melts at 69.5° .

Amidorecins (Stenhouse, *Proc. Roy. Soc.* xxi. 122).—*Amido-diimido-orein*, $\text{C}^{\text{H}}(\text{NH}^2)(\text{NH})\text{O}_2$.—This base is produced by the oxidation of the triamido-orein prepared by the action of reducing agents, such as sodium-amalgam, tin and hydrochloric acid, or zinc and an acid, on trinitro-orein. It is better, however, to treat trinitro-orein, suspended in water, with sodium-amalgam in a closed vessel until the solution becomes colourless, then to oxidise the clear solution by agitating it with air until it assumes a brilliant blue colour; and finally to precipitate the amido-diimido-orein thus formed as hydrochloride by the addition of an excess of strong hydrochloric acid. On treating the hydrochloride with a slight excess of dilute ammonia, it is decomposed, leaving the free base in an impure state. This is dissolved in warm dilute acetic acid, filtered, and precipitated by a slight excess of ammonia. Two or three solutions and reprecipitations suffice to render it pure, when it forms small needles, having a deep green metallic lustre by reflected light. They are insoluble in most liquids; a solution of sodium hydrate, however, dissolves them with a fine deep blue colour. Treatment with sodium-amalgam reconverts them into triamido-orein.

The *hydrochloride*, $[\text{C}^{\text{H}}(\text{NH}^2)(\text{NH})\text{O}_2]\text{HCl}$, crystallises, according to circumstances, either in long silky needles of a brownish-red colour, in rhomboidal plates, or in dark-red thick prisms. It is insoluble in alcohol and ether, moderately soluble in cold, and easily in boiling water, but is at the same time partially decomposed. The *sulphate*, $[\text{C}^{\text{H}}(\text{NH}^2)(\text{NH})\text{O}_2]^2\text{SO}_4 + \text{H}_2\text{O}$, forms minute lustrous plates, which are purple by reflected light, and much less soluble in water than the hydrochloride. The *nitrate* closely resembles the sulphate in appearance, but is much more soluble in water. The *oxalate* is obtained in very slightly soluble purple scales, and the *picrate* in iridescent green needles and plates, which are insoluble in alcohol and almost insoluble in water. The *acetate*, which is very soluble in cold water and does not crystallise well, is prepared by dissolving the free base in acetic acid. As the aqueous solutions of the amido-diimido-orein salts are decomposed under the influence of heat, it is best to prepare them by adding the corresponding acid to a solution of the acetate.

Triamido-orein.—On boiling trinitro-orein with tin and hydrochloric acid until it becomes colourless, separating the tin by hydrogen sulphide, and evaporating the solution in a vacuum, long colourless needles of triamido-orein hydrochloride are obtained, but owing to their great solubility and the readiness with which they absorb water and deliquesce, the salt has not been obtained in a state fit for analysis. On passing a current of sulphuretted hydrogen through a solution of ammonium sulphhydrate in which amido-diimido-orein is suspended, the latter rapidly loses its colour and becomes converted into a sandy deposit consisting of colourless crystals. These are apparently triamido-orein, and on exposure to the air rapidly acquire a metallic green lustre and become converted into amido-diimido-orein. They also dissolve in hydrochloric acid, the solution acquiring a deep red colour and depositing crystals of amido-diimido-orein when exposed to the air.

O'RILEYITE. This is a native arsenite from Burmah, described by D. Waldo (*Chem. News*, xlii. 19). It is steel-grey with metallic lustre on the fresh surface, black and earthy on tarnished faces. Hardness = 5.3. Sp. gr. = 7.243 to 7.423.

Analysis A shows the complete composition, B the mean of two determinations of the chief constituents:

Cu	Fe	As	Sb	X*	Y†
12.13	43.12	38.45	0.54	0.12	6.19 = 100.55
13.28	43.88	37.03			

* Earthy admixtures.—† Dissolved after 12 hours' digestion with dilute sulphuric acid, and consisting of 1.21 CaO, 1.97 FeO, 1.89 PbO, and 1.12 As²O₃.

ORTHOCLASE. See FELSPAR (p. 508).

OSSEIN. *Bone Cartilage* (i. 619).—In the organic matter of fossil bones, A. Scheurer-Kestner (*Compt. rend.* lxx. 1179; further, *J. Pharm.* [4], xvii. 111) distinguishes a soluble and an insoluble ossein. The latter is not dissolved by weak hydrochloric acid containing only 0.5 p.c. HCl, but is dissolved by stronger acid. Treated with acid of this strength, a mammoth-bone yielded 63.7 p.c. insoluble and 36.3 soluble ossein, and the bone of *Ursus spelæus* yielded 37.4 insoluble and 62.6 soluble ossein. The soluble ossein exists ready formed in fossil bones, and is not formed—at least not altogether—by the action of the hydrochloric acid on ordinary ossein.

OXALIC ACID, C²H²O⁴. *Formation.*—According to Bertholot (*Compt. rend.* lxx. 256) charcoal (from spindle-tree wood) is attacked by solution of chromic acid, yielding a small quantity of oxalic acid. According to Wippermann (*Deut. Chem. Ges. Ber.* iii. 337) oxalic acid is found amongst the products of the action of ethyl dibromacetate on the mixture of sodacetic ethers obtained by Frankland and Duppa. According to Carius the formation of oxalic acid under these circumstances is due to the decomposition of the ethyl dibromacetate by the sodium ethylate which is likewise present.

Recovery from the Residues of the 'Discharge' process.—When cloth which is in parts impregnated with tartaric or oxalic acid, or both, is passed through the discharge-vat, which contains chloride of lime with a greater or smaller excess of lime, decomposition takes place, and the acids are converted into their calcium salts, which, being insoluble, settle, together with the excess of undissolved lime, at the bottom of the vat. If the slimy deposit so produced is allowed to remain in the working vat for some weeks, with frequent agitation, it becomes continually richer in the salts and poorer in free lime, till it attains even such a percentage of the former as 65.5 p.c. calcium tartrate, and 18 p.c. calcium oxalate.

From this mixture, washed and somewhat diluted with water, the acids are liberated by addition of a previously determined quantity of sulphuric acid of 1.568 sp. gr., and after stirring and boiling with as much more water as is equal to the weight of the original deposit, the liquid is separated from the calcium sulphate by means of a centrifugal machine. Any excess of sulphuric acid contained in the liquid is removed by boiling with barium tartrate.

This method affords still better results when chloride of soda (Eau de Labarraque) is employed in the discharging vat in place of the chloride of lime. As the tartrate and oxalate of sodium remain in solution, it is only necessary to add from time to time a sufficient quantity of chloride of lime solution to precipitate all the tartaric and oxalic acids as lime salts, and to restore the original working strength of the vat. In this case the precipitate will contain no calcium hydrate or carbonate, and consequently a great saving of sulphuric acid will be effected.

A further advantage is found to follow the use of the soda-solution, namely, that the whites are whiter, and the reds are less injured, than when the chloride of lime is employed (A. Müller, *Chem. Centr.* 1871, 134).

Reactions.—According to G. Bizio (*Zeitschr. f. Chem.* vi. 52) oxalic acid in very dilute solution is oxidised by the oxygen of the air, in shorter or longer time according to the temperature; but in more concentrated solutions this oxidation does not take place.

According to P. Carles (*Compt. rend.* lxxi. 226) when a stream of pure oxygen is passed through a strong solution of oxalic acid, no carbonic acid is formed at ordinary temperatures; but if the oxalic acid be heated to 100°, and oxygen, hydrogen, or nitrogen passed through it, the gas which passes off precipitates barium carbonate from baryta-water, and reduces silver solution. Carles infers from this that the oxalic acid is split up into carbon dioxide and formic acid, and thinks that Bizio's result may be explained in a similar manner.

Oxalates. The following table of the solubility of oxalic acid and several metallic oxalates in water is given by W. R. Nichols (*Chem. News*, xxii. 14).

2nd Sup.

3 L

Solubility of Oxalates.

	Tempera- ture	Quantity of water required to dissolve 1 part of salt
Oxalic acid, $C^2H^2O^4 + 2H^2O$	14° 5	10·46
Neutral sodium oxalate, $C^2Na^2O^4$	13	31·60
Acid sodium oxalate, $C^2NaHO^4 + H^2O$	10	67·57
Neutral potassium oxalate, $C^2K^2O^4 + H^2O$	16	3·03
Acid potassium oxalate, $4C^2HKO^4 + H^2O$	8	26·21
Potassium quadroxalate, $C^2HKO^4.C^2H^2O^4 + 2H^2O$	13	55·25
Neutral ammonium oxalate, $C^2(NH^4)O^4 + H^2O$	15	23·69
Acid ammonium oxalate, $2C^2(NH^4)HO^4 + H^2O$	11·5	15·97
Ammonium quadroxalate, $C^2(NH^4)HO^4.C^2H^2O^4 + 2H^2O$	7·75	39·68

Aluminium oxalates.—The following double oxalates of aluminium have been prepared by A. Z. Collin (*Deut. Chem. Ges. Ber.* ii. 315):—

Antimony oxalates.—The following are described by N. Svenssen (*Deut. Chem. Ges. Ber.* iii. 314):—

- (1). $Sb^2O^3.2C^2O^3 + H^2O$
- (2). $K^2O.C^2O^3 + Sb^2O^3.3C^2O^3 + H^2O$
- (3). $3(K^2O.C^2O^3) + Sb^2O^3.3C^2O^3 + 6H^2O$
- (4). $K^2O.C^2O^3 + Sb^2O^3.3C^2O^3 + K^2O.H^2O.2C^2O^3 + 3H^2O$
- (5). $3(K^2O.C^2O^3) + Sb^2O^3.3C^2O^3 + 2(K^2O.H^2O.2C^2O^3) + 5H^2O$
- (6). $3(Na^2O.C^2O^3) + Sb^2O^3.3C^2O^3 + 9H^2O$
- (7). $(NH^4)^2O.C^2O^3 + Sb^2O^3.3C^2O^3 + 10H^2O$
- (8). $3[(NH^4)^2O.C^2O^3] + 2(Sb^2O^3.3C^2O^3) + 16H^2O$
- (9). $3[(NH^4)^2O.C^2O^3] + Sb^2O^3.3C^2O^3 + (NH^4)^2O.H^2O.2C^2O^3 + 15H^2O$

The salt (5) was deposited from the mother-liquors of (3) and (4), for the preparation of which acid potassium oxalate was mixed with antimonious oxide and caustic potash. The salt (4) forms large well-defined crystals. The salt (2) is decomposed by water; so likewise is (8), which was obtained but once. The salts (5) and (9) may be recrystallised from water without alteration.

Bismuth-potassium oxalate, $K^2O.C^2O^3 + Bi^2O^3.3C^2O^3 + 2H^2O$ (Svenssen).

Cerous oxalate, C^2CeO^4 , in the air-dried state contains 4 mols. water; after drying at 100° only 1 mol., and this is given off at a higher temperature, partial decomposition, however, taking place at 180°. The air-dried salt gives off 3 p.c. water over sulphuric acid (Erk, *Zeitschr. f. Chem.* vii. 100).

Lead oxalate, C^2PbO^4 .—Experiments on the calcination of this salt have been made by E. J. Maumené (*Compt. rend.* lxxi. 797, 837).

The black product left on calcining lead oxalate was considered by Berzelius, and after him by Dulong, to be a suboxide of lead. Subsequently Boussingault found that on exposing this body in a muffle to an incipient red heat, it experienced a gain in weight corresponding with the difference between Pb^2O and $2PbO$. Lastly, its formation and properties were examined by Pelouze, who found, on keeping the oxalate at a temperature of 310°, at which it begins to decompose, that the gases disengaged are carbon monoxide and carbon dioxide in the ratio of $1CO : 3CO^2$, according to the equation $2C^2O^4Pb = Pb^2O + CO + 3CO^2$.

Maumené, however, finds: 1. That the black residue is a mixture of metallic lead with the monoxide PbO , inasmuch as, when triturated with mercury for a considerable time—or for a shorter time if previously moistened with alcohol—it yields an amalgam of lead, and when boiled with a solution of sugar it gives up a considerable quantity of lead oxide.

2. That the proportions of carbon monoxide and dioxide evolved in the decomposition are not constant, but vary according to the temperature and other conditions of the experiment. When the oxalate was heated in an oil-bath to 310° – 315° , the gas collected in the early stages of the decomposition exhibited nearly the ratio $1\text{CO} : 2\text{CO}_2$; but on collecting successive portions of the gas evolved at 315° , the proportion of carbon dioxide was found gradually to increase, till at length the evolved gas consisted almost wholly of that compound. This result is due to the gradual oxidation of the carbon monoxide by the lead oxide in the residue. Similar results were obtained at higher temperatures. By calcining a small quantity of the oxalate (1 gram) in a narrow gas tube, of which it occupied a considerable length, and using a regulated flame, a gaseous mixture was obtained exhibiting very nearly the ratio $1\text{CO} : 3\text{CO}_2$ mentioned by Pelouze.

Oxalic ethers. On the action of Sodium on Ethyl oxalate, see GLYCOLLIC ACID (p. 569); also Eghis (*Deut. Chem. Ges. Ber.* iv. 580; *Chem. Soc. J.* [2], ix. 820).

Perfectly dry ethyl oxalate, treated with phosphorus oxychloride, forms ethyloxy-oxalylechloride, $\text{COCl} - \text{CO}(\text{OC}_2\text{H}_5)_2$, which is a colourless mobile liquid having a suffocating odour, a sp. gr. of 1.2160 at 16° , and boiling at 140° . It fumes strongly in the air, and when exposed to the air for some time is converted into oxalic acid. With water it decomposes very rapidly; with alcohol it instantly forms ethyl oxalate; with alcoholic ammonia it yields ethyl oxamate; and with aniline ethylic phenyloxamate (L. Henry, *Deut. Chem. Ges. Ber.* iv. 598).

When ethyl oxalate is digested with isopropyl iodide and zinc, first at ordinary temperatures and afterwards at 100° , the ethylic ethers of oxy-isocaproic acid and oxy-isovaleric acid (p. 885) are produced, together with a third ethylic ether, which is obtained by heating the lower boiling portion of the crude product with baryta-water to 100° , removing the excess of baryta with sulphuric acid, and concentrating the solution. The ether in question then separates in needle-shaped crystals, coloured by iodine. The free acid forms white crystals easily soluble in water, sublimes below 100° in white needles, melts at 91° – 92° , and solidifies at 85° . This ether is perhaps the isopropyl-compound, $\begin{matrix} \text{C}^{\text{H}}_3 \\ | \\ \text{C}^{\text{H}}_3\text{O} \end{matrix} \left\{ \begin{matrix} \text{C}^{\text{H}}_3 \\ | \\ \text{C}^{\text{H}}_3\text{O} \end{matrix} \right\} \text{CH} \cdot \text{CO}_2\text{H}$, analogous to Frankland & Duppa's amyl-ethyl-hydroxalic acid (*iv.* 276).

Action of Oxalic acid on Polyatomic alcohols.—Oxalic acid forms with glycerin a compound called Oxalin, a white solid hygroscopic substance which, when heated, melts, gives off vapours, and decomposes, evolving carbon dioxide and leaving glycerin. With ammonia it forms oxamide. Similar compounds are formed with mannite, dulcitate, erythrite, quercite, ethene glycol, and octene glycol (Lorin, *Compt. rend.* lxxvii. 329, 363; *Ann. Chim. Phys.* [4], xxix. 367).

OXALURIC ACID, $\text{C}^{\text{H}}_2\text{N}_2\text{O}_4 = \begin{matrix} \text{CO}-\text{NH}_2 \\ | \\ \text{C}^{\text{O}}_2-\text{OC}^{\text{H}}_2 \end{matrix} \left\{ \begin{matrix} \text{CO}-\text{NH}_2 \\ | \\ \text{C}^{\text{O}}_2-\text{OC}^{\text{H}}_2 \end{matrix} \right\} \text{NH}$. The ethylic ether of this acid is formed by the action of ethyloxy-oxalyl chloride on urea:—

The action takes place at ordinary temperatures; it is very energetic, and accompanied by considerable evolution of heat. As the hydrochloric acid formed unites with the urea, it is necessary to use a double quantity of the latter. The product is exhausted with cold water, and the residual ethyl oxalurate is recrystallised from boiling water.

Ethyl oxalurate separates from water in thin, white, silky, anhydrous needles; from alcohol as a white crystalline powder.

OXAMIC ETHERS. On the formation of these ethers by the action of ammonia and amines on ethyloxy-oxalyl chloride, see above.

OXAMIDONAPHTHOL. See NAPHTHOLS (p. 842).

OXAMMITE. This name is given by C. U. Shepard (*Sill. Am. J.* [2], i. 272) to ammonium oxalate found in the vertebral column and the stomach of a bird buried in guano.

OXIDATION. On the Heat developed in Oxidation, see HEAT (pp. 606–618).

Lecture experiments on alternate Oxidation and Reduction are described by A. W. Hoffmann (*Deut. Chem. Ges. Ber.* iii. 658), and by J. Thomsen (*ibid.* 930); see also *Jahresb. f. Chem.* 1870, 197; also by Wartha (*Deut. Chem. Ges. Ber.* iv. 94; *Jahresb.* 1871, 197).

On Oxidation in the Animal Organism, see Pflüger (*Pflüger's Archiv. f. Phys.* vi. 43; *Chem. Soc. J.* [2], x. 1030).

On the Oxidising Power of the Blood, see p. 200 of this volume; on the Influence of Quinine on the Oxidation in the Blood, see p. 197.

OXIDES. On the alleged Influence of Calcination on the Heat disengaged in the Solution and certain Reactions of Metallic Oxides, see p. 617.

On the Effect of various metallic Oxides in facilitating the Decomposition of Potassium Chlorate by Heat, see p. 315.

OXIMIDO-HYDROXYL-ANTHRAQUINONE. See ANTHRAQUINONE (p. 91).

OXIMIDONAPHTHOL. See NAPHTHOL (p. 812).

OXINDOL. See INDIGO (p. 666).

OXYAZOBENZENE. See BENZENE (p. 151).

OXYANTHRAQUINONE. See ANTHRAQUINONE (p. 92).

OXYBENZOIC ACID. On the relative positions of the radicles OH and COOH in this acid and its isomerides, see BENZENE (p. 133).

OXYBUTYRIC ACIDS, $C^4H^3O^3 = C^4H^2(OH)O^2$ (Markownikoff, *Ann. Ch. Pharm.* cliii. 228, 251; *Zeitschr. f. Chem.* iv. 620; vi. 421). The following observations on these acids are supplementary to those reported in the 1st *Suppl.* (p. 891).

(1). *Theoryisobutyric acid*, $\begin{matrix} H^3C \\ H^2C \end{matrix} \begin{matrix} \diagup \\ \diagdown \end{matrix} \begin{matrix} COH \\ - COOH \end{matrix}$, formed from bromisobutyric

acid, is a white crystalline body easily soluble in water, and separates from the aqueous solution over sulphuric acid in prismatic crystals, from ether in stellate groups of needles. When continuously heated it sublimates at 50° in slender flexible needles, which melt at 79° and resolidify at 76° . It absorbs moisture from the air. The *ammonium salt* is very soluble. The *calcium salt* crystallises in spherical groups of slender needles having a silky lustre. Alcohol throws it down from its aqueous solution as a gelatinous precipitate which dissolves when heated, but separates in needles on cooling. The *barium salt* dissolves easily in hot water and in hot alcohol, and crystallises in prisms. The *zinc salt* dissolves sparingly both in hot and in cold water, and separates on evaporation by heat in microscopic six-sided laminae, on spontaneous evaporation in four-sided plates. It contains 2 mol. water of crystallisation. The *lead salt* is very soluble. The *silver salt* crystallises from hot aqueous solution in shining scales, by slow evaporation in large flat prisms. It dissolves in 14 parts of water.

Oxyisobutyric acid is converted by oxidation with potassium dichromate and sulphuric acid into carbon dioxide, acetone, and acetic acid. According to Markownikoff, it is identical with acetic acid, dimethoxalic acid, and butylactic acid.

(2). *α -Oxybutyric acid* is prepared from chlorinated or brominated butyl chloride in the same manner as oxyisobutyric acid. This acid, represented by the formula $CH^3.CH^2.CHOH.CO^2H$, is identical with that which Friedel and Machuca obtained from bromobutyric acid (1st *Suppl.* 891). It crystallises from aqueous solution over sulphuric acid in stellate groups of needles; from solution in aqueous ether in small flat prisms. It deliquesces in moist air, melts at 43° – 44° , sublimes below 100° , and begins to boil, with incipient decomposition, at 225° . The *calcium salt*, $2Ca(C^4H^3O^3)^2 + 6H^2O$, is easily soluble in water, and crystallises in nodular masses. The *zinc salt*, $Zn(C^4H^3O^3)^2 + H^2O$, crystallises from hot aqueous solution in nodular aggregates consisting of slender four-sided prisms united in tufts; by slow crystallisation it is obtained in long needles. The *lead salt* and the *silver salt* are easily soluble in water, the latter crystallising therefrom in druses.

(3). *β -Oxybutyric acid*, $CH^3.CH(OH).CH^2.COOH$, prepared from propylene-chlorhydrin, has already been described (1st *Suppl.* 301).

OXYCAMPHORIC ANHYDRIDE, $C^{10}H^{14}O^4$. See CAMPHORIC ACID (p. 236).

OXYCAMPHORONIC ACID, $C^{10}H^{12}O^4$. See CAMPHORONIC ACID (p. 238).

OXYCARBONS or CARBON OXIDES. Two of these bodies, C^2O^2 and C^2O^4 , analogous to the hydrocarbons, crotonylene C^4H^2 , and valerylene C^5H^2 , have been obtained, together with others of undetermined composition, by exposing pure dry carbon monoxide to the action of electricity in an induction tube (Brodie, p. 350).

OXYCUMIC ACID, $C^6H^4.C^2H^2OH.CO^2H$, and **OXYTETRACUMIC ACID,** $C^6H^4.C^2H^2OOC^2H^2.CO^2H$, are formed, together with other compounds, by boiling bromocumic acid with alcoholic potash (p. 403). The former yields a *barium salt* which crystallises in nodules (Czempelik).

OXYGEN. *Preparation.*—A process for obtaining oxygen from atmospheric air for industrial use, founded on the property possessed by water, of absorbing oxygen more readily than nitrogen, has been devised by Mallet (*Dingl. pol. J.* exxcix. 112). Air is pressed into water by means of a forcing-pump, and the gases which escape on diminishing the pressure are subjected to the same treatment eight times in succession, by which time nearly pure oxygen is obtained. The following table shows the composition of the gaseous mixture at each successive stage.

Atmospheric air			Composition after successive pressures							
			1	2	3	4	5	6	7	8
N	.	79	66·67	52·5	37·5	25·0	15·0	9·0	5·0	2·7
O	.	21	33·33	47·5	62·5	75·0	85·0	91·0	95·0	97·3

The difficulty of obtaining oxygen free from nitrogen arises, according to Houzeau (*Compt. rend.* lxx. 39), from the adhesion of atmospheric air to the surface of the glass, which is so strong that the air cannot be completely removed even by washing with large quantities of oxygen. The difficulty may, however, be overcome by keeping the glass-red-hot while a strong stream of oxygen is passed over it. The oxygen is evolved from fused potassium chlorate in retorts heated over their entire surface, and containing ignited asbestos in their necks.

On the influence of various metallic oxides in facilitating the evolution of oxygen from potassium chlorate, see CHLORATES, p. 315; also G. Krebs (*Zeitschr. f. Chem.* vi. 243; *Jahresb. f. Chem.* 1870, 208).

Experiments on the effect of dilution on the oxidising power of oxygen have been made by W. Müller (*Pogg. Ann.* cxli. 95). In the case of iron, copper, and arsenic, oxidation was found to commence in atmospheric air at a lower temperature than in pure oxygen, whereas in the case of charcoal, sulphur, antimony, potassium, iron sulphide, and lead, no difference in the temperatures of commencing oxidation was observed.

OXYHYDROMUCONIC ACID. See MUCONIC ACID (p. 827).

OXYISOBUTYRIC ACID. See OXYBUTYRIC ACID (p. 884).

OXYISOCAPRYLIC ACID, $C^8H^{14}O^2 = \begin{smallmatrix} C^8H^7 \\ C^8H^7 \end{smallmatrix} COH.CO^8H$ (Markownikoff, *Zeitschr. f. Chem.* vi. 516). The *ethylis ether* of this acid, $C^8H^{13}(C^2H^5)O^2$, is prepared by digesting rather more than 2 mol. isopropyl iodide with 1 mol. ethyl oxalate and zinc for some days at the ordinary temperature; the mixture is then diluted with water, mixed with hydrochloric acid to remove the zinc, and then distilled as long as drops of oil continue to pass over. The portion of the oily distillate which goes over between 180° and 205° is boiled for six hours with a weak solution of potash, after which the ether, when fractionally distilled, passes over for the most part between 198° and 200°. It is a thick pale yellow liquid having a faint mouldy smell, boiling at 202°–204° (corr.). It is not saponified by caustic potash at 180°, but baryta at 160° saponifies it slowly.

Oxyisocaprylic acid is best obtained by heating the ether with alcoholic potash. After the alcohol has been distilled off, the residue solidifies on addition of hydrochloric acid to a pasty mass, from which it may be obtained by recrystallisation from water, in slender colourless needles. By spontaneous evaporation longer needles are obtained and sometimes rather large transparent flat prisms. It dissolves sparingly in cold water, easily in alcohol and ether; melts under water, and volatilises with aqueous vapour. It melts at 110°–111°, and then often remains liquid below 80°. When heated above its melting point it sublimes in long needles.

Barium Oxyisocaprylate, $Ba(C^8H^{13}O^2)^2 + 3H^2O$, crystallises from hot water in small prismatic needles which appear to effloresce easily. The *calcium salt* is easily soluble in water, and crystallises with difficulty. The *zinc salt* separates as an amorphous precipitate on heating the *ammonium salt* with zinc sulphate.

OXY-ISOVALERIC ACID, or *Pseudo-propyl-hydrovalic acid*, $C^8H^{14}O^2 = C^8H^7.CO^8H.CO^8H$ (Markownikoff, *loc. cit.*) This acid is obtained, on evaporating the potash-solution used in the preparation of crude oxyisocaprylic acid, then acidulating with sulphuric acid, agitating with ether, and evaporating the ethereal solution, as a

thick liquid which solidifies in the exsiccator. It appears to be identical with the acid which Fittig & Clarke obtained from bromovaleric acid. The *barium salt*, $\text{Ba}(\text{C}^4\text{H}^4\text{O}^2)^2$, which is anhydrous, is best obtained by precipitating its aqueous solution with hot strong alcohol. The aqueous solution, when concentrated by heat, leaves it in the form of a syrup; by spontaneous evaporation, it yields crystalline nodules. The *silver salt*, $\text{AgC}^4\text{H}^4\text{O}^2$, is slightly soluble in cold water, rather more soluble in hot water, from which it crystallises in dendrites. The *zinc salt* is a white flocculent precipitate but slightly soluble in water, either hot or cold.

OXYLEPIDENE, $\text{C}^3\text{H}^2\text{O}^2$. See **LEPIDENE** (p. 773).

OXYMETHYL-PHENYL-FORMIC ACID, $\text{C}^8\text{H}^6\text{O}^3 = \text{C}^6\text{H}^5 \cdot \begin{Bmatrix} \text{CH}^2\text{OH} \\ \text{COOH} \end{Bmatrix}$ (Dittmar & Kekulé, *Deut. Chem. Ges. Ber.* iii. 894). This acid is formed by heating 1 mol. of ordinary toluic acid to 160° – 170° in a long-necked flask, and slowly drawing 1 mol. bromine-vapour through the apparatus by means of an aspirator. A brominated toluic acid is thereby formed having its bromine in the methyl, and capable of exchanging it for hydroxyl when boiled with alkalis or baryta-water:

The oxyacid forms white plates or smooth needles, very soluble in hot, moderately in cold water. It melts at a temperature somewhat higher than toluic acid and sublimes in feathery groups of needles.

OXYNAPHTHAQUINONE. See **NAPHTHAQUINONES** (p. 836).

OXYNEURINE. This base, produced by the action of trimethylamine on monochloroacetic acid, is identical with betaine from beet-juice (p. 186).

OXYPICRIC or **STYPHENIC ACID**, $\text{C}^6\text{H}^3(\text{NO}^2)^3\text{O}^2$, is identical with trinitroresorcin (see **RESORCIN**).

OXYPYROTARTARIC ACID, $\text{C}^4\text{H}^2\text{O}^5 = \text{C}^2\text{H}^2(\text{OH})(\text{COOH})^2$. This bibasic acid, homologous with malic acid, was obtained by Maxwell Simpson (*Proc. Roy. Soc.* xiii. 44), by heating dichlorhydrin with potassium cyanide in alcoholic solution, and boiling the product with potash. An acid apparently identical with this is produced by the action of melting potassium hydrate on either of the three sulphopyrotartaric acids formed by the combination of sulphurous acid (sulphites of alkali-metal) with citraconic, itaconic, or mesaconic acid. The oxypyrotartaric acid thus obtained forms hard crystals very soluble in cold water, slightly soluble in alcohol and in ether. From a neutralised solution it is precipitated bluish-white by cupric salts. The *silver salt*, $\text{C}^2\text{H}^2\text{Ag}^2\text{O}^5 + \text{H}^2\text{O}$, gives off its water of crystallisation at 65° and decomposes at 100° (Wieland, *Ann. Ch. Pharm.* clvii. 34).

OXSALICYLIC ACID, $\text{C}^7\text{H}^4\text{O}^4$. According to Liechti (*Zeitschr. f. Chem.* vi. 193), this acid prepared by Lautemann's process (decomposition of iodosalicylic acid by potash) is not identical with hypogallic acid, inasmuch as it cannot be made to unite with water of crystallisation, whereas hypogallic acid crystallises with $1\frac{1}{2}$ mol. water (148 p.c.), which it gives off at 100° (see further **SALICYLIC ACID**, 1st *Suppl.* 1005).

OXSULPHAZOTATES. See **SULPHAZOTIC ACIDS**.

OXSULPHIDE OF CARBON, COS. See **CARBON OXSULPHIDE** (p. 262).

OXSULPHOBENZIDE, $\text{C}^7\text{H}^5\text{SO}^2 = (\text{C}^6\text{H}^4\text{OH})^2\text{SO}^2$. This compound, discovered by Glutz (1st *Suppl.* 894), has been further examined by Annaheim (*J. pr. Chem.* [2], i. 14; ii. 385). It is best prepared by heating equal weights of phenol and strong sulphuric acid to 190° – 195° for five or six hours, and pouring the mass into two or three times its volume of water.

Ethyl-oxysulphobenzide, $(\text{C}^6\text{H}^4\text{OC}^2\text{H}^5)^2\text{SO}^2$, is formed by treating oxysulphobenzide with ethyl iodide and alcoholic potash. It is insoluble in water, nearly insoluble in cold alcohol, easily soluble in ether and hot alcohol, and crystallises from the latter in white laminae which melt at 160° . Strong nitric acid converts it into a nitro-product, $[\text{C}^6\text{H}^4(\text{NO}^2)(\text{OC}^2\text{H}^5)]^2\text{SO}^2$.

With methyl iodide and amyl iodide oxysulphobenzide yields derivatives of similar character.

Tetrachloroxysulphobenzide, $(\text{C}^6\text{H}^4\text{Cl}^2\text{OH})^2\text{SO}^2$, is formed, together with other products, by treating oxysulphobenzide with potassium chlorate and hydrochloric acid, and purified by washing it with water and with alcohol, dissolving it in alcohol, and separating by water. It forms short thick prisms or white needle-shaped crystals, insoluble in water, sparingly soluble in cold alcohol, easily in hot alcohol, and in ether, benzene and alkalis. It melts at 298° – 299° .

OXYTOLUIC ACID, $C^8H^9O^3$. Syn. with Oxymethyl-phenyl-formic acid (p. 886).

OXYTHYMOQUINONE. See THYMOQUINONES.

OZONE. *Formation*.—From numerous experiments on the formation of ozone under the influence of the spark of a Ruhmkorff coil, Houzeau (*Compt. rend.* lxx. 1286) finds that the formation is more rapid in renewed than in confined air, and that it takes place more abundantly at the negative than at the positive pole. The formation of ozone increases with the duration of the electrification up to a certain point only; it increases with the intensity of the electricity; diminishes as the distance between the electrodes is increased; varies with the length or surface of the electrodes; and increases, under otherwise similar circumstances, when the action of both electrodes is made available. Ozone is likewise formed when the electrodes are surrounded through their whole length with thin glass tubes, either closed or open, less abundantly, however, than when the air has free access to the platinum wires. In this case also the quantity of ozone formed varies with the length and surface of the electrodes. The formation of ozone increases considerably as the temperature is lowered, and under otherwise similar circumstances oxygen yields from 7 to 10 times as much ozone as atmospheric air. The ozone produced by electrification of air is contaminated with small quantities of nitrogen-compounds. Guided by these experiments, Houzeau has constructed an apparatus called an 'ozoniser,' by which ozone is produced in considerable quantity.

In an ordinary straight gas-delivery tube is placed a wire of copper, lead, or better, of platinum, 4 to 6 decimeters long, with one of its extremities passing through the side of the upper portion of the tube. On the exterior of the tube is coiled a similar wire over the path of the preceding. When the two are placed in communication with a Ruhmkorff's coil giving a 2 or 3 centimeter spark, a slow stream of oxygen passing through the tube will be strongly charged with ozone. By this apparatus, Houzeau has prepared oxygen containing 60 to 120 (once 188) milligrams of ozone per litre. Electrolysis of water furnished only 3 to 5 milligrams, barium peroxide and sulphuric acid 10 milligrams per litre.

A somewhat similar apparatus is described by A. W. Wright (*Sill. Am. J.* [3], iv. 26; *Chem. Soc. J.* [2], x. 1071).

Boillot (*Compt. rend.* lxxv. 214; *Chem. Soc. J.* [2], x. 879) describes an apparatus consisting of two glass tubes one fitting within the other, and each coated externally with powdered coke made to adhere by means of gelatin. The coatings of the two tubes are connected with the poles of an induction coil, and a stream of oxygen is made to pass between the tubes. The oxygen is thus exposed to the influence of the silent discharge, and a considerable proportion of it is converted into ozone.

On the formation of ozone in rapid combustion, see A. Loew (*1st Suppl.* 894).

On the simultaneous formation of ozone, hydrogen dioxide, and ammonium nitrite by the combustion of hydrogen in the air, see p. 660 of this volume; also C. Thau (*J. pr. Chem.* [2], i. 415; *Chem. Soc. J.* [2], ix. 482).

Supposed formation of Ozone by the Oxidation of Essential Oils.—It is commonly stated, on the authority of Schönbein and others, that the oxidation of oil of turpentine, and other essential oils in the air, is attended with formation of ozone, inasmuch as the oxidised oil and the air in its vicinity exhibit the reaction of ozone with potassium iodide (v. 921); this active substance likewise resembles hydrogen dioxide in giving a violet coloration with chromic acid solution, acidulated with sulphuric acid. The nature of this compound has lately been examined by Kingzett (*Chem. Soc. J.* [2], xii. 511), who finds that it cannot be either ozone or hydrogen dioxide, because it is destroyed at the boiling-point of turpentine-oil, viz. 160° , at which temperature ozone and hydrogen dioxide are permanent; moreover it resists to a certain extent the action of sodium thiosulphate, and its solution in water retains its properties after long-continued boiling. Kingzett attributes the active properties of the oxidised turpentine-oil to the formation of monohydrated terpene oxide, $C^{10}H^{14}O.H^2O$, which was shown some time ago by Sobrero (*Ann. Ch. Pharm.* lxxx. 106) to be formed when turpentine-oil containing water is exposed to the sun's rays in a vessel filled with oxygen (see TURPENTINE-OIL).

Properties and Reactions.—According to Carius (*Deut. Chem. Ges. Ber.* v. 520), 1,000 c.c. of distilled water at 0° and 0.76 m.m. pressure absorb from 3.86 to 5.41 c.c. of ozone.

According to Jonglet (*Compt. rend.* lxx. 539), nitroglycerin, dynamite, iodide of nitrogen, and chloride of nitrogen explode in a vessel containing ozone. Powder made with potassium picrate decomposes slowly under the same circumstances; ordinary gunpowder alters considerably in the course of six weeks.

On Atmospheric Ozone, see ATMOSPHERE (p. 113).

Gorup-Besanes finds that the air in the neighbourhood of graduation-houses for the evaporation of saline springs, is more highly charged with ozone than ordinary air (*Ann. Ch. Pharm.* clxi. 232; *Chem. Soc. J.* [2], x. 384).

The so-called 'Autozone.'—This supposed modification of oxygen is formed, according to Houzeau (*Jahresb. f. Chem.* 1855, 286), and Schönbein, (*ibid.* 1861, 96), by the action of strong sulphuric acid on barium dioxide; according to Moissner (*ibid.* 1863, 106), simultaneously with ozone, by electrification of oxygen. On the other hand, v. Babo (*ibid.* 1863, 135), and Weltzien (*ibid.* 1866, 106), found that the supposed peculiar modification of oxygen thus produced was nothing but hydrogen dioxide; and this conclusion has lately been confirmed by an elaborate series of experiments made by Engler n. Nasse (*Ann. Ch. Pharm.* cliv. 215; *Jahresb.* 1870, 210).

P

PALLADIUM. On alloys of Palladium and Lead, see LEAD (p. 729).

On Hydrogenised Palladium, see HYDROGEN (p. 658).

Palladic Chloride, PdCl⁴. Double salts of this chloride, analogous to those of platonic chloride, have been prepared and examined by H. Topsøe (*Chem. Centr.* 1870, 684). The potassium and ammonium salts are obtained as crystalline precipitates on mixing palladic chloride with potassium or ammonium chloride; the other compounds, which are easily soluble, are obtained by mixing the respective solutions and evaporating over sulphuric acid, taking care that the liquid is always saturated with chlorine. These double salts are very unstable; those of the magnesium series give off chlorine even on keeping or on solution in water, whereas those of the alkali-metals do not decompose till their solutions are heated. They have a crimson colour.

The following have been prepared:—

PdCl ⁴ .2NH ⁴ Cl:	Regular. Combination, O.∞O∞. Sp. gr. = 2.418.
PdCl ⁴ .2KCl:	Regular. Combination, O.∞O∞. Sp. gr. = 2.738.
PdCl ⁴ .2MgCl ² + 6H ² O:	Deliquescent. Hexagonal. Combination, ∞P∞ and R of 127°. Sp. gr. = 2.124.
PdCl ⁴ .2NiCl ² + 6H ² O:	Deliquescent. Hexagonal. Combination, ∞P∞ and R of 127° 14'. Sp. gr. = 2.353.
PdCl ⁴ .2ZnCl ² + 6H ² O:	Isomorphous with the two preceding. R of 127° 10'. Sp. gr. = 2.359.

The analogy of these salts with the platonic double chlorides is exhibited by the following comparison:—

PdCl ⁴ .2NH ⁴ Cl	147.1	PtCl ⁴ .2NH ⁴ Cl	148.6
PdCl ⁴ .2KCl	145.3	PtCl ⁴ .2KCl	138.2
PdCl ⁴ .MgCl ² + 6H ² O	212.6	PtCl ⁴ .MgCl ² + 6H ² O	222.6
PdCl ⁴ .NiCl ² + 6H ² O	206.7	PtCl ⁴ .NiCl ² + 6H ² O	206.3
PdCl ⁴ .ZnCl ² + 6H ² O	208.0	PtCl ⁴ .ZnCl ² + 6H ² O	214.8

Oxides. When a sulphur-salt of palladium is fused with a mixture of potassium hydrate and nitrate, a dark brown-black powder is formed, consisting of an oxide of palladium, which is reduced to the metallic state by strong and prolonged ignition, and gives up variable quantities of palladium to nitromuriatic acid, leaving an oxide having the composition Pd²O³, or perhaps 4PdO.PdO². This oxide is not decomposed by nitromuriatic acid, but is easily reduced by hydrogen. When ignited over an ordinary gas-burner it gives off its oxygen but slowly, the reduction being complete only after strong and prolonged ignition. Under the microscope it presents the appearance of a perfectly homogeneous light-brown lustreless powder (R. Schneider, *Pogg. Ann.* cxli. 519).

Sulphides. The *bisulphide*, PdS², is formed by decomposing sodium sulphopalladate, Na²S.PdS² (*infra*) with hydrochloric acid. After drying it forms a dark black-brown rather dense crystalline powder, exhibiting under the microscope the acicular form of the sulphopalladate from which it has been separated. It is permanent in the air. When moderately heated (in carbon dioxide) it yields a considerable

sublimate of sulphur, and is converted first into monosulphide, then at a higher temperature into the hemisulphide. The bisulphide is slowly dissolved by nitric acid, quickly and completely by nitromuriatic acid.

The *hemisulphide*, Pd^2S , is also produced by fusing an intimate mixture of 1 pt. ammonio-palladious chloride (or $\frac{1}{2}$ pt. palladium monosulphide), 6 pts. of potassium carbonate (or an equivalent quantity of sodium carbonate), 6 pts. of sulphur and 3 pts. of sal-ammoniac, for 15–20 minutes at a bright red-heat. On treating the fused mass with water, and washing away the potassium-palladium sulphopalladate formed at the same time, the hemisulphide remains as a fused regulus. It is rather hard, very brittle, and easily pulverised; the powder is ash-grey. On recent fracture-surfaces it exhibits a rather bright metallic lustre, a whitish-grey colour, and a fine-grained crystalline structure. Sp. gr. = 7.303 at 15° . It is not attacked by acids, and but very slightly even by nitromuriatic acid. At a red-heat it melts slowly, gives off sulphur, but still retains some of that substance even after prolonged ignition. It behaves in the same way when heated in a stream of hydrogen.

Sulphide or Palladium Sulphopalladate, Pd^2S^4 (see below).

Sulphopalladates (R. Schneider, *Pogg. Ann.* cxl. 519; cxlviii. 625; *J. pr. Chem.* [2], iii. 103). *Sodium Sulphopalladate*, $\text{Na}^2\text{S}.\text{PdS}^2$, is formed in thin brown needles by fusing 1 pt. of ammonio-palladious chloride (or $\frac{1}{2}$ pt. palladium monosulphide) with 6 pts. of dry sodium carbonate and 6 pts. of sulphur, and treating the coarsely-pounded fused mass with absolute alcohol (out of contact with the air) till the sodium polysulphide is completely dissolved out. The remainder is a mixture of sodium sulphate with the sulphopalladate, $\text{Na}^2\text{S}.\text{PdS}^2$.

This compound forms thin needles partly somewhat flattened, having a brown colour or (especially in the larger specimens) reddish lead-grey on the surface, and a faint metallic lustre. Very thin layers appear translucent with red-brown colour under the microscope. The streak-powder is yellowish-brown. The aqueous solution, when exposed to the air, soon deposits palladium sulphide.

Silver Sulphopalladate, $\text{Ag}^2\text{S}.\text{PdS}^2$, is formed by adding the sodium salt just described to an alcoholic solution of silver nitrate, diluting with water and stirring, and finally treating the black-brown crystalline powder with aqueous silver nitrate.

Potassium - palladium Sulphopalladate, $\text{K}^2\text{PdS}^4 = \text{K}^2\text{Pd}^2(\text{Pd}^2)^2\text{S}^4 =$
 $\begin{array}{c} \text{K}-\text{S} \quad \quad \quad \text{S}-\text{Pd} \\ \quad \quad \quad \diagdown \quad \diagup \\ \quad \quad \quad \text{Pd} \\ \quad \quad \quad \diagup \quad \diagdown \\ \text{K}-\text{S} \quad \quad \quad \text{S}-\text{Pd} \end{array}$ This salt is produced by fusing 2 pts. ammonio-palladious chloride (or 1 pt. of ordinary palladium sulphide) with 12 pts. of potassium carbonate and 12 pts. of sulphur. On treating the fused mass with water, the double sulphur salt remains undissolved, while potassium polysulphide is dissolved, together with potassium sulphopalladate, which has not yet been isolated.

Potassium-palladium sulphopalladate forms very thin six-sided crystalline laminae, having a bright metallic lustre and a splendid blue colour. It is insoluble in water, whether cold or hot. The crystals, heated out of contact with the air, acquire a vortical movement, and at a strong red-heat split with faint sparkling into smaller fragments, without separation of sulphur or of gas. Heated in a stream of hydrogen, they decompose, apparently according to the equation:

and on treating the residue with water, the basic potassium sulphopalladate, $2\text{K}^2\text{S}.\text{PdS}^2$, is dissolved.

Palladium Sulphopalladate, $\text{Pd}^2\text{S}^4 = 2\text{PdS}.\text{PdS}^2 = \text{Pd} \begin{array}{c} \text{S} \\ \diagdown \quad \diagup \\ \text{S} \end{array} \text{Pd} \begin{array}{c} \text{S} \\ \diagdown \quad \diagup \\ \text{S} \end{array} \text{Pd}$,

is formed by treating potassium-palladium sulphopalladate with hydrochloric acid, the action apparently taking place by two stages, in the first of which the potassium is replaced by hydrogen, yielding the compound, $\text{H}^2\text{S}.\text{Pd}^2\text{S}.\text{PdS}^2$, which is then acted upon by atmospheric oxygen in the manner represented by the equation:

The palladium bisulphide in this compound exhibits nearly the same properties as when it is by the free state. By strong ignition in the air half of the sulphur of the bisulphide is driven off in combination with oxygen; and the residue consists of palladium monosulphide, which as thus obtained is a blackish-grey crystalline powder very little acted on by nitromuriatic acid.

Silver-palladium Sulphopalladate, $\text{Ag}^{2\text{S}}_{\text{PdS}}$.—When two molecules of silver nitrate in dilute aqueous solution are added to one molecule of potassium-palladium sulphopalladate suspended in water, the latter salt loses its blue colour, becomes whitish-grey, and at the same time an amount of potassium nitrate equivalent to that of the silver nitrate used is formed. A new salt is also produced, which, however, contains varying amounts of finely divided metallic silver. But by using a dilute ammoniacal solution of silver nitrate, and treating the product with cold nitric acid for a short time, silver-palladium sulphopalladate is obtained in whitish-grey metallic-looking hexagonal plates having the composition above given. It is characterised by great stability, not being acted on by water, ammonia, potash, or even boiling hydrochloric acid. The residue, after heating out of contact with air, is partially decomposed by boiling nitric or nitromuriatic acid. Heated in the air it absorbs oxygen, the residue when heated with water yielding silver sulphate, but no palladium salt. On heating it in a stream of hydrogen, sulphuretted hydrogen is evolved. Boiling nitric acid removes all the silver and a part of the palladium from the residue, a grey crystalline powder remaining, which is probably palladium subsulphide.

PALM OIL. Oudemans (*J. pr. Chem.* [2], ii. 393) has examined the fat of palm kernels, by saponifying it with caustic potash, separating the fatty acids with sulphuric acid, washing with water, and distilling for a long time with water; then—(1) saturating the distillate with baryta and analysing the barium salt; (2) dissolving the residue of the distillation in alcohol, mixing the solution with water, and crystallising out the fatty acids by exposure to a low temperature. Those acids were separated by Heintz's method (iii. 1070). To separate the oleic acid, the soap-solution was precipitated with lead acetate, the air-dried precipitate treated with ether, the acid separated from the ether-solution by hydrochloric acid, and then distilled in a stream of hydrogen. In this manner the following results were obtained:—

Triolein	26.6 p.c.	Trilaurin	
Tristentin		Tricaprin	
Tripalmitin	33.0 p.c.	Tricaprylin	
Trimyristicin		Tricaproin	
			40.4 p.c.

PAPAVERINE, $\text{C}^{21}\text{H}^{21}\text{NO}^4$ (Hesse, *Zeitschr. f. Chem.* vii. 641; *Ann. Ch. Pharm. Suppl.* viii. 261). Respecting the separation of this base from the other alkaloids of opium, see 1st *Suppl.* 896, and p. 876 of this volume.
